cities are not simply green cities; the abundant presence of nature is a necessity but it is not a sufficient condition. In biophilic cities, the residents are directly and actively engaged in learning, enjoying, and protecting the nature that surrounds them and with which they have developed an important emotional connection (idem, 2011).
The possible indicators that should be integrated in a city in order to be considered biophilic are composed by the conditions and infrastructure, behaviors, patterns, practices and lifestyles, attitudes and knowledge, as well as institutions and governance (see Table 3).

3. Green Infrastructure (GI)

Green Infrastructure (GI) is a strategically planned network of high quality natural and semi-natural areas with other environmental features which must be designed and managed to provide a wide range of ecosystem services and to protect the biodiversity in both rural and urban settings (EEA - European Environment Agency, 2011).
The GI is a tool to deal with environmental problems through different solutions based on natural processes. Biodiversity acts as its central axis, since the functioning, resistance and quality of ecosystem services depend directly on the richness and abundance of the species that house the elements that make up the system. It also promotes the creation of ecological networks at different scales, requires spatial and temporal planning as well as an adequate design and is based on collaboration between citizens, managers and politicians (idem, 2011).

Habitat Services	Biodiversity and species protection.	-Wildlife habitat. -Migratory species permeability. -Habitat networking.
Regulating Services	Adaption and mitigation against climate change.	-Mitigation of the urban heat island effect. -Reinforcement of the resilience of ecosystems to climate change. -Retention of water and decrease of runoff to reduce flood risks. - Carbon seize and storage. -Encouragement of sustainable traveling. -Reduction of energy consumption to heat and cool buildings. -Encouragement of renewable energies. -Promotion of sustainable mobility.
Provisioning Services	Water regulation	-Sustainable drainage systems –reduction of runoff. -Increased water infiltration. -Water treatment.
	Food production and security	-Food supply and production of raw materials in agricultural areas, orchards, among others. -Maintenance of the fertility of agricultural land. -Development of the soil and the cycle of nutrients. -Prevention of soil erosion.
Cultural Services	Recreation, wellness and health.	-Recreational activities. -Aesthetic appreciation of nature. -Clean air. -Tourism / Ecotourism.
	Land value.	-Positive impact on the land and its property.
	Culture and sense of community.	-Local identity. -Opportunities for education, training and social interaction. -Opportunities for tourism.

Table 4. Ecosystem services provided by green infrastructure. Self-elaborated with information from Millenium Ecosystem Assessment, 2005 and European Environment Agency, 2011.

According to the classification of ecosystem goods and services, the benefits of the GI are classified into four groups: habitat services, regulating services, provisioning services and cultural services (idem, 2011). The first ones refer specifically to the habitat of species of flora and fauna; the second are those that generate benefits from the regulation of ecosystem processes; the third to products that are generated directly in the ecosystem; and the cultural ones are intangible benefits that people obtain from ecosystems through spiritual enrichment, cognitive development, reflection, recreation and aesthetic experiences (see Table 4). The incorporation of these services into a public policy instrument at the metropolitan level is fundamental. For this reason, “The Economics of Ecosystems and Biodiversity – TEEB” (2011) a global initiative focused on making nature’s values visible, establishes a six-step methodology for ecosystem services to be included in the processes of developing public policies for the creation of a GI network. The first step is to develop the problem; what it means and what the lack of green infrastructure can mean, what should be discussed together with the stakeholders, then the most relevant ecosystem services of the metropolis should be identified, as well as determining valuation methods for them, and then the valuation must be made. Once the management alternatives have been identified, the impact of the options that are available to the stakeholders will be assessed, so that they are included in a public policy instrument that can be a Metropolitan GI Plan (see Figure 1).

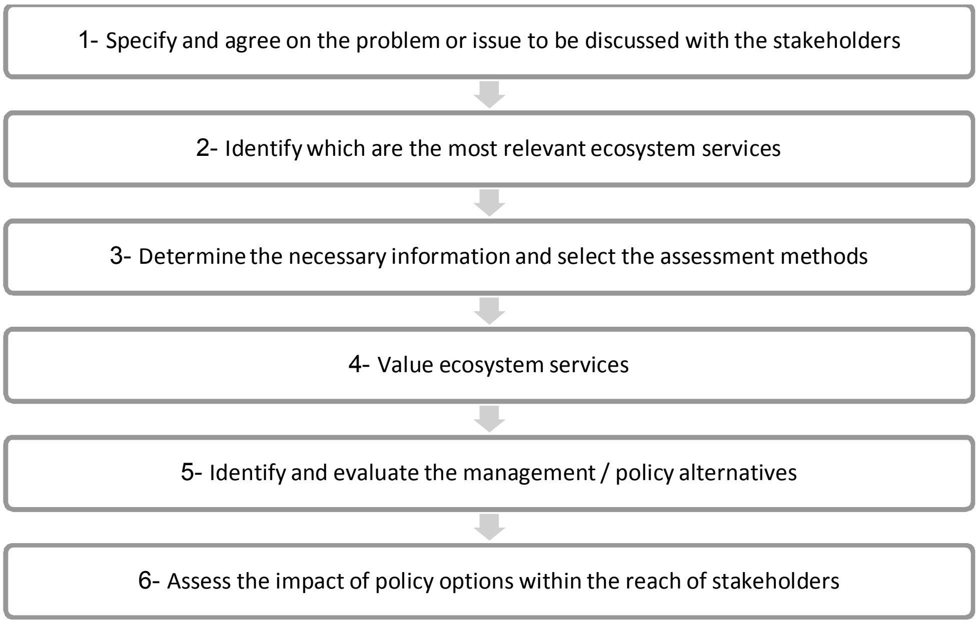

Figure 1. Methodology to include ecosystem services in public policy decision making. Adapted from The Economics of Ecosystems and Biodiversity, 2011).

The ecosystem services must be valued in order to be able to assign to each green space that integrates a GI network the importance and the hierarchy that corresponds to it according to its scope, so a set of indicators must be determined for each type of service. As part of the indicators of habitat services, there is the abundance of birds, butterflies and other species valued for their aesthetic characteristics. Among the supply services is the production of food, expressed in tons per year (T/year), as well as water supply, expressed by spending in cubic meters per year (m^3/year). While on those of regulation, there are the infiltration capacity, measured by the percentage of impermeable surface in relation to the permeable surface in hectares (Ha); the regulation of the urban temperature can be measured by the *leaf area index*; the reduction of noise by the leaf surface (m^2) and the distance to the roads (m) and the reduction of noise (dB (A)) / unit of vegetation; the purification of the air by means of the measurement of polluting particles O_3, SO_2, NO_2, CO and PM_{10} (g/cm^2/s) multiplied by the arboreal coverage (m^2). With regard to water treatment, the suggested indicator is the amount of Phosphorus, Potassium and Magnesium in mg/kg compared to the averages of soil and water; for climate regulation the amount of CO_2 absorption by trees (carbon multiplied by 3.67 to convert to CO_2). Among the cultural ones, the key indicator is the surface of public green spaces (Ha/inhabitants) and its proximity to the districts or neighborhoods of the Metropolitan Areas.

Some of the services provided by urban green spaces are the regulation of air quality, the regulation of water in floods, the regulation of local climate, as well as direct services such as recreation and environmental education, particularly when these spaces have witnessed historical events to become cultural heritage (see Table 4). The elements that make up the urban landscape and constitute the Green Infrastructure (GI) of urban areas are classified according to their scale of service. This scale is related to the frequency of use of the facilities and the distance to which these should be located. The service scales considered in Handbooks for Urban Design Criteria such as SEDESOL standards (1999) are: neighborhoods, districts and cities, but there are other sources that also address scale issues (see Table 5) and which refer to the neighborhood, city and regional scales (Vásquez, 2016).

Planners, and governmental authorities should be aware of the services provided by GI in Metropolitan Areas; but even more important is that ordinary citizens recognize their value and how they can generate opportunities for sustainable development, but they can also serve as evidence for environmental policies in any governance setting. Some ecosystem services such as air cleaning and noise reduction are regulatory services which are often not recognized even by the planners or by the citizens themselves (Kabisch, 2014).

Neighborhood Scale	City Scale	Regional Scale
Wooded streets	Rivers and flood plains	Wild protected areas
Green roofs and walls	Inter-communal parks	National parks
Neighborhood squares	Urban channels	Coastline and beaches
Private garden	Lagoons	Strategical and long distance pathways
Open institutional spaces	Suburban forests	Forests
Ponds and streams.	Natural parks	Protective belts in high voltage lines
Walkways rights	Continuous water fronts	Network of roads and railways
Pedestrian and bike paths	Municipal squares	Designated green belt
Cemeteries	Hills	Agricultural lands
Sport tracks	Large recreational spaces	Rivers and flood plains
Ditches	Estuaries	Canals
Small forests	Deserted lands	Open-fields
Playground areas	Community forests	Mountain range
Streambeds	Deserted mining sites	Common territory
School yards	Agricultural lands	Aqueducts and gas pipelines
Orchards	Wastelands	Geological faults
Deserts		Lakes

Table 5. Green Infrastructure Scales. Elaborated by Vasquez, 2016, based on EEA - European Environment Agency, 2011 and Landscape Institute, 2009.

This approach based on ecosystem services -which includes green spaces for the sustainable development of metropolises, could benefit metropolitan planning instruments such as urban development plans.

The literature determines a series of approaches for Green Infrastructure planning: the need for a holistic design as it occurs with other infrastructures such as the one for mobility; the comprehensive planning, as it happens with the electric power network attending to social, economic and environmental issues; strategic territorialization including various jurisdictions and government levels; public planning and implementation, which refers to the generation of the GI with public participation; multidisciplinarity, because it must be based on science and should be strengthened with knowledge of professional disciplines, including landscape ecology, ecological economics, urban and regional planning, and landscape architecture (Benedict & McMahon, 2001). In addition to these, it is essential that the GI is financed through specific funds as happens with the other sectoral programs, and not only be a recipient of residual monies.

4. GI in Mexico and the Guadalajara Metropolitan Area (GMA)

Because it has not been adopted as a public policy concept yet, Mexico lacks regulations for GI implementation. However, there is a legal framework that allows to include GI.
Article 4 of the Political Constitution of the United Mexican States (Spanish: *Constitución Política de los Estados Unidos Mexicanos*) establishes that every person has the right to an adequate environment for their development and well-being. The National Development Plans (NDP) have included principles to protect natural resources and to guarantee their permanence in the future. For example, in the NDP of 2007-2012, a strategy was specified so that the preservation of ecosystems and biodiversity could be achieved under schemes of conservation, management and sustainable use. Despite the fact that the need to protect natural resources is recognized as a goal in the NDP for the current administration (2013-2018), the strategies to achieve it are not in place.
Within the territorial environmental policies that have been implemented in Mexico, we can include the designations of protected natural areas, the ecological planning of the territory, the environmental impact assessment, and the payment for environmental services (Quadri de la Torre, 2006). Among these, the Protected Natural Areas (PNAs) are defined as "zones of the national territory and those on which the nation exercises its sovereignty and jurisdiction, where the original environments have not been significantly altered by human activity, or those which require preservation and restoration" by the General Law of Ecological Equilibrium and Environmental Protection (Spanish: *Ley General del Equilibrio Ecológico y la Protecció al Ambiente* - LGEEPA). The PNAs are usually established by presidential decrees whose main purpose is the conservation of biodiversity. The PNAs can also be constituted by states and municipalities through decrees that must be approved in state congresses.
The determination of PNA of state or municipal nature, has among its objectives the preservation of representative natural environments to ensure the balance and continuity of the environmental processes, and the assurance of the sustainable use of ecosystems and their elements.
There is also more specific legislation: Law for the Protection, Conservation and Promotion of Trees and Urban Green Areas of the State of Jalisco and its Municipalities (Spanish: *Ley para la Protección Conservación y Promoción del Arbolado y Áreas Verdes del estado de Jalisco y sus municipios)*, which aims to establish the provisions for expanding, protecting, managing, preserving and restoring urban green areas, palms and trees that are located over non-forest areas of the state. For its effects, the following are considered as public green areas: parks and gardens, wooded or gardened squares, planters, median strips, groves, outdoors sport courts with natural vegetation of public property, and areas or structures with any vegetal cover on public spaces.
In the V Volume of the National System of Urban Facilities (Spanish: *Sistema Nacional de Equipamiento Urbano*), the Ministry of Social Development (SEDESOL, for its initials in Spanish) makes recommendations for recreational and sport spaces, which are considered as areas that "promote communication, interrelation and social integration, as well as coexistence with nature and its conservation inside the urban areas, contributing to their ecological improvement". This regulation dates back to the 1970s, and it has been used as a standard for the design of urban facilities; however, it is not mandatory, since its implementation is optional for the stakeholders interested in urban development.
The Guadalajara Metropolitan Area (GMA) includes 9 municipalities: Guadalajara, Zapopan, Tlaquepaque, Tonalá, Tlajomulco de Zúñiga, El Salto, Juanacatlán, Ixtlahuacán de los Membrillos and Zapotlanejo, where a population of 4’865,122 inhabitants is settled.

Year	Guadalajara	Zapopan	Tlaque-paque	Tonalá	Tlajomulco de Zúñiga	El Salto	Juanacatlán	Ixtlahuacán de los Membrillos	Zapotlanejo	Metro Guadalajara (GMA)

*Table 6. Population 1970 - 1980 AMG. Source: INEGI and * CONAPO, 2017*

With regard to the footprint of the city, this has experienced a stronger and disproportionate increase in relation to the population, which is evident in the period of 15 years comprised between 1990 and 2015. While the population of the GMA went from 2'870,417 in 1990, to 4'865,122 in 2015 -that is, an increase of almost two million inhabitants (1.59 times); the footprint of the city increased 1.9 times its size (IMEPLAN, 2016). This data allows us to determine that the occupation of the territory is more accelerated than the population increase up to 21% (see Table 6).

Consolidated	Potential Consolidation
Parque Agua Azul	Bosque urbano Miravalle
Parque Metropolitano	Cerro El Gato
Parque González Gallo	Parque Lomas del Cuatro
Parque Solidaridad	Parque Cerro del Tesoro
Parque Natural Huentitan	Parque Las Liebres
Parque Morelos	Cerro Santa María

Parque Alcalde	Parque San Rafael
Parque Eca Do Queiros	Parque Roberto Montenegro
Parque Agroecológico Ixtépete	Bosque urbano El Palomar
Parque Tucson	Cerro de la Reina

Table 7. Urban Forests in the Guadalajara Metropolitan Area (IMEPLAN, 2016).

At the metropolitan level, there is a recently created planning instrument: the Metropolitan Territorial Plan (Spanish: *Plan de Ordenamiento Territorial Metropolitano* - POTMet). This plan must define a metropolitan structure to be developed along with the municipalities within the GMA. This is why the inventory of GI that currently exists is fundamental. The POTMet (IMEPLAN, 2016) tries to determine this infrastructure of metropolitan scale and character under the concept of urban forests. These are considered as ecosystems composed of trees and other vegetation with a dense tree mass, which provide different ecosystem services to cities for the well-being of their inhabitants (idem, 2016). As a result of a mandatory national policy to favor the development of compact cities (H. Congreso de la Unión, 2016), the POTMet itself establishes the need to inhibit urban development in areas far from the boundaries of

already existing urbanized areas, however it doesn't include a strategy to increase green spaces that at least correspond proportionally with the number of new inhabitants that are expected to return to the central city as a result of this policy.
POTMet considers two sets of green open spaces: consolidated and with potential for consolidation (see Table 7). Although they are already presented as strategic urban forests should also be valued according to the particular ecosystem services they provide. For this purpose, assessments of those green spaces should be based on the existence of evidence of the provision of ecosystem services.
The assessment proposed refers to a rating of 1-10, and considering the services that are ideal for the improvement of the quality of life conditions of the inhabitants of the GMA; or simply considering the existence of any evidence that proves that the green space is actually providing the service (see Table 8).

	Mobility	Provisioning services		Regulating services								Cultural services				Habitat services	
Space	Mobility Corridor	Food	Water	Urban weather regulation	Noise regulation	Air purification	Extreme weather moderation	Runoff decrease	Water treatment	Polinization, pest control	Global climate regulation	Recreation	Landscape/ Aesthetics	Education	Social cohesion and values of the place	Biodiversity	TOTAL

Cerro El Gato	0	0	0	1	0	1	0	1	0	0	0	0	1	0	0	1	5
……… ……																	

Table 8. Assessment of Urban Forests. Evidence of provision of Ecosystem Services. Self-elaborated with criteria from (EEA - European Environment Agency, 2011).

In order to calibrate the criteria, it is necessary to establish ideal objectives considering the opinion of the citizens, because as it has already been said they are the ones who may or may not legitimize the priority character of the elements of the GI network.
According to the legal and regulatory framework in the state of Jalisco, where the Metropolitan Area of Guadalajara is located, the State Law of Ecological Equilibrium and Protection of the Environment consigns as protected natural areas within the competence of the state government: state parks, natural formations of the state interest and state areas of hydrological protection. And as a competence of the municipal governments: the municipal ecological parks, the ecological preservation zones of the population centers, and municipal areas of hydrological protection.
POTMet states that within the GMA there are five decreed natural protected areas: one is federal (Bosque de la Primavera), two state (Cerro Viejo - Chupinaya - Los Sabinos and Colomos) and two municipal (Bosque el Nixticuil y Barranca del Río Santiago), which altogether occupy an approximate area of 73,330 hectares. The adequate conservation of these areas is relevant for territorial planning, since it helps to maintain the quality of ecosystems and their biodiversity, as well as their provision of environmental services which are achieved through their conservation and sustainable management (IMEPLAN, 2016).

5. Recommendations

As previously explained, not only the presence of nature in abundance is needed for a city to qualify as biophilic, since it must also be one that holds green infrastructure and adequate governance and institutions. The latter would favor the development and strengthening of the other dimensions that make up a city of this kind: behavior, patterns, practices and lifestyles of its inhabitants, as well as attitudes, and the generation of knowledge about nature.

Metropolitan Scale
-Rivers and flood plains. -Lagoons. -Urban forests. -Natural parks. -Continuous water fronts. -Large recreational spaces. -Deserts. -Wild protected areas. -National parks. -Coastline and beaches. -Strategical and long distance pathways. -Forests. -Protective belts in high voltage lines. -Network of roads and railways. -Designated green belts. -Agricultural lands. -Canals. -Open-fields. -Mountain range. -Common territory. -Aqueducts. -Gas pipelines. -Geological faults. -Lakes.

Table 9. Metropolitan Green Infrastructure. Based on EEA - European Environment Agency, 2011; Landscape Institute, 2009; Vasquez, 2016.

In addition to urban forests, some elements of a metropolitan scale could be considered to be integrated into the GMA's Green Infrastructure (see Table 9). These elements must be assessed to confirm their relevance based on criteria such as the one described in the previous section. That is the reason why it is recommended that before establishing a proposal for the GI system, this evaluation should be carried out.

It is foreseeable that some elements are left out of this classification, but they should be integrated into the urban or neighborhood scales, and will continue to be part of the large GI multi-scale system.

Among the recommendations we could consider the proposal of Valdes and Folukes (2016) that refers specifically to mobility, safety, recreation and sports as well as to the economic, environmental and management issues, such as the sectors in which it is opportune to influence in order to define a strategy for generating a GI network.

In terms of mobility, it emphasizes green corridors or linear parks for cyclists and pedestrians that interconnect public places such as squares, parks, schools, libraries, workplaces, even shopping centers, including universal accessibility for these corridors to guarantee its utilization to every user. In Mexican metropolises, security is also fundamental, so the system should take into account both lighting and space monitoring. The use of the GI as recreational spaces, which allows outdoor exercises (depending on air quality), to lead a healthy lifestyle. The GI should also be used to educate and raise awareness about the importance of green areas, particularly by making the value of spaces known; it is advisable to use maps with information such as physical characteristics, and services that are provided inside of them. In the economic aspect, the GI must be considered to attract tourists to urban areas; it must recognize the increase of surplus value of the properties located in the vicinity and that the citizens through the authorities are able to capitalize it; there must be an annual operating budget that ensures continuity in the maintenance of green spaces. It is also recommended the application of tax

incentives to encourage both individuals and companies to donate land destined to increase the GI network, as well as considering as a generator of transfer rights, in order to obtain compensations for the maintenance of properties with the potential to increase floor area ratios (FAR). On environmental matters, spaces in the GI network should be considered as part of the flood reduction strategy in the metropolises, and simultaneously as aquifer recharge areas. About management, it is necessary to prepare, as part of the metropolitan planning instruments, a GI network that includes its implementation through an organizational structure for the planning of the metropolitan territory; an organization must also be created in order to launch a public awareness campaign, integrating volunteer programs, and encouraging fundraising to manage green infrastructure in the Metropolitan Areas.
Although this study concludes that GI is necessary for metropolitan resilience, ultimately, the participation of citizens and their recognition is the only essential element for the GMA to have a GI system/network suitable for their needs.

Case Study: Urban Green Belt Planning in Foshan City, China

Xin Feng, Yunfeng Jin[1]

Abstract
We examine how Chinese planners proposed a green belt to make Foshan resilient to climate change while enhancing recreational opportunities and conserving open space. This effort is noteworthy as the accelerated urbanization in China has created a series of environmental problems.

Introduction

Foshan is a prefecture-level city (herein after also referred to as a municipality) located in central Guangdong Province in southeastern China. The entire prefecture covers 3,848.49 km2 and has an urban population of about 7.2 million. The local government has made substantial investments into technological innovation and its strong support to face environmental challenges has been widely recognized in China.

Green space also plays an important role in urban ecosystems and provides significant ecosystem services with environmental, aesthetic, recreation and economic benefits. Their natural resources and river valleys provide flood protection, fresh water, clean air, local food, and the enjoyment of nature to rural and urban residents. As the population and urbanization of the region expands, the economic, environmental and quality of life solutions delivered by the greenbelt become more important. Through a climate mitigation and adaption lens, the health of the greenbelt and its river valleys is essential to improving resilience in the region.

In recent years, green belts have incorporated the principles of landscape planning into city design, giving predominance to green structures where the relationship between the environment, nature and the landscape are not merely spectators but are key players in the design of cities. These principles were set out in 1988 at the UNESCO Environment and Biosphere Conference which established the need to work jointly on a systematic and collective description for the green areas in a city and suggested that green belt plans must respond to the union between function and design as an integral and active concept. In China, it is possible to find plans based on criteria, but it is difficult to find references to projects which cover all these aspects at once.

In the late 2000's, planners in Foshan developed a greenbelt strategy focused on building a resilient living system which addressed multiple objectives such as recreation, protection, conservation and landscape preservation[i]. As land in China is owned by the government, there is a great deal of potential to conserve the landscape and enhance a resilient ecological strategy.

The overview of Foshan and its existing greenway system

GIS maps of natural and man-made features were created and analyzed. Below are the major findings revealed because of this process.

The administrative region of Foshan had an unbalanced urban construction (Figure 1), by which we mean that there was a greater concentration of high density development in the

[1] Dr Xin Feng, Postdoc Research Fellow, College of Architecture and Urban Planning, Tongji University, China
e-mail: fengxinhome@outlook.com

Professor Yunfeng Jin, College of Architecture and Urban Planning, Tongji University, China

eastern urban area than found in the Western and Northern urban areas. The sprawling urban pattern occupied and split the original “green” natural system with blurred cluster boundaries.

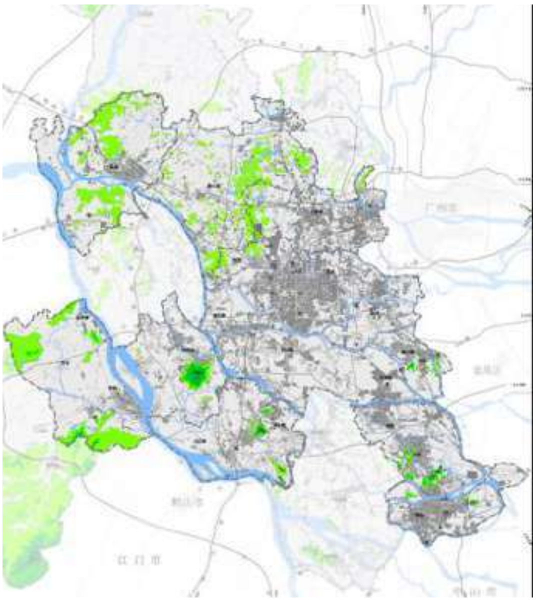

Figure 1 The overview of greenbelt resources in Foshan

Foshan also had unequally distributed forest resources that were mainly located in the Gaoming District in the West (69% of all forests) and the Sanshui District (17% of all forests) in the North (Figure 2). The more developed Nanhai District and Shunde District had fewer forest resources with 9% and 5% of the total Prefecture’s resource respectively. South Asia tropical vegetation accounted for 17.6% of the forest coverage.

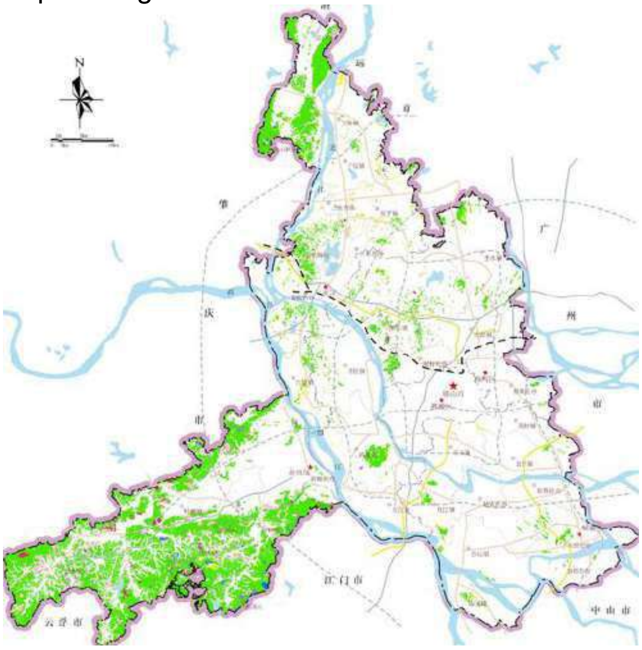

Figure 2 The forest resources of Foshan

Located in the hinterland of Pearl River Delta, Foshan is traversed by the Xijiang and the Beijiang rivers. Both have large flows and boast networked river branches, including the tributary Lubaoyong, Xinanyong and Jiliyong rivers. The land along these rivers is characterized by a typical crisscross water network and a flat terrain. The rivers and their associated wetlands occupy 347.04 square kilometers, or 9.1% of the municipal area (Figure 3). Dike-ponds and farmland cover an area of 731 square kilometers, accounting for 19% of the municipal area. Foshan had three more-than-medium sized water reservoirs.

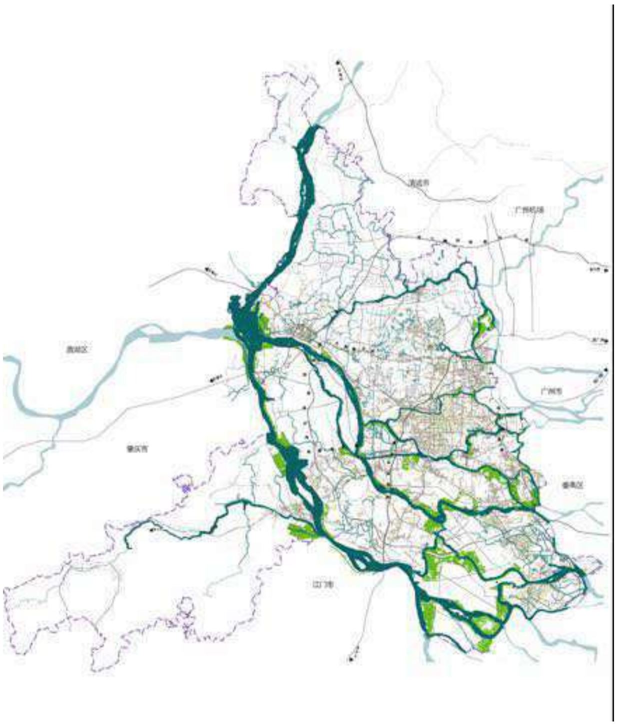

Figure 3 The riverfront green space of Foshan

We also found that although existing regional greenways connected some places of interest, such as forest parks, scenic attractions, and suburban parks, they mostly only connected recreational green spaces. In addition to linking recreational lands, greenways should also serve other purposes, such as eco-conservation and natural feature protection, if they are to become a resilient system.

Our strategy

A regional greenbelt system concept was adopted. Our strategy was to develop a regional greenbelt system which would: 1. include essential ecological elements; 2. reinforces the functions and processes in our current land use plans; and, 3. guarantee the conservation and restoration of key ecological systems. We adopted the concept that the regional green belt is a living system. To keep a healthy green belt, connections with the main supplying areas and natural corridors must be insured.

In landscaping, and specially in large green areas, it is fundamental to maintain a tension which features contradictory characteristics. Therefore, Greenbelts must be flexible, adaptable, socially dynamic, and revive environments that are absent from the city. They must be 'resilient' spaces. In other words, our green belts must be capable of responding to changes or disruptions without modifying their fundamental state (Ahern, 2011). To build up a resilient system, we adopted the recommendations of Jack Ahern (2011) who suggested the following greenbelt characteristics. First, greenbelts must have a multifunctional perspective which brings an integrative ecological-social view. Secondly, the design must prevent functional redundancy and fragmentation, while promoting the diversification of mechanisms, solutions and interlocutors which offer more options for assimilating ecological and social changes. Finally, the project should incorporate adaptive planning and design and be used as a laboratory of ideas which can offer dynamic solutions.

We worked with local government officials to increase public benefits from Foshan's greenbelt and regional resiliency. Our work plan started with an analysis of ecological, social and spatial information at regional and urban scales to offer responses based on resilience. Based on our analysis the following objectives were established:

1. Enhance social wellbeing and identity. The planned greenway should reflect the existing communities and their life styles, related to the prior use of the land and at the same time contribute to the wellbeing and improve of the quality of life, by means of increased accessible and by creating recreation subsystems within the larger project area.

2. Create regenerative and resilient systems and boost the landscape's capacity for recovery, promotion of biodiversity and mitigation of risks. This would be achieved by designing green wedges to penetrate urban boundaries with regional eco-green spaces and by establishing a continuous conservation corridors system to leverage the natural green space resources, ensure the provision of future natural resources, and fight against climate change in urban area.

Background: Management and execution by level

As an of this subordinate green space system planning, *The Master Plan of Foshan* (2008-2020) provided important guidance for developing regional and urban parks and established criteria for establishing the overall area for green space development. That plan called for 9,349 hectares of urban green space, 11.6 m2 of per capita urban green space, and 6,803.5 hectares of urban public green space (8.44 m2 per capita). In total green spaces were to account for 8.3% of urban construction land and an urban greening rate of 48%. Urban green space planning indicators were determined based on the demands and possibility of urban construction and holistic considerations covering short term & long-term development, the development rate, and the special need for urban greening.

Development control of municipal green space were planned to adhere to the regulations of level-based management control and be subject to more specific planning related to the subordinate downtown or the requirements of single green spaces as appropriate.

The programs for new urban green spaces were mainly considered on a case by case basis considering their relationship to existing facilities and in compliance with recreational green space subsystems or landscape green space subsystems criteria. Residential areas and quarters were to be provided with access to municipal park, regional park, residential district park, residential quarter park based on service radius and quantity criteria. For landscape-based subsystem, the instructions on the planning and layout of overall landscape, building and green space areas; greening style and tree species selection were defined in standards and should be executed in the urban design to the scale of detailed single block green spaces and architectural design of subordinate level.

The regional green space system and subsystems

Common to many open space and park systems, the plan envisioned a hierarchy of facilities ranging from regional to neighborhood in scale. This concept was referred to as one consisting of a use classification system and a sub-system based on the function of the facilities.

The regional green spaces were divided into 5 classes and 15 sub-classes (Table 1). Except for the water surfaces of the main rivers, the green space delineated totaled 114,318.35 hectares, accounting for 29.70% of Foshan area. The delineated areas of main rivers and reclamation land reached 30,685.46 hectares (excluded from the statistics).

Table 1 The 5 classes and 15 sub-classes of the regional green spaces

Based on an in-depth survey regarding the diversified functions and inherent connections among regional green space systems, the organization and planning of regional green subsystems (Table 2) was divided into three categories: regional conservation green space subsystem; regional recreational green space subsystem; and, regional protective green space subsystems. This system is displayed in Table 2.

Table 2 Regional green space subsystems

	Natural disaster sensitive zone
Regional protective green space subsystem	Green beltway
	Infrastructure protection

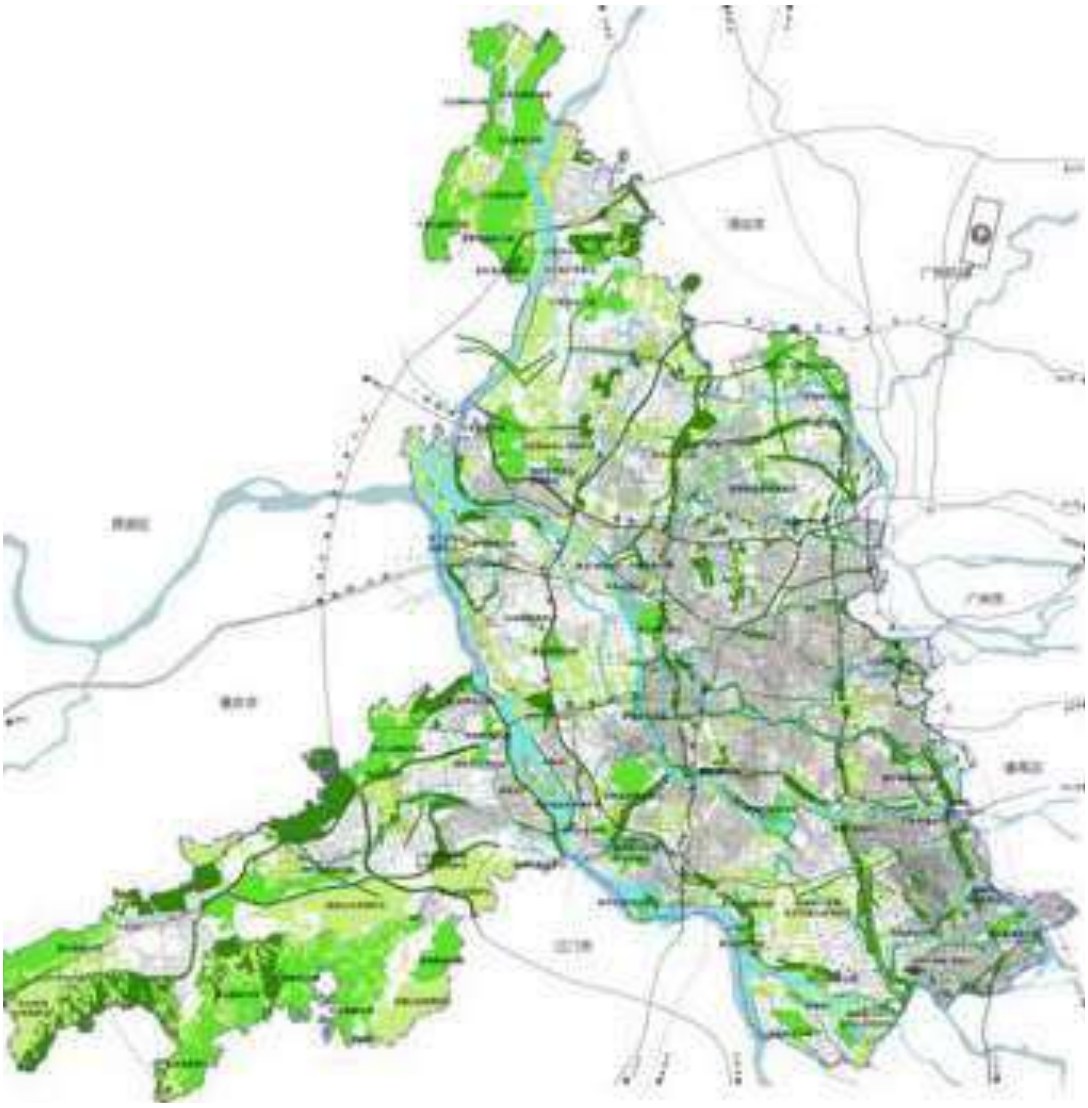

Figure 4 The regional green space system

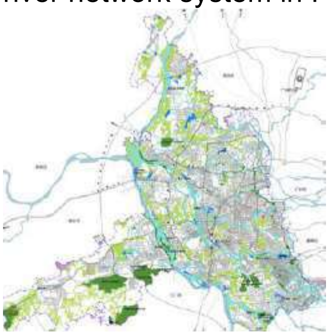
Regional recreational green space subsystem

The planning of municipal recreational subsystem (Figure 5) was arranged based on scenic attractions, forests parks and resorts along greenways, and was integrated with the green space resources, cultural relics and road traffic throughout the municipality.

Figure 5 Regional recreational green space subsystem

Regional conservation green space subsystem

The municipal conservation green space subsystem (Figure 6) covers water source conservation zones, natural conservation zones, seedling nurseries, flower nurseries, grass nurseries and basic farmland conservation zones. It is planned and organized based on the river network system in Foshan.



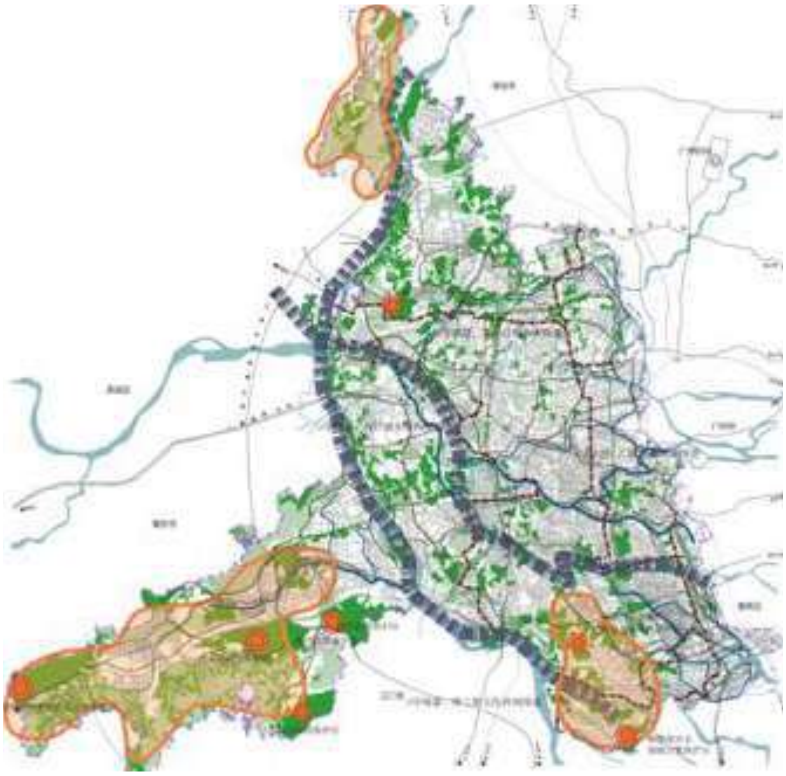


Figure 6 Regional conservation green space subsystem

Our strategy: The urban green space system planning
The principles used to define green land system planning in the urban area (Figure 7) were: first, reflection about the basic structure and layout of regional green space system, and maintenance of the constancy and completeness of natural eco-system; second, defining and coordinating the functions of green spaces and organize the green spaces with similar functions into a subsystem; and third, to ensure a fair and convenient public access. We tried to distribute green spaces evenly.

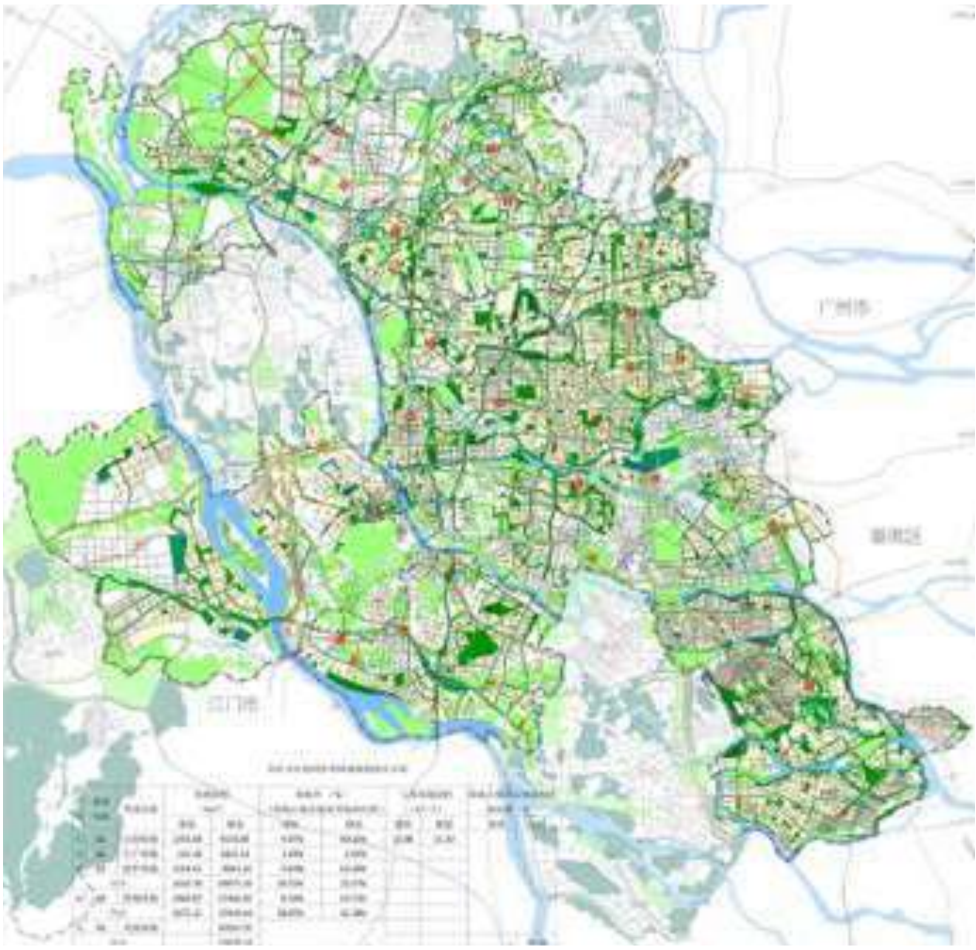

Figure 7 The Urban Green Space System Planning

The layout of green spaces in Central cluster

The layout of green spaces in the central cluster (Figure 8) could be described as **“Four-ring, five-wedge, and multi-axis”. “Four-ring”** refers to the relatively independent, but related, four small clusters formed by Jiliyong Water Branch, Tanzhou Waterway and Dongping waterway. The urban green space forms a ring boundary around all the clusters to protect the landscape system in the cluster. **“Five-wedge”** refers to the municipal green-space-composed broad green belts that connected the periphery and centre of clusters and further divide the cluster interior. The green wedges of clusters were arranged in the same positions of the green wedges in the municipal green space system structure. **“Multi-axis”** refers to the North-South landscape axis of the central zone and its roads. Due to the dense development in these central clusters, the axis planning along with the prevailing wind direction helped a lot to improve urban climate and landscape development.

Figure 8 The layout of green spaces in Central cluster

The layout of green spaces in Daliang-Ronggui

The green space layout of Daliang-Ronggui could be described as **“one-ring, one-core, and two-corridor”**. **“One-ring”** refers to the 200-500 m wide green beltway of Shunde composed of the Shunde, Ronggui, Hongqili, Guizhou, and Jiya Waterways and their waterfront green spaces. Shunde Waterway runs along the North, the Lijiasha Waterway headed to the East and then the West front; relocated No. 105 National Highway and the waterway along Lungui Road extend to the West;and, Guizhou Waterway approached the South. “**One-centre**” referred to the urban green centre surrounding Shunfeng Mountain and the extensive lake. The centre consists of a large-scale area connected with the small waterways and green belts that run through clusters to define a closely interconnected green space system. It is the most prominent recreational and landscape system in the cluster. **“Two-corridor”** referred to the areas consisting of waterways and 400-800 m green belts which separate each cluster. The corridor between Lunjiao and Daliang was formed by municipal buffer green spaces (more than 200 m) along Guangzhou Ring Expressway and that between Daliang and Ronggui is established with Ronggui Waterway and riverfront green space (including the Shunfeng Island and Dashan Island in Desheng River). These two broad corridors separated Daliang-Ronggui Cluster further to form a relatively independent yet interconnected urban land structure.

Figure 9 The layout of green spaces in Daliang-Ronggui

The layout of green spaces in Shishan Cluster

The layout of green spaces in Shishan Cluster (Figure 10) could be described as **“a big green spot+ a large green corridor**” following the green space systematic structure positioning of Shishan Cluster in the Master Plan. The “**big green space**” referred to the concentration of shallow hills, reservoirs and fish ponds, including the extensive hills, lakes, plantation and waters (as part of the Green Centre in municipal green space system) between Nanguo Peach Garden Tourist Holiday Resort, Emperor's Tomb (Tianzimu) Scenic Spot, East of Shishan, Songgang, Dali and Luocun. If we interpreted the whole cluster as a figure-ground diagram, the municipal serves as the ground, and the construction land, the figure. Shishan Cluster worked as an essential urban green core in the overall structure of municipal green space in Foshan.

“**Large green corridor**” referred to the channels consisting of the the scattered water branches and fishponds. This corridor brings waterfront green spaces in the cluster. It could separate the construction land blocks and buffer each eco-blocks and serve a crucial eco-corridor to connect with the Big Green Spot, contributing to a conservation system featuring eco-diversity.

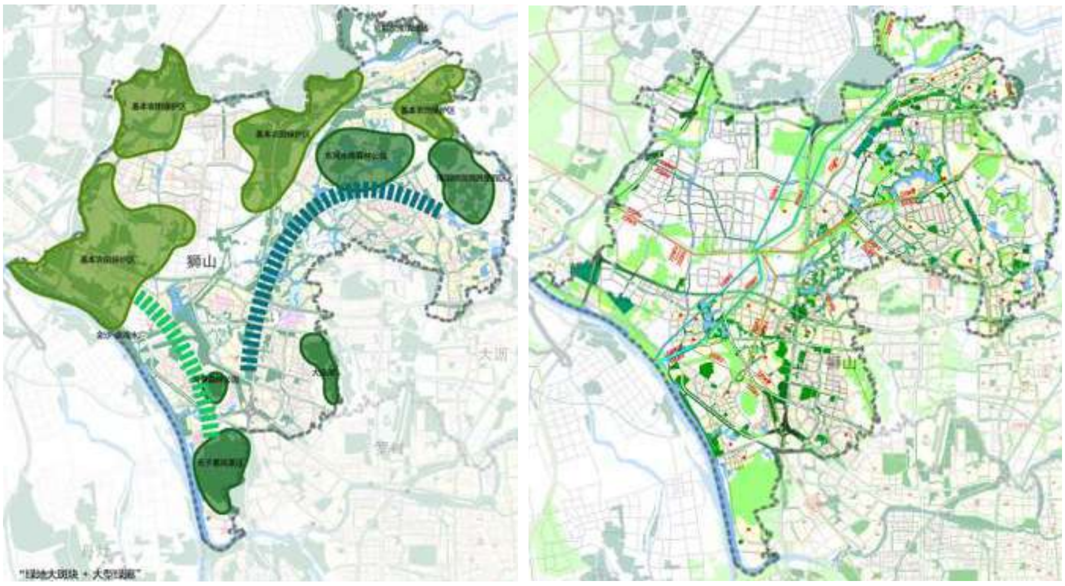

Figure 10 The layout of green spaces in Shishan Cluster

The layout of green spaces in Xi’nan Cluster

The layout of green spaces in Xi’nan Cluster (Figure 11) could be summarized as “**one-axis, two-belt and three plots**”. “**One-axis**” referred to the city axis, composed of various urban green spaces, that connects Yundonghai and Ma’angang,. This cluster connected two important large green spaces in the Xi’nan Cluster, the Yundonghai Wetland Conservation and the Ma’angang Suburban Park. It serves to make the urban green space landscape more consistent, holistic and enhances city ventilation with its North-South orientation. **“Two-belt”** referred to the trunk streams of the Xijiang and Beijiang Rivers as well as the buffer green spaces along the rivers and riverfront green space. It protected city water resources and shapes the urban waterfront landscape. “Three-plots” referred to the three large green spaces which serve as the cardinal conservation system in the cluster. One green space is an essential area for wetland conservation that featured a special geographic landscape located at an estuary. It is the intersection of two rivers, where a group of concentrated islands could be found. The other two green spaces are Yundonghai Wetland Conservation and the South-extending hills of Ma’angang; both important municipal green spaces. Located in the North and South of the city along the dominant wind direction, these Green Spaces helped to improve the climate and environment of the city.

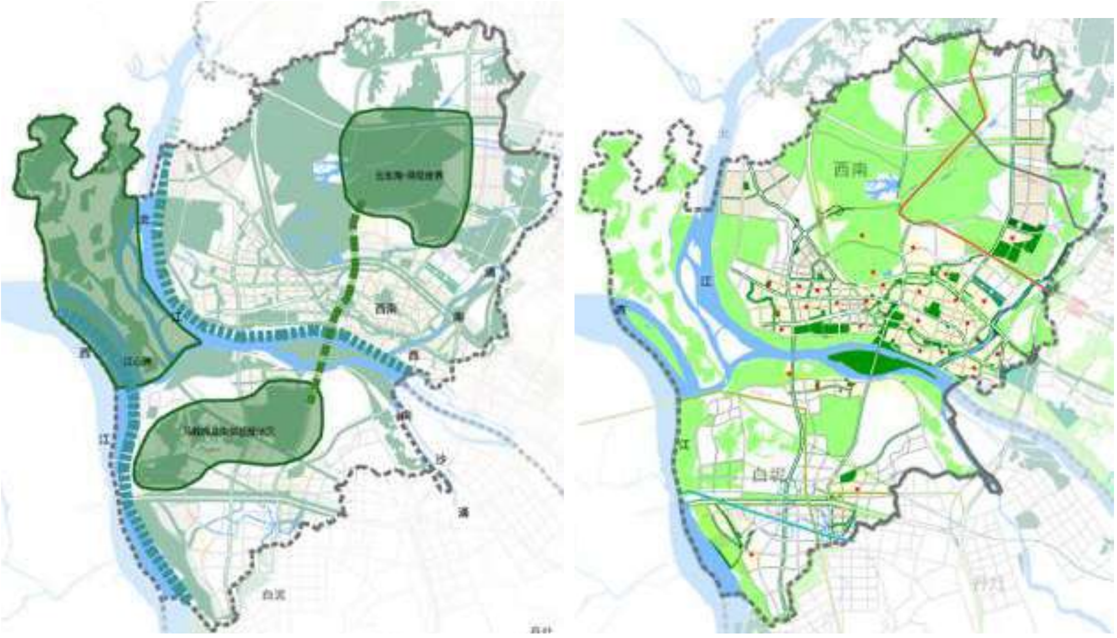

Figure 11 The layout of green spaces in Xi'nan Cluster

The layout of green spaces in Xijiang Cluster
The layout of green spaces in Xijiang Cluster could be described as **"One-river, multi-corridor and three-spot"**. "**One-river**" refers to the Fuwan trunk of Xijiang Riiver. The flat shoal in this section was planned as a suburban park themed for wetland conservation. "**Multi-corridor**" referred to the green beltways along the Guangzhou Ring Expressway and the green belts on, or along, the water system across the cluster. The green belts along traffic paths and water branches, constituted eco-corridors that run through the cluster and connect green spots and Gaoming Forest in the West. The criss-cross pattern of the corridor and green spot helped to organize urban recreational and landscape system.**"Three-spot"** referred to the Xiqiao Mountain Scenic Spots and its dike-pond system agricultural conservation zone, the West Bank Conservation Zone, and, the Lingyunshan Forest Park recognized by UNESCO.

Figure 12 The layout of green spaces in Xijiang Cluster

The layout of green spaces in Dali Cluster
The layout of green spaces in Dali Cluster (Figure 13) could be understood to be **"One-ring, two-corridor and two-axis"**. The term "One-ring" referred to the intersection between Huangqi, Yanbu and Guangzhou set aside for water resource conservation forests; the intersection between Northern & Western Songgang, Luocun and Shishan (dense hills and reservoirs are distributed in the junction of Western Dali, Luocun and Shishan); and the

waterfront green space which is an important buffer green space separating the cluster and central cluster. These water resources areas consisting of conservation forests, hills, reservoirs, waterways, and waterfront green spaces constituted a green beltway for Dali Cluster. **"Two-corridor"** referred to two eco-corridors. Dali Cluster was planned with a North-South green corridor to link the forest oxygen source, where the Nangou Peach Garden Tourist Holiday Resort is located (in the north of the cluster) and the Dali Cluster, intended to improve the domestic environment in the Cluster. Another eco-corridor, combined with the Southern green space resources form a wider green belt which serves as the wind inducing forests and a buffer between industry and residence. For the **"two-axis"**, one axis referred to the urban landscape axis, an extension of the green axis in Nanhai centre landscape which is an essential urban public green space for sightseeing and recreation. The other axis, a road green axis formed with the green belts of Foshan ring by ring, which provided a green open space between the urban areas and North of Foshan.

Figure 13 The layout of green spaces in Dali Cluster

The layout of green spaces in Jiujiang-Longjiang Cluster

The overall layout of green spaces in Jiujiang-Longjiang Cluster could be defined as "**a green beltway, a cross-shaped green corridor and multi-spots**". The "**green beltway"** referred to the ring green belt enclosed by the Jiujiang-Longjiang Section Xijiang (in the North-South boundary of the Cluster); the Shatou-Longjiang Section of Dongping Waterway, and the extensive farmlands in the eastern and western boundaries. The "**cross-shaped green corridor**" referred to the protective green spaces that transverse the middle of cluster, W-E extending along Guangzhou Ring Expressway and those running along Foshan-Kaiping Expressway in North to South direction. Since the area is an important traffic hub, we planned to delineate a nearly 200 meter wide buffer green spaces along the key traffic path at both sides (including Guangzhou Ring Expressway and Foshan-Kaiping Expressway) and establish a reserved right of way for regional traffic. "**Multi-spots**" referred to the massive green spaces, Huangji Heron Conservation Zone, Longfengshan Forest Park, Dajinshan Forest Park and the concentrated farmland in the west, and southeast of Longjiang area.

Figure 14 The layout of green spaces in Jiujiang-Longjiang Cluster

Our strategy: Urban Green Subsystem Planning

The planning of urban green space subsystems
Besides the **quantitative** demands to be fulfilled, the urban green space system should be provided with defined urban **functions** and a **rational layout**. An urban green space system, can be divided into four subsystems: the green space for recreation, the green space for protection, the green space for conservation; and, a landscape preservation green space.

The urban green space should be arranged based on the land use pattern of the urban master plan. It should highlight the functions of urban green space system to the whole city, maximize the connections to other functional green space, balance the distribution of greenway activities and rationalize the spatial arrangement for each green space type.

Recreational green space is provided for the daily activities of citizens and should be fully integrate into the urban areas, such as residential land, commercial land, and road and river system. To integrate urban recreational green space resources, it was necessary to establish green network for people’s daily and holiday access. Therefore, the green space with recreational as major function will become an independent system for such outdoor leisure activities as sightseeing, exercise and social intercourse to enhance urban life quality (Figure 15).

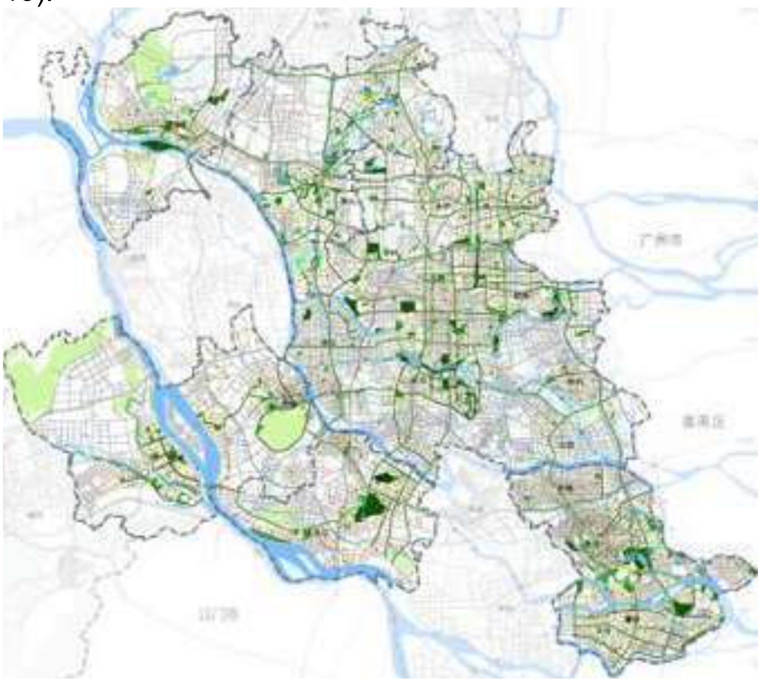

Figure 15 The urban recreational green space subsystem of Foshan

Recreational green space subsystem was divided into two factors (Table 3): planning for recreational spots and recreational corridors. The former mainly consisted of the planning of green space for holiday, daily recreation, and theme recreation. The planning of recreational corridors integrated the planning of **greenway and greennet with the layout of recreational spots**, and provide corresponding classification.

Table 3 The components of urban recreational green space subsystem

	Subsystem components	Planning contents	Types of green space	Notes
			Municipal park	Area ≥45 hm^2

Recreational green space subsystem	Recreational spot	Planning of holiday recreational green space	Suburban park	Excluded from indicator statistics
		Planning of daily recreational green space	Regional park	Service radius: 1,600 m, area: 5-20 hm^2
			Residential district park	Service radius: 600 m, area: 1.5-3 hm^2
			Residential quarter park	Service radius: 350 m, area: 0.5-1 hm^2
			Roadside green space	Determined base on road traffic organization and community park distribution
		Planning of theme recreational green space	Children's park, botanical garden, historical legacy park, scenic attraction park, playground, other theme park	Determined base on green space resources and historic legacy of Foshan
	Recreational corridor	Planning of municipal recreational corridor	Planned based on roadside Greennet and Greenway	Connecting municipal park
		Planning of district recreational corridor	Ditto	Connecting regional park
		Planning of community recreational corridor	Ditto	Determined on regulatory planning
		Planning of theme recreational corridor	Planned based on belt park, river net, etc.	Connecting theme recreational green spaces or comprehensive recreational green spaces

The planning of protective green space subsystem

The planning of protective green space should be arranged based on the local climate and the priority of urban hazards and other disadvantages. A protective green space should not only protect the city from flood, fire or pollution, but also can improve the natural environment by inducing wind, a crucial factor to improve urban residence given Foshan's climate features.

Moreover, the protective green space system provides post-disaster a sheltering system that can accommodate people after evacuations. The planning of protective green space system mainly includes the planning of wind-inducing forests, separating green space, disaster prevention green space and sheltering green space (Table 4).

Table 4 The components of urban protective green space subsystem

Subsystems	Subsystem component	Types of green space
Protective green space subsystem	Green space with wind-inducing forests	Urban wind-inducing forest in North-South direction
	Separating green space	Traffic separating green space (including protective green space for railway, expressway, urban freeway and urban main road), sanitary separating green space
	Disaster prevention green space	Waterfront protective green space, green space along high-voltage grid corridor and other hazardous protective green space
	Sheltering green spaces	Sanctuary and escape passage

Figure 16 The urban protective green space subsystem of Foshan

The planning of conservation green space subsystem
In this planning, conservation green space contains resources to be protective and nourished and includes natural zones and the eco-rehabilitating lands crucial for the integrity of urban ecosystem. These areas should maintain and enhance the stability and continuity of local natural eco-system. Based on the natural characteristics of Foshan, planning of the subsystem consists of four parts (excluded from indicator statistics): planning for protective green space, for rehabilitating green space, for productive green space and for conservation corridor.

Subsystems	Subsystem components	Types of green space
Conservation green space subsystem	Protective green space	Riverfront green space (medium reservoir, dike-pond system) Eco-conversation zone (natural conservation zone, water resource conservation zone, water resource conversation zone and basic farmland conservation zone)
	Rehabilitation green space	Natural disaster sensitive zones, soil erosion prevention zone, water &soil conservation zone, landfill rehabilitation land, etc.
	Productive green space	Seedling nursery, flower nursery, grass nursery, etc.
	Conservation corridor	Green beltway and infrastructure separating zone

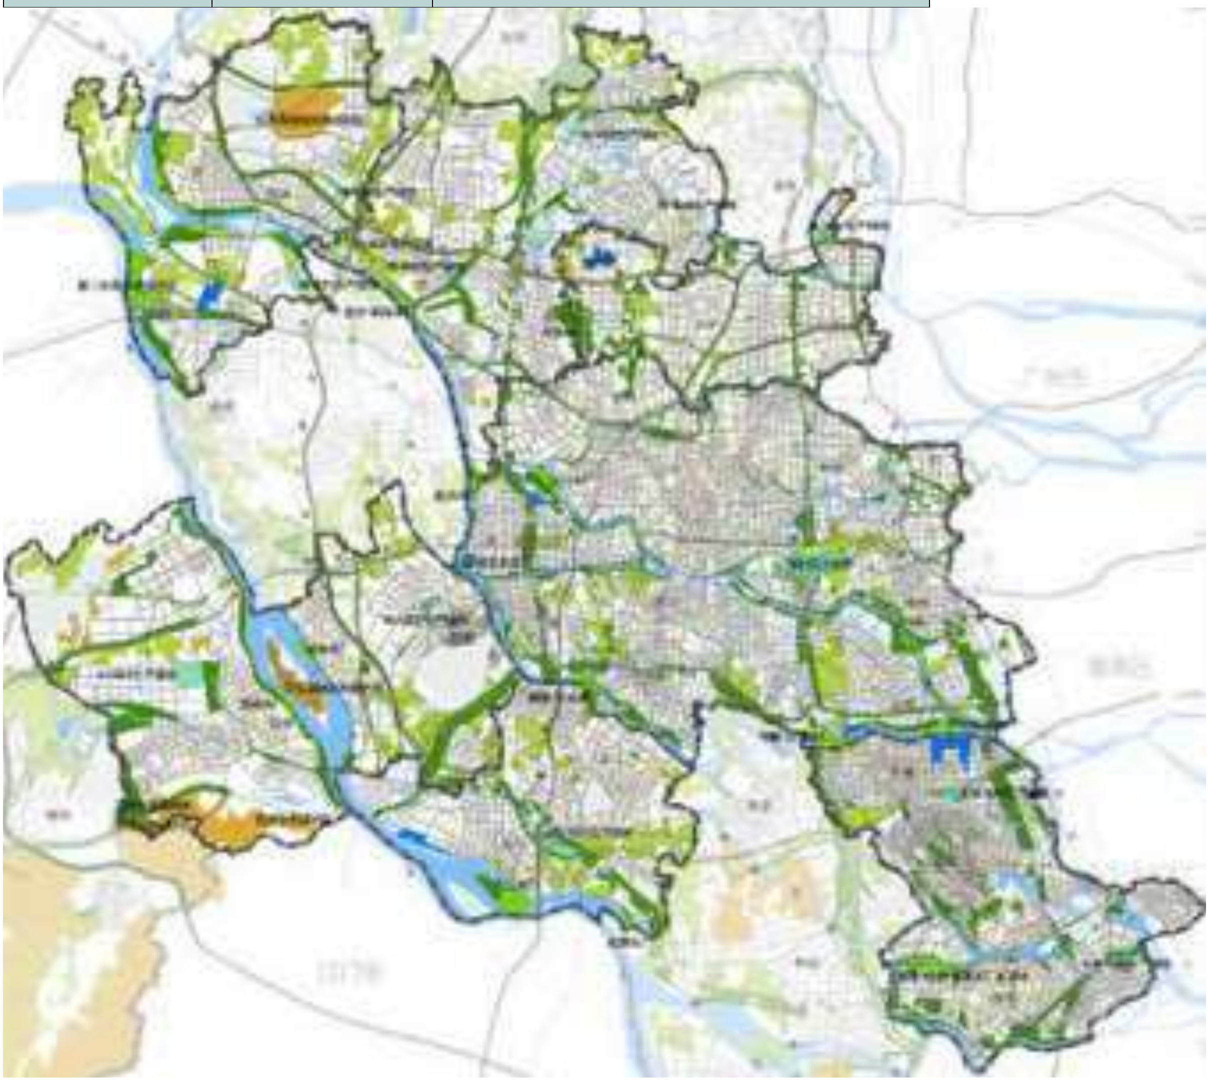

Figure 17 The planning of urban conservation green space subsystem

The planning of landscape green space subsystem

The green space crucial for a city's characteristics and identity is called the urban landscape green space. A landscape green space should focus on the holistic urban arrangement, organize the link between natural and artificial environments, and enhance the key segment to establish a subsystem by planning and integrating. We divided the landscape green space subsystem planning into the following three parts: Planning of landscape guiding control cluster, planning of landscape nodes and planning of landscape corridor.

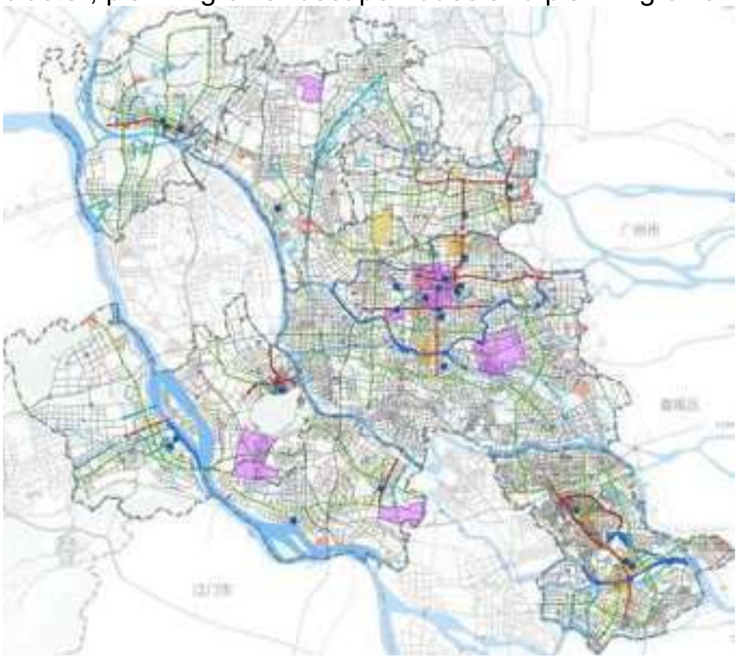

Figure 18 Urban landscape green space subsystem

The planning of urban disaster preventive & sheltering green space

The development of **s**heltering bases, passage and waterfront facilities are the key factors of the urban disaster preventive and sheltering green space system. The location of such green spaces should established where most people live and dwell. The size of a sheltering urban green space should be 1-2 m^2 per capita with an average area of 5-10 hectares.We have identified several types of sheltering green spaces.

1) A **temporary shelter** domestic green space is generally no less than 1 hectare and desgned to accommodate at least 500 people. Its service radius is about 600 meters and travel distance to the shelter should be no more than 10 minutes of walk, including residential district parks.

2) A **fixed shelter** domestic green space should be more than 10 hectares, with a short edge of more than 300 meters. Its service area ranging from 1 to 2 km and it should be accessible with about a 1 hour walk, including regional parks.

3) A **central shelter** domestic green space should cover an area of nearly 50 hectares, with a short edge of more than 300 meters. The service radius extended to 2 to 3 km, and it should be accessible with less than a 2-hour walk. Such facilities would be mainly included in municipal parks and suburban parks.

(II) A **disaster preventive corridor** is a network connecting disaster preventive spots with urban main roads. We plan to divide the disaster preventive corridors into ones for cars and ones for walking access. To ensure smooth and accessible corridors, the buildings along the road should be set-back from their property lines by 5 to 10 meters. High-rise buildings should set-back more. Both sides of the main corridors should be planned with green belts with width ranging from 10 m to 30 m.

Figure 19 The planning of urban disaster preventive & sheltering green space

Tree species planning
Urban tree species planning is the foundation and basis to achieve diversity of garden plants, to upgrade the ecological functions of urban green space system, and develop the eco-network of urban open space.

Foshan has a South Asia tropical and subtropical humid monsoon climate. Foshan's local forests consist of South Asia tropical evergreen broad-leaved species. However, there is only a small block of natural secondary evergreen broad-leaved forests and other plantations are mostly artificial forests. Most lower slopes serve as fruit orchards, while the plain is dominated with cultivated plants. The common garden trees in the municipal area total 116 families, 333 categories and 546 species.

The Basic principles of tree species planning were: 1. develop an urban greening landscape dominated with South Asian tropical plants with local charm; 2. plant mainly evergreen trees in embellished with deciduous trees, combining slow-growing trees with those growing fast and bring together the landscapes of short-term, medium-term and long-term performance; 3. highlighting the diversities in species and genetic inheritance; and, 4. developing the green space mainly with arboreous species, auxiliary areas with bushes & vines, and combine the bio-benefits with landscape performance

Discussion

The condition of green space underpins the functioning of urban ecosystems, which plays a key role in supporting biodiversity and providing important ecosystem services in urban areas. We added the new features of using green development to mitigate heat sinks and moderate summer temperatures, and the use of greenways to provide emergency shelter in the event of disasters. The provision of urban green belt systems and subsystems has given a permanent counterthrust to regular urban planning. The strategy of developing green belts has attained social acceptance and successfully resolves environmental issues while balancing ecological and economic development.

The greenbelt is indeed a physical reality today, but it is also 'a way of doing things'. We believe that this should be a desirable and feasible step towards making real progress

[i] For example, in Foshan, the wind is an important factor to mitigate climate change impacts and therefore our greenbelts include a wind induced forest. These green belts can also serve as evacuation locations and provide shelter after disasters.

A Climate-Adaptation Based Study on Comprehensive Planning Strategy of Urban Water Systems

—Taking the Comprehensive Planning of Water Systems in Xiangyang City, Hubei Province as an Example

(1) Hong Geng, Department of Urban Planning, School of Architecture and Urban Planning, Huazhong University of Science and Technology; Deputy Director of Academic Committee of China Small Town Planning, China
(2) Yue Li, Ph.D. candidate of Huazhong University of Science and Technology, School of Architecture and Urban Planning, China

1. Introduction

The United Nations Intergovernmental Panel on Climate Change (IPCC) predicts that there will be a 90-100% probability of experiencing the increase of precipitation frequency, precipitation intensity and heavy rainfall in the global mid-latitude and tropical humid regions in the late 21st century (2081-2100) and a 66-100% probability of experiencing the increase of drought intensity and duration from the regional scale to the global scale.[1] Climate change has become a big issue concerning the destiny of mankind. The city, as a gathering point of human beings, accounts for only 2% of the total surface of the Earth, but the greenhouse gas emissions account for 70% of the total. [2] Hence, the effect on city's "Carbon Reduction & Carbon Sink Increment" largely determines the success or failure of climate change. Meanwhile, the global climate change also greatly affects cities and urbanized areas that the adaption of city and its respond to other disruptive events have been greatly reduced. Therefore, it is urgent to introduce the climate impact factors to the city and retard and adapt to the impact of poor climate on cities with urban factors.

Urban water system, as an important city element, mainly includes aquatic ecosystem, aquatic environment system, aquatic resources system and aquatic security system, which is a significant component to maintain the normal operation of city. Under the influence of climate change, the urban water system is characterized by sensitivity, vulnerability and adaptability. It is susceptible to the disturbance and causes the damage to aquatic ecosystem and aquatic environment, the reduction of aquatic resources and the decrease of aquatic security index.[3] At the same time, the urban natural water system, as an important cold source of city, is also one of the important ways to alleviate the urban heat island effect. Therefore, it is of great significance for the improvement of the urban climate adaptability to study the adaptation and mitigation of climate impacts on the urban water system. In this paper, the rich water system in Xiangyang City is selected as the research object to explore the water system planning strategy that is suitable for the climate adaptability.

2. Overview of Planning Scope

2.1 Natural Conditions within the Planning Scope

Xiangyang City, located in the northwestern part of Hubei Province, the middle reaches of Han River that is the largest tributary of the Yangtze River, and the Qinling Daba Mountain, is a national historical and cultural city known as the "Landscape City of Chinese Hinterland". The urban water system in Xiangyang City is unique endowed by nature and its central city is divided into four areas, namely Xiangcheng, Fancheng, Xiangzhou and Dongjin, by the natural division of Han River, Tangbai River and Xiaoqing River. There are four rivers passing through four cities respectively, namely Xiangcheng's Nanqu-City Moat, Fancheng's

Dali Moat, Xiangzhou's Lianshan Moat and Dongjin's Haoran River, which constitutes the city map of "one river and eight streams" for the reason that Dongjin is surrounded by Chunhe River and Gunhe River (Figure 1). The urban water system is still difficult to bear the future development of city despite the dense current urban water network and the rich water body. Main reasons are as follows: ①Seasonality of water flow exacerbated by climate change: only Han River, Tangbai River and Xiaoqing River are the flowing water in the urban area and others are changed by natural conditions and become the city inland rivers. Some rivers have the seasonal dryness due to the lack of fixed water sources. ② Serious pollution: all rivers pass through the urban built-up area and the imperfect sewage system in the initial stage of urban construction has led to serious water pollution in that a lot of water body has become urban sewage drains, so it is urgent to carry out the water environment remediation. Furthermore, the limited assimilative capacity has also become an important factor to restrict the urban development. ③ Insufficient carrying capacity of water sources: the average annual rainfall of Xiangyang City is 869.2mm, the average annual runoff depth is 217.1mm and the average annual evaporation is 1,430.7mm. In addition to the seasonality of rainfall and water pollution, Xiangyang City is still a relatively deficiency area of water resources.[4]

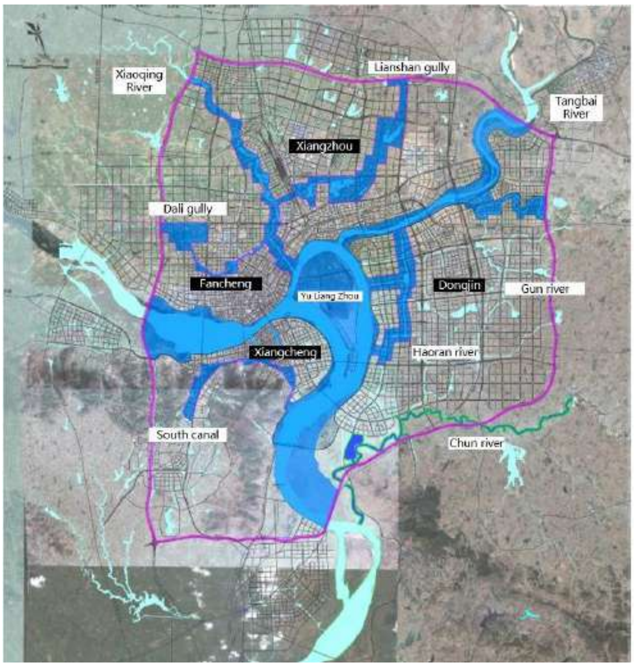

Figure 1: The pattern of ecological water system in Xiangyang City (drawn by the author)

2.2 Regional Climate Characteristics and Variation Trends

Xiangyang City, located in the transition zone from subtropical monsoon climate to temperate monsoon climate, is characterized by four distinct seasons and large temperature differences in winter and summer. The perennial measurement statistics of Xiangyang meteorological station shows that the extreme maximum temperature in the region is 41.1 ℃, the extreme minimum temperature is -14.8 ℃, the average annual temperature is 15.6 ℃, the annual sunshine hours are above 1800h and the frost-free period is 318d. The regional heavy rain mainly occurs in summer, with the highest in July and August, accounting for 40% of annual precipitation. The uneven temporal distribution of rainfall leads to the exuberant ecological water network in the summer, but in other seasons, except for Han River, Xiaoqing River and Tangbai River, the remaining water systems basically dry up.

With the global climate change, the extreme climate in Xiangyang City has happened in the recent years frequently. In 2017, the city's average precipitation was 1,176mm, which was 30% more than the average year and the distribution trend of precipitation was on a diminishing scale from the south to the north and from the east to the west, among which the urban precipitation had reached a record high. From August 25th to October 19th, 2017, the total number of rainy days was as high as 40-50 days and it was rare for rainy and sunless days. The overall precipitation was sudden and local, and the rainfall distribution was uneven, which caused the severe urban waterlogging and the several overflow disasters.

3. Comprehensive Planning Strategy of the Climate-adapted Urban Water System

Based on the goal to mitigate and adapt the climate, the climate-adapted urban water system planning adopts the corresponding planning techniques to increase the resilience of urban water system and maintain the normal operation of aquatic ecology, aquatic environment, aquatic resources and aquatic security system. The planning of “Nourishing City with Nine Rivers” in Xiangyang City relies on the above-mentioned principle to focus on the path and technical means of water system planning to resolve the climate change from the perspective of problems and targets. [6, 7]

3.1 Pre-planning: Establish the “Pre-assessment” System of Climate-adapted Urban Water System

Based on the assessment of the current capacity of water system in the planning area, “pre-assessment” refers to the targeted assessment for adapting and offsetting the climate change’s impact on the urban water system to enhance the flexibility of cities to cope with climate disasters. It mainly includes basic information collection, current situation and ability assessment and targeted goal setting (Figure 2).

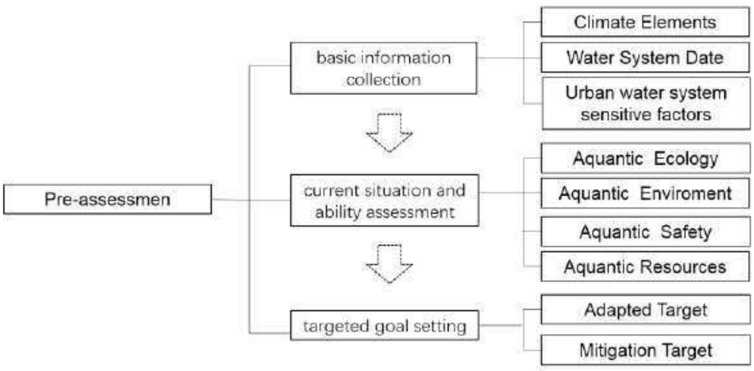

Figure 2: “Pre-assessment” system （drawn by the author）

The basic data for climate-adapted water system include not only the traditional water system planning data, but also the data of urban climate and urban water system sensitive factors. In Xiangyang City, the recent extreme climate is dominated by high temperature, drought and heavy rainfall, and the high-intensity development and traffic load around rivers and lakes have become important factors in urban water systems. Under the impact of climate change, the urban aquatic ecology, aquatic environment, aquatic resources and aquatic security system are faced up with the potential risks.(Table1)

The basic data on nine natural water systems and artificial municipal pipelines in the planning area are collected and comprehensively evaluated, which can be included in the impacts on the climate change and urban water sensitive factors. Meanwhile, the planning target is proposed from two aspects of mitigating and adapting the climate. From the perspective of mitigation, the urban development path, surrounding land utilization and transportation mode are guided to reduce the pollution and carbon dioxide emissions from the source combined with water system planning; and from the perspective of adaption, the planning for natural water system and artificial water system can improve the capability of water system to cope with the climate disasters and enlarge the carbon sink area to alleviate the urban heat island effect and reduce the adverse effects of climate.

Table1：The pre-assessment based on the climate-adapted water system in Xiangyang City

（drawn by the author）

Main Climate Characteristics	Aquatic Ecology	Aquatic Environment	Aquatic Resources	Aquatic Security System
Seasonal Temperature Difference, Obvious Summer Heat-waves	Increased water metabolism required for plants and animals	Water blackening and smell	It causes the outbreak of algae and the water quality is hypoxic. Increased consumption of evaporation and urban and tight water supply.	Increased sludge treatment capacity and difficulty, difficult sewage plant work.
Uneven Spatial and Temporal Distribution	Seasonal dryness, unable to guarantee ecological base flow, declined groundwater level.	Seasonal dryness leads to the water blackening and smell.	Increased the concentration of pollutants, decreased water quality.	Seasonal flood control and difficult sewage discharge.
Short-term Heavy Rainfall	Damaged ecological landscape and serious soil erosion.	Serious non-point source pollution.	Increased the turbidity of water source and decreased water quality.	Urban waterlogging and frequent dam-break.

3.2 Interim Planning: The Utilization of "Interim Technology" Strategy to Copy with the Climate Change

3.2.1 Water System Restoration: Construct the Urban Healthy Water Ecological Structure

The "pre-assessment" of climate-adapted water system shows that the water system in Xiangyang City is faced up with the severe climate change situation and the poor current status of water system. Several inland rivers in the city have the function of urban flood control and drainage, while some ditches need to be discharged. Meanwhile, the unstable water source leads to the poor water quality and serious polluted rivers. It is urgent to establish a set of systematic positive cycle of urban water system to prevent the external shocks such as floods, droughts, pollution, etc., which is incapable of endangering other systems and can meet the requirements of water system's function and safety. The current status of regional water system shows that it is the primary task to carry out the flood control and drainage, water diversion into the city and water system connection.

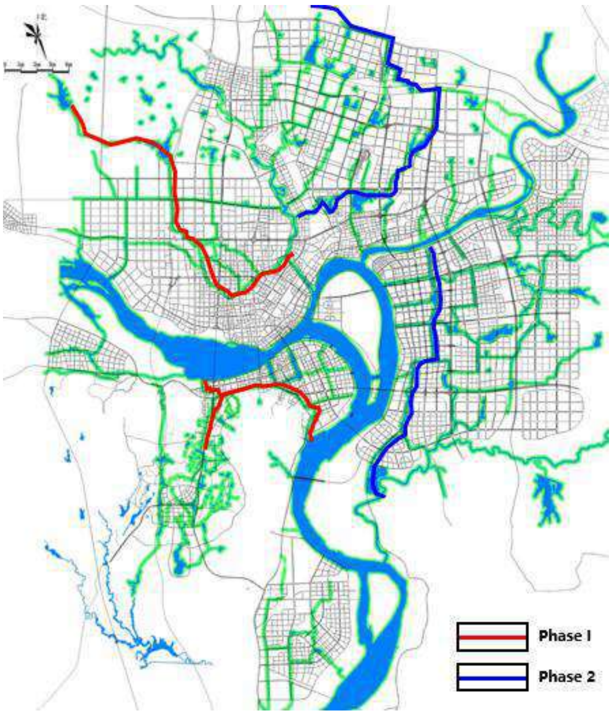

Figure 3: Implementation of the water diversion period（drawn by the author）

The relevant research shows that the

running water in cites is of great significance to realize the connection of water system: ① Balance the uneven spatial and temporal distribution of precipitation; ② Enhance the capacity to cope with the global climate change and prevent the floods and droughts; ③ Achieve the new situation of water resources development and utilization on the wet-dry season diversion and multi-source complementation by the smooth water system network; and ④ Utilize the connection of water system to maintain the health and long-term stability of rivers and lakes, exert the ecological comprehensive benefits, enhance the stability of regional natural ecology and environmental systems, and realize the positive cycle of drainage basin. Furthermore, the relevant technical results show that the temperature of flowing water body is low and the surface temperature can be taken away during the flow process. Meanwhile, the natural air passage can be formed by the open river channel to reduce the urban heat island effect effectively. [5]

Therefore, the urban water system can be restored by three methods of “Water Diversion, Communication and Interception”. On the basis of maintaining the basic trend of water system, the issue of no running water source aiming at three urban inland rivers (Dali Moat, Lianshan Moat and Nanqu Moat) has been analyzed to determine the water source, waterway, water volume and the short-term and long-term water diversion plan (Figure 3). Meanwhile, the “Three Rivers Connection” project will be carried out in the unconnected Han River, Nanqu Moat and City Moat (Figure 4), which not only can alleviate the flood prevention problems caused by the lack of sections of Nanqu Moat and City Moat, but also can lay a good foundation on building the “Clear Water and Green Shore-side” ecological landscape, cultural scenery and waterfront leisure area of Nanqu moat. On the basis of respecting the status, the sewage system is optimized by the water system aiming at the problems of sewage discharge to collect the sewage from the source and prevent the untreated sewage from being directly discharged into the water body. Meanwhile, the serious polluted rivers can be treated to remove the sludge and purify the water quality of urban water system, and the aquatic ecological system can be restored radically by the measures of introducing aquatic animals and plants and improving the regional water environment, which can construct the water ecological system of “Nourishing City with Nine Rivers” with Han River as the main line.

Figure 4: Three rivers connection project

(drawn by the author)

3.2.2 Nourishing the City with Rivers: Construct the Strategy of Urban Water System Carbon Sink and Green Net

As an important way to reduce the urban heat island effect, the urban water system is a significant measure to cope with the climate change by combining with the urban water system and the low-carbon green net of water system. Taking the “Nourishing the City with Nine Rivers” as a key strategic goal, this planning utilizes the water system’s ecological corridor to build up the green net and form the green carbon sink network by the connection of urban artificial green land and natural ecological base, thus reducing the urban heat island by plants, water areas and soil carbon pool.

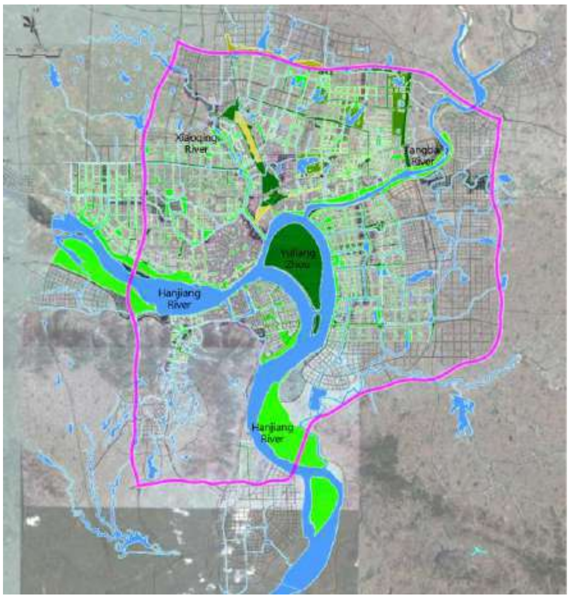

Figure 5: The pattern of water system green net in Xiangyang City

(drawn by the author)

The urban greenway is constructed along with the dredging water body and combined with the waterfront green space, and four wedge-shaped ecological corridor formed by Han River, Tangbai River, Xiaoqing River and main ecological matrix directly are connected with Yuliangzhou ecological green island to form the whole urban wind channel, which can effectively separate the comprehensive group of overall urban planning and extend the landscaping to the central city to improve the central city's environmental quality and the heat island effect. The inside and outside ecological corridor and city wind channel are connected in and around the city with the network of four ecological rivers connected with Nanqu Moat, Dali Moat, Lianshan Moat and Haoran River in four urban areas, and Gunhe River and Chunhe River natural river-way are regarded as the platform outside the city to strengthen the natural ecological environment protection and form an urban micro-environment conservation area of water body. Meanwhile, the water body in the central city and urban streets is connected with the urban comprehensive park and street landscaping to form several secondary ecological landscaping corridors and construct the urban low-carbon ecological green land systematic network (Figure 5).

3.2.3 Multi-protection: Construct the Resilience System of Urban Aquatic Security

(1) Construct the urban security pattern of rainfall flood

Recently, except for Han River, Dali Moat and Xiaoqing River, the flood control standard for others of nine rivers is relatively low, which increases the pressure of urban flood control. Furthermore, the outside flood control system is also uncompleted and the flood drainage standard is about once in 5-10 years, which cannot meet the requirements of urban flood control.

According to the results of "pre-assessment", the recent heavy rainfalls are taken into account comprehensively in the planning. The assessment level has been re-evaluated to plan nine dikes of waterways and construct the resilience flood-control protection with the combination of dam protection, water system connection and ecological corridor. The specific goals of various flood-control protections can be determined in the planning based on the water system's function position. Moreover, the security protection of waterfront space can be strengthened by controlling the dam or greenbelt width, section form, flood-control standard. Aiming at the issue on Nanqu Moat flood-control that the old city is difficult to be widened, the "Han River-Nanqu Moat-City River" water system connection project has been adopted. Based on the existed section of Nanqu Moat, the upstream to Han River flood diversion is connected and the downstream is connected with the city moat channel, which can enhance the regulation and storage capacity of nature to meet the whole regional flood-control standard by utilizing the storage of city moat.

Figure 6: Tangbai River ecological corridor *（drawn by the author）*

Meanwhile, in response to the severe situation of climate change, the green corridor protection area is established on both sides of the river-way with a once-in-a-century standard to reserve the flood-control channel. Connect the ecological corridor with the surrounding water catchment region, construct the natural protection system of water ecological infrastructure by ecological wetland and artificial lakes, adopt the multi-functional storage facilities to regulate the discharge of runoff rainwater, and establish the six-in-one "city sponge" of "seepage, stagnation, storage, purification, usage and drainage" to enhance the resilience of urban rainfall flood (Figure 6).

(2) Build up the "rainfall flood cell" of sponge city

As a kind of management method based on the principle of "natural accumulation, natural infiltration and natural purification", the sponge city is of great significance to relieve the urban flood, cope with the dry climate, and reduce the urban heat island effect, building energy consumption, consumption treatment and water consumption, which is an important measure for cities to cope with climate change.

The planning aims to break up the past pattern that the city rainwater is unified in the pipelines and is discharged after the unified treatment by constructing the "ecological rainfall flood cell" and "community rainfall flood cell". The local absorption is actively adopted to divide the large-scale catchment area into "sponge cells" with small areas and carry out the reasonable rainfall flood planning aiming at the water catchment situations, thus reducing the surface runoff and large-scale rainfall gathering.

Table 2: The indicator control of low-impact development facilities（drawn by the author）

<table>
<tr><th>Category</th><th>Land Usage</th><th>Land Code</th><th>Sunken Green Belt Ratio</th><th>Green Roof Coverage Ratio</th><th>Permeable Pavement Ratio</th></tr>
<tr><td rowspan="6">Building and Residential Quarter</td><td>Residential land</td><td>R</td><td>New-built≥30%
Rebuilt ≥25%</td><td>Low-rise Construction≥20%</td><td>New-built≥50%
Rebuilt≥40%</td></tr>
<tr><td>Commercial Service Land</td><td>B</td><td rowspan="2">≥40%</td><td rowspan="2">≥50%</td><td rowspan="2">≥50%</td></tr>
<tr><td>Public Management and Service Facilities Land</td><td>A</td></tr>
<tr><td>Industrial and Storage Land</td><td>M</td><td>≥40%</td><td>—</td><td>≥30%</td></tr>
<tr><td>Utilities</td><td>U</td><td>≥40%</td><td>≥50%</td><td>≥50%</td></tr>
<tr><td>Transportation Facilities</td><td>S</td><td>≥30%</td><td>—</td><td>≥30%</td></tr>
</table>

The "ecological rainfall flood cell" mainly utilizes and integrates the urban ecological resources to form the "rainwater receivers", which organically combines the forest, wetland, grassland and river channels through point, line and surface to form the dense, scattered and connected arrangements and increase the probability of local absorption. The “community rainfall flood cell” mainly utilizes the strategy of “low-impact development” to encourage the community construction and enhance the absorption or stagnation of rainwater from multiple levels of sites, buildings, roads, squares and green belts. The proportion of community sunken greenbelts, green roof coverage and permeable pavement is controlled in the planning to ensure that the total annual runoff is within a certain range and realize that the rate of final urban annual runoff control is 77%.

3.2.4 Strategy Four: Promote the Transition of Low-carbon Cities with Water as a Medium

(1) Transfer the industrial city to the low-carbon city by water resources

As a historical and cultural city, Xiangyang City has a history of more than 2,800 years with rich water resources. However, its urban development mainly relies on industries such as automobile and textile industry. The scenery resources have not been effectively utilized and the urban water system pollution has become one of the factors that restrict urban economic and social development instead.

By means of the treatment of urban water system to construct the landscape structure of mountains and rivers, the planning further optimizes the green space of riversides to promote the adjustment of industrial structure and the transformation of development model and gradually realize the transition from “industrial city” to “landscape cultural city”. On the basis of different geographical locations of each water system, different locations of cities, different cultural background, the local cultural exploration is taken as the starting point to build up the unique district and promote the industry transformation. Taking Xiangyang City as an example, it aims to build up the distinctive tourism industry with history, culture, folk customs and ecological civilization by connecting with water system connection project, restoring the historical culture, improving the ecological environment, optimizing the surrounding green space and connecting Zhenwu Mountain, Mayuetan Stream, Zhang Clan Temple, Yang and Du Clan Temple, Xi Clan Park, Guanyin Pavilion and many other historical interests

(2) Rational land-use: build up the shared, ecological and low-carbon public space

The urban water resources are susceptible to the external environment that is characterized by fragility and sensitivity. Several rivers in Xiangyang City all pass through the interior of the city and the non-point surface of water system is seriously polluted. The improper development of waterfront sensitive areas is an important factor for city’s disturbance to water bodies. The rational land-use of waterfront sensitive areas is the key way to alleviate the urban aquatic environment, adapt and mitigate the climate change.

The urban waterfront space development and construction standards for different types of rivers have been formulated to divide the waterfront space into ecological protection zones, ecological control zones and ecological coordination zones. Meanwhile, the land along the water system has been controlled to adjust the waterfront construction type and the quantified waterfront space to reduce the disturbance of urban water body. Considering the operability of implementation, the waterfront greening control can be regarded as the foundation and the waterfront construction control can be regarded as the complement in accordance with the principle of "combination of unified control and hierarchical control, forced control and coordinated control". The basic flood control security of rivers can be regarded as the reference to determine the water face control line and formulate the blue line setting standards for each river water body aiming at the rivers management. According to the waterfront space control requirements, the construction requirements of urban development, urban greenway and urban open space are combined to formulate the waterfront green line and jointly build up the layered protection control system of water body.

In addition, the combined use of waterfront land-use and the dynamic, shared, low-carbon waterfront space with the public transportation as the core and the waterfront slow-moving system as the link can be encouraged to alleviate the urban heat island effect and reduce urban carbon emissions. The public service system characterized by space-efficiency, compact development and moderate advancement has been formed to guide the rational layout and diversity allocation of layered public service facilities by the urban design of waterfront areas(Figure 7).. Meanwhile, the dense pedestrian network-small street layout is formed in the waterfront areas to create the walking space characterized by high-accessibility and beautiful environment, which can reduce the dependence on automobile traffic, effectively reduce traffic carbon emissions, alleviate the negative impact of regional environment on the urban construction activities and promote the resilience of city.

Figure 7: Schematic diagram of the riverside slow-moving traffic and ventilation corridor

（drawn by the author）

3.2.5 Strategy Five: "Net-zero" Vision: Promote the Comprehensive Utilization of Urban Water Resources

The US Environmental Protection Agency defines that "net-zero" vision refers to the restriction of regional water consumption in city and the recycle of water extracted from the river basin to the natural watershed with the same water quality and quantity, avoiding the water depletion. 8 The net-zero strategy mainly achieves the protection of water resources by reducing urban water use, water resources recycling and water environment management.

In order to reduce the urban water consumption and promote the recycling of water resources, the municipal facilities are optimized to establish the dual water supply network, and reduce the conventional water use by the optimization of water supply pipelines and sanitary ware. Furthermore, the water resources optimized strategy is proposed to guide the urban construction: ① Establish the regional shared water resources, rationally allocate the wading facilities to realize the large-scale balance of water supply and demand, and alleviate the uneven distribution of water resources; ② Use the local or local-adapted native landscape plants as much as possible to reduce the amount of water for municipal watering;

and ③ Actively adopt the unconventional water resources, develop and utilize the recycled water with multiple channels. The rainfall collection and utilization and the recycling of recycled water have been included in the urban construction management and control indicators. The roof rainwater collection and recycling system has been encouraged in the urban new buildings to improve urban green belts and large public spaces, which can provide the water collection function and can be used as the municipal water, such as spraying, irrigation, fire-fighting, landscape and others.

In response to the water environment management, it needs to not only strengthen the urban infrastructure to improve the sewage treatment capacity, but also enhance the self-purification capacity of water bodies to improve the resilience of urban water environment to cope with climate change. The planning aims to adopt the ecological water body remediation technology, ecological revetment technology and ecological landscape technology to establish the waterfront ecological buffer zone or water ecological wetland by connecting with water system, and build up the ecological restoration and protection system. The restoration of revetment vegetation, river wetlands and river greening can provide the habitats and foraging environments for birds, insects, and small fish at the bottom of rivers and improve the self-purification capacity of water bodies by means of planting aquatic plants.

3.3 Late Planning: Construct the "Post-evaluation" System of Urban Water System Planning

The "post-evaluation" of urban water system planning mainly measures the urban water system planning effect by the evaluation indicator of sponge city and river ecological construction effect, which can be used to measure, adjust and guarantee the healthy operation of urban water system.

(1) The evaluation indicators of sponge city

The planning of "Sponge City Planning Guideline of Xiangyang City" has proposed the control requirements of aquatic ecology, aquatic environment, aquatic resources and aquatic security to guide the urban construction. As for the spongy city, on the one hand, each construction project implementation has been monitored and evaluated according to all indicators (Table 2); and on the other hand, the factors on the urban climate in Xiangyang City, water resources conditions, the difficulty of urban old and new district reconstruction and land-use conditions have determined the total annual runoff target of Xiangyang City and the adjustment value of total runoff control in various types of lands. Whether the land can meet the control requirements of annual total runoff depends on the calculation of annual average integrated rainfall runoff coefficient and the water storage capacity of each land.

(2) The evaluation indicators of river ecological construction effect

According to the requirements of comprehensive aquatic ecosystems, the evaluation indicators can be divided into aquatic ecosystem status indicators and aquatic ecological construction indicators in the planning, which can measure the effect of river ecological construction. The aquatic ecosystem status indicator reflects the capacity of aquatic ecological self-repair and the aquatic ecological construction indicator mainly reflects the coordination level of water and city, which can guide the formation and daily management of constructive planning. (Table3)

With the gradual construction of China's "Multi-standard Integration" platform and the continuous optimization of intelligent monitoring technology, the future "post-evaluation" system should be more perfect: ① Construct the spatial data of planning area with GIS and compare the pre-assessment target for the optimization and adjustment by implementation, monitoring and evaluation; ② Consider the dynamic factors of climate change to realize the dynamic tracking; ③ Evaluate the actual effect of planning for the climate change by carbon emissions and related indicators of aquatic ecology and security; and ④ Optimize and adjust the existed technical defects in the planning by the evaluation results.

Table 3: The evaluation indicators of river ecological construction effect

（drawn by the author）

No.	Indicators Types	Names of Indicators	Unit	2015	2020	2030
1	Aquatic Ecological Status Indicators	Water quality standard rate of water functional area	%	50	60	95
2		Chlorophyll of urban water body	μg/l	>65	30～65	<30
3		Transparency of water body	m	≤0.5～1.5	0.5～1.5	>1.5
4		Water quality standard rate of urban centralized drinking water source	%	96	100	100
5		Submerged plant coverage	%	10	20	30
6		Species diversity indicator （Shannon-Weaver Index）	!	0～2	1～2	1～3
7	Aquatic Ecological Construction Indicators	Urban sewage centralized treatment rate	%	37	80	90
8		Urban domestic sewage pipe network collection rate	%	41.6	83.2	92.4
9		Urban non-point source pollution treatment rate	%	0	20	50
10		Waterfront greening rate	%	30	40	50
11		Harmless disposal rate of domestic garbage	%	50	80	100
12		Soil erosion control rate	%	20	50	100

4. Conclusion

It is an important part of urban construction in the future to strengthen the ability of urban planning to cope with the climate change. Taking the planning of “Nourishing Cities with Nine Rivers” as an example, the comprehensive planning methods and technical strategies of aquatic system for climate change have been discussed respectively in this paper. On the one hand, the climate change factor has been included in the system of “pre-assessment”, “interim technology” and “post-evaluation” according to the methods and characteristics of planning; on the other hand, the strategy on the climate-adapted urban water system comprehensive technology has been discussed and the implementation strategy and path of urban water system for the climate change has been explored by combining with the core content of “alleviating and adapting the climate”. Due to the shortcomings of urban basic data and technology, the related research on the pre-assessment and post-evaluation system is week. With the establishment and optimization of urban intelligent information platform, the index assignment and calculation of aquatic system to cope with the fragile climate change should be included in the following planning, and meanwhile the application and verification of technical simulation in this process and the dynamic real-time evaluation system should be strengthened.

César VALMASEDA TRANQUE, Fundación CARTIF, Spain

1. Abstract

Current urban growth rates represent a major challenge in the fight against Climate Change and the willingness to implement a more sustainable future, where the environment, health and well-being are not compromised, and a low-carbon and secure energy provision is granted. Several global actions have emerged, such as the Paris Agreement, which highlighted the general problems and set some objectives. These were then followed by the generation of Energy Directives at European level, which shaped and detailed the objectives of the agreement, which should be complied with by Member States. All of these challenges end up having an impact on planning processes, which need to give answers to all of the demands and aim for holistic and integrated approaches.

However, achieving these goals is a daunting task that requires the careful and accurate analysis of both current energy conditions (baseline) and the evaluation of the impact of energy actions to be implemented. This usually implies devoting a high amount of resources and time, which would otherwise decrease and be shortened if adequate tools existed in order to support this decision making processes at urban level. The effort and progress achieved in the building simulation tools has not been observed in the simulation of energy performance at urban level.

Having these aspects into consideration, the goal of the ENERGIS project is the development of a tool that supports stakeholders involved in energy planning in the decision making process in specific areas or urban settings by automatically estimating the energy demand of the residential sector using publicly available data and representing geo-referenced results through a web platform.

All in all, this platform will ease the decision making process when planning urban refurbishments by obtaining a better vision of the as-is-state situation in terms of energy demand of selected areas. This will help making informed decisions when selecting the areas needing improvement and thus better establish new objectives for long-term plans.

2. Introduction

Current urban growth rates have exponentially multiplied in the last century: from only 746 million people (29,6% of global population) living in urban settlements in 1950 to 6.3 billion (66%) [1]. In this context, cities are the key elements to tackle, since even though they occupy only 2% of global land, they account for 70% of GDP, 60% of energy consumption, 70% of greenhouse gas emissions and 70% of solid waste [2]. Bearing this numbers in mind, it can be seen that cities both represent opportunities for growth as well as great challenges to achieving a more integrated, more socially inclusive and connected cities in the framework of sustainable urban development, which is resilient to climate change [2].

One of the main challenges is assuring the development of cities which grant a heathy environment and assure the well-being of inhabitants, while granting their sustainable development. In this line it is important to consider the impact cities have on aspects such as energy consumption, which in the end mirror the CO2 emissions produced and thus, the degree to which not only a healthy environment and the well-being of inhabitants can be compromised, but also the assurance of a secure provision of energy. To this respect, according to the European Parliament and the Council of the European Union [7], almost 50% of the Union's final energy consumption is used for heating and cooling, 80% of which is used in buildings. More in particular, according to Eurostat figures [3], households account for 25.4% of this consumption, similar to the industry sector.

These alarming figures are the origin for initiatives such as the 21st Conference of the Parties of the United Nations Framework Convention on Climate Change (COP21), where the Paris Agreement was signed (2015) [4] that urged for taking specific actions against Climate Change and established guidelines and objectives to stop the current temperature rise below 2ºC. This universal agreement was the seed for the subsequent legislative actions set at European level, such as the "Clean Energy For All Europeans" directive package, aiming at establishing more specific goals and obligations to be followed at Member State level. Then, each Member State had to implement the legislation at national level with even more specific goals, which should be measured, monitored and reported, so as to assure the adequate implementation of the energy actions and check their effectiveness.

To this end it is of the utmost importance to invest in energy planning, and quantify the current status of cities in an unbiased fashion, as well as be able to evaluate what will happen in the future if a determined action is carried out. The more accurate and close to reality this analysis is, the more successful the energy actions carried out will be, since specific problems will be identified and actions will be well-targeted. These issues are closely being followed and analysed by the Global Covenant of Mayors [24], in particular by Edmonton Declaration signatories [25] and by Covenant of Mayors signatories [26], who need to reflect these aspects in Sustainable Energy and Climate Action Plans (SECAPs).

However, these established goals often represent a burden to comply with. Not only because of the efforts and the energy actions that need to be carried out, but also because of the difficulties to adequately evaluate and measure the benefits achieved, which often lead to distrust in the construction sector, among investors, for instance, and in general public. As a consequence, further advancing towards a decarbonised and more efficient building sector is hindered. Irrespective of the reasons why this occurs, providing the adequate mechanisms to evaluate and easily plan energy refurbishments at urban scale will prove highly beneficial in order to achieve the goals established either by European Directives and be able to monitor the improvements. Therefore, in order to alleviate the problems emerging from these lack of data, lack of understanding of the issue and, consequent lack of support; it is necessary to provide effective tools to measure the baseline status of urban settings.

In this line, ENERGIS is proposed as energy demand mapping platform to aid in the decision support making in energy planning processes. This user friendly platform will provide estimated demand values based on calculations performed with validated Energy Performance Certificate tools at national level, which will be displayed in a map with a colour code that will enable to identify which urban areas are most in need of refurbishment.

This paper delves into all the problematics presented above. First, in Section 3, a review of current European Energy Directives will be shown. Here the main energy directives will be explained, as well as a more in depth description provided of the Energy Performance of Buildings Directive [6], which has been recently updated. Then, the energy planning context in Europe will be presented (Section 4), where the link with energy planning strategies will be analysed, as well as the need for the platform clarified. After, the specific goals covered by the ENERGIS platform will be listed in Section 5 and the main differences with similar projects illustrated. Later, a more detailed and technical description of the platform and its main components is introduced in Section 6. Finally, lessons learned during the platform development and conclusions and future work are provided in sections 7 and 8, respectively.

3. Current European Energy Directives and their deployment at Member State level

The "Clean Energy for All Europeans" [5] legislative framework proposed by the European Commission on November 2016 was the first action towards achieving a clean energy transition and contributing to the goals established in the Paris Agreement. This package of measures was based on three main goals: putting energy efficiency first, achieving global leadership in renewable energies and providing a fair deal for consumers. It includes as well eight different legislative proposals that tackle, among other, Energy Efficiency, Energy Performance in Buildings, Renewable Energy and Governance.

The most relevant directives for the purpose of this paper of this legislative framework proposal are the Energy Performance of Buildings Directive (2010/31/EU) [6], the Renewable Energy Directive (2009/28/EC) [8] and the Energy Efficiency Directive (2012/27/EU) [9]. These directives set certain objectives to Member States and should be transposed by each nation in order to comply with them by establishing plans and strategies. After each Member State has carried out his strategies, the results should be reported at European level.

When considering energy planning at urban level, the Energy Performance of Buildings Directive has to be taken into account. Entered into force in 2010, it has set some measures among which the following can be highlighted: all buildings must be nearly zero-energy buildings by 2020, EU countries must establish inspection schemes for heating and air conditioning systems and also cost-optimal energy performance requirements should be established for new buildings. However, the most interesting of the legislative measures contained in this Directive is the obligation in Member States of issuing Energy Performance Certificates for every dwelling, building block, or commercial premise to be leased or sold, as well as for every new construction and public building [10]. In order to assure coherence among the results obtained in each Member State, a methodological framework is described in the annex of the aforementioned Directive. This annex does not exactly set the formulas to be deployed, but instead presents the type of calculations to perform or which aspects to consider (for instance, thermal bridges). To this respect also Mandate 480 [27] has been defined, for the elaboration and adoption of standards for a methodology calculating the integrated energy performance of buildings and promoting the energy efficiency of buildings. Each Member State has the obligation to transpose this framework in their country and develop either a concrete methodology or develop specific tools to serve this purpose, leading sometimes to inhomogeneous approaches within the European Union. Nevertheless, even when representing a major challenge, a great leap forward has been achieved by providing the general public with information on energy performance of buildings and thus, aiming to make them aware of the relevance of these issues.

This Directive of 2010 has recently been updated and entered into force in July 2018. This recast of the EPBD (2018/844/EU) [7] directive aims for a more comparable and measurable energy performance among Member States. To do so, countries, will not only have to establish national energy performance requirements, but also will have to foster the use of smart technologies and should rely on real consumption data to measure energy performance. All in all, it sets the adequate steps towards a more homogeneous view on energy performance within the EU.

In relation to this, the ENERGIS platform aims to support the implementation and compliance of the Energy Performance of Buildings Directive by providing a tool that supports energy planning processes. Additionally, the estimation of the energy demand contemplated within the platform is based on the calculation methods set by the EPBD and transposed in the Spanish legislation, from which four validated Energy Performance Certificate tools were generated: HULC, CERMA, CE3X and CE3. One of these tools, CE3X, has been the base for the calculations performed within the platform, which have been automatized, as it will be later explained. This way, the platform both ensures to be providing adequate data to the user and also contributes to the compliance of the Energy Performance of Buildings Directive.

4. Energy planning context in Europe and platform need

The implementation of European Energy Directives and energy planning are closely related to each other. The achievement of the first in different Member States is performed differently depending on the administrative structure of each country. While in some of them the Directives are transposed and enforced at national level, in other actions are taken at regional level. Thus, these authorities will have to further detail the specifications established at European level and set plans for a determined period of years to comply with European goals. In particular, the general stages within the energy planning process and the roles of these authorities and involved stakeholders are the following:

1. **Stage 1: development of the enforcing norm**. Before transposing the goals established at European level, it is of the utmost importance to have a clear idea of what the current status of the country or the region is in terms of energy needs so as to be able to define realistic goals to be complied with. Having a clear basis will grant the establishment of coherent goals at national or regional level that can be achieved in a reasonable manner.
2. **Stage 2: definition of energy actions**. Once the European directive has been transposed at national or regional level, the corresponding public authorities (regional or local) should define the action plans and specific energy actions should be carried out, such as refurbishment of district or buildings. At this stage, not only authorities, but also energy planners, energy service companies or investors will be willing to know how to target their resources effectively, that is, knowing which urban area counts with the most adequate conditions for an energy action to be implemented: it is the most unfavourable in terms of building construction, energy demand, or it is a socially deprived area, or other criteria that can be measurable and analysed.
3. **Stage 3: evaluation of different scenarios**. Once a determined area has been selected, the design and implementation of a specific energy action needs to be defined, tailored specifically to the area at hand. At this stage it is crucial for energy planners or designers to be able to compare the effect different actions can have in comparison to the current status of the area (the baseline). By performing an intense study and comparing a number of possibilities (different scenarios), the most adequate one can be selected according to the criteria of the designer or energy planner (for instance, being the main goal the reduction of the consumption and not exceeding a certain investment amount).
4. **Stage 4: monitoring the results of the energy actions.** Once the optimal energy action has been implemented, the impact obtained in terms of achieving the established goals should be measured and compared with the initial status. This monitoring process, apart from enabling the reporting of results as the norm demands, it allows for further reflection on the impact each measure has had. This way, it fosters a better decision making in stages 2 and 3, by feeding them with knowledge and experience generated in implementing energy measures, as well as objective indicators that measure the positive impact of each measure.

As it has been explained, for a successful decision making at all of the stages a great deal of analysis and simulation of results is required. This processes, when performed aiming for accuracy, end up being a time-consuming process. Also, because of the amount of data involved it can tend to be an error-prone process when performed by humans, leading to uncertainty and inaccuracies, thus, to inadequate decisions.

For all of these reasons, there is a need for tools that automate all of these processes, which can provide an adequate accuracy for the decision making at urban level to be able to cover all of the abovementioned stages. However, in the energy field, while there are a great amount of tools for dynamic simulation at building level (requiring a high amount of input data), there are not many tools to simulate at urban level energy related aspects. In this sense, some examples of projects tackling these problems will be presented in Section 5, and will be contrasted with what the ENERGIS platform can provide.

In general terms, and bearing in mind the stages described above, the ENERGIS platform, (being an online platform that maps the energy demand in cities and regions at different scales) is oriented to supporting the decision making at Stage 1 and Stage 2.

5. ENERGIS objective and main differences with other approaches in the energy planning field

The ENERGIS platform main objective is to provide an easy to use energy decision support tool to map energy demand at urban and regional level calculated through validated methods. To this end, public data is collected, analysed and processed; the energy demand building by building is automatically calculated using a validated Energy Performance Certificate tool; and all of the information mapped in friendly web maps, making use of the functionalities provided by Geographic Information Systems. Therefore, the three main pillars in the development of the platform are:

1. **To make use of publicly available repositories**: all of the data deployed within the platform are publicly available and approved by official authorities. The main data source is the Spanish Cadaster [20], which provides information on the geometry of buildings and semantic data on them, such as the year of construction or the number of heights.
2. **To implement a calculation method based on validated Energy Performance Certificate tools**: to this end, the four validated tools at national level in Spain were analysed and one of them (CE3X) chosen as the base for the energy demand estimations displayed in the platform. The objective was to automatically create the input files and run the process to obtain the output results.
3. **To exploit Geographic Information Systems possibilities:** a great amount of synergies can come from linking GIS with planning because of the nature of both disciplines. The ENERGIS platform will therefore display a coloured map at three scales where analysis widgets will be added in order to classify the content displayed in the screen.

Some of these objectives are sought in projects sharing a similar approach to that of ENERGIS. Below, two of them are listed, as well as the main differences with the ENERGIS platform explained.

1. **Estimated total annual building energy consumption at the Block and Lot level for NYC [12]:** Developed by the Sustainable Engineering Lab, this project aims at analysing the dynamics of final energy consumption in the city of New York. To this aim, the final heating, cooling, DHW and electricity energy consumption in the built environment are estimated, based on data at district level on the energy use, natural gas, diesel and vapour consumption of 2009 and it was combined with information coming from MapPLUTO, a geographical database of the Urban Planning Department in NYC. The results are then displayed following a colour code through a web map, providing two levels of aggregation: at block and at lot level. The information is complemented with a pop-up that appears when clicking on a block or lot. However, this map only covers the city of New York, where the calculations have been estimated, without offering the capability to replicate this methodology in other cities.

2. **Energie label atlas [14]**: The objective of the Energie Label Atlas is to represent the estimated Energy Labels of buildings in Holland. This project was carried out with the aim of covering almost all residential buildings in the country and of offering citizens the possibility to obtain an accurate EPC of their dwelling. This would require performing additional calculations over the estimated value proposed in the map, but at a lower cost than usual. The estimated values shown have been calculated using

reference buildings and assigning a label to each of them, which implied the study of a number of building typologies that was representative enough of the residential sector in the Netherlands. In addition, real Energy Labels coming from real EPCs were also mapped and the comparison among both results enabled. This results in some cases in high discrepancies between both results. The visualization capabilities are similar to those of the NYC case; however, the whole country was covered providing the estimated results at block level, regardless of the visualization scale. The information is also complemented by a widget, which serves to detail information at dwelling level, if real EPC information is available.

The projects described above represent interesting approaches to the energy planning problem, by providing basic information on the energy status of a city (in the case of NYC) or of a country (in the case of the Netherlands). However, it is worth highlighting the main differences to the ENERGIS platform, which are related to the calculation methodology, automatization of the process and the scale tackled.

The **calculation methodology** is considered highly relevant in order to provide accurate results. Therefore, instead of deploying estimated approaches in order to calculate consumption (as in the NYC case) the ENERGIS project is constrained to the estimation of the energy demand. This is due to the fact that there is no source of public information that can provide data on the energy systems, rendering it inaccurate to assume the existence of a determined energy system. The approach used in NYC to calculate consumption, that is, assigning an energy system according to the typology of the building would be highly beneficial if applied within ENERGIS and would improve the quality of the platform. However, since there is no available database where these systems are described in Spain, no reliability can be assumed from this process. Moreover, the calculation is focused on the **automation of validated tools** to generate EPCs in Spain. This fact ensures a determined level of precision to the results obtained, opposed to the abovementioned approaches.

With respect to the **scale** considered, aggregation possibilities are granted as in the case of the NYC map, but the unit of measure used to estimate the demand is the block, as in both showcased projects. Nevertheless, the scope to which the ENERGIS platform can be applied is the same as in the Netherlands case: at country level, since the main source of data is the Spanish Cadastre [20] which covers the whole country.

6. Components of the ENERGIS platform

The ENERGIS platform, in order to achieve its objectives, deals with three main aspects: (1) information processing and treatment; (2) estimation of the energy demand and (3) the storage, mapping and visualisation of the data (3). The platform scheme can be seen below:

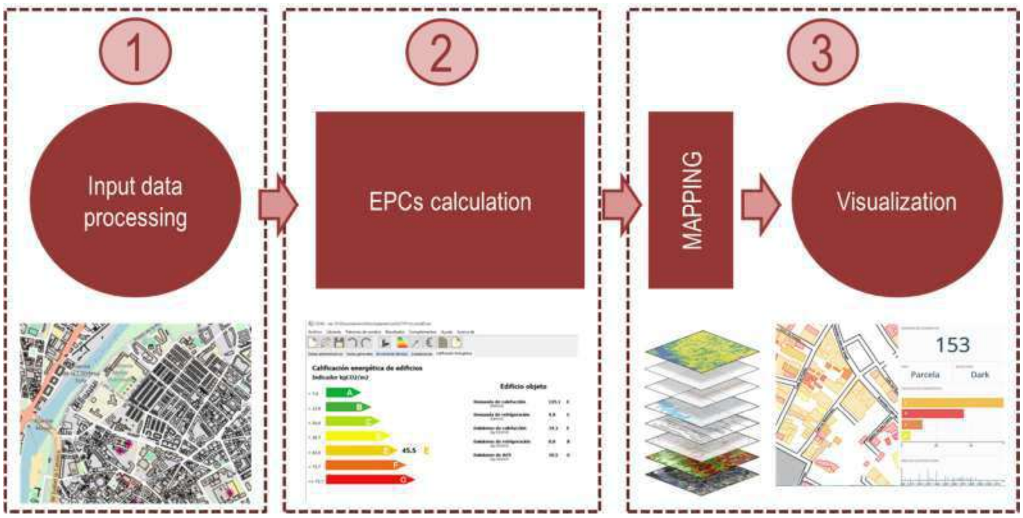

Figure 1: Scheme of the ENERGIS platform

6.1 INFORMATION PROCESSING AND TREATMENT

One of the main requirements of the platform is the use of open public data from official sources to be deployed in the estimation of the energy demand, which should be retrieved in an automated manner. These data are collected from different sources and they must be transformed to meet the input requirements of the estimation engine. Therefore, after being gathered, these data should be processed and transformed.

There are three main types of data required by the platform: (1) geometry data on buildings, (2) climate zones and (3) building thermal properties, which are explained below.

For the **geometry data on buildings** the key data source is the Spanish cadastre. The cadastre, for each building, provides geometrical information (in a GML file) and general semantic information that will be used in order to identify and to characterize the building. More specifically, the information obtained from the cadastre to be used within the platform is the geographical information of the building, i.e. the footprint of the building, and also important information as the number of the building floors above ground, and below ground, the year of the construction, current use of the building and the address of the building. Additionally, apart from these data that can be directly used, there is other data that needs to be inferred according to certain established hypotheses. This is the case of some building envelope elements, such as windows or thermal bridges, whose dimensions were estimated according to each building's dimensions [20].

The geometry information automatically collected from the cadastre in GML files is processed to offer the energy demand estimation engine the information as is required. The main processes are on the one hand the generation of the information for the different envelope elements of the building, with their dimensions and the orientation, and on the other hand the production of shadows patterns with the information of the façades of neighbouring buildings and the implementation of calculation methods to obtain how this façades influence the direct incidence of the sun.

For **climate-related data**, the National Code for Building Construction [21] in Spain was queried, since it establishes reference climate zones according to the province or town (static) and their height above sea level, having different climate data each zone.

In the case of the **building thermal properties**, no information was directly found through public data sources so the National Building Code was consulted. Based on several studies a Catalogue of building elements and materials was generated. This catalogue of building elements is used by the different EPC tools in order to assign default thermal property values to walls (external and internal), roofs, floors, windows, etc. The ENERGIS platform is able to use this catalogue in order to consider different building characteristics, where according to the type of element, the year of construction and the climatic zone, some thermal characteristics and other parameters are assigned in the same way that the EPC tools use this catalogue of building elements.

All this aforementioned information is encapsulated in one only file per building, in *.json* format, that will be used directly in the next process.

6.2 ESTIMATION OF THE ENERGY DEMAND

In this process the energy demand of each building of interest is estimated. As it has been commented the estimation engine is based in one of the EPC calculation tools recognized by the Spanish government for the energy certification of existing buildings. In the case of Spain four validated tools are available to the public free of charge: *Herramienta Unificada Líder-Calener* (HULC), CE3, CE3X and CERMA. The tool selected as basis of the estimation engine should enable the introduction of an adequate amount of data that can be fed by the public data sources identified.

For this aim the study of the abovementioned tools was performed, choosing in the end CE3X because of it being easy to use and because of having data requirements that can be easily covered with information coming from public sources. Moreover, CE3X files are the reference in terms of data model at national level (the data model proposed at national level to represent information related to EPCs follows the same structure as the output of CE3X). Additionally, the accuracy behind the results provided in the calculations of the tools was also tested prior to the selection of the EPC calculation tool.

The basic operation of the engine consists of the automatic creation of the *.cex* format file by processing the *.json* file created in the previous step and, after that, the automatic execution of the CE3X tool and the exportation of the results in *.xml* format, among which are the energy demands of the building: cooling, heating and global energy demand.

The process was validated, first at building block level, then at district scale and, finally, citywide, in order to improve the engine and thus achieve more accurate results, which were more in line with the actual demand values of the buildings.

6.3 MAPPING AND VISUALISATION

The output information of the ENERGIS tool is stored in a geodatabase, which is structured in three tables: one table for buildings, one for blocks (groups of buildings) and one for cadastral zones (neighbourhood). These three scales come inherent in the project, since they are the ones provided by the Spanish Cadastre's online services and data. These three scales are not arbitrarily defined in the cadaster, but are common definitions set in the INSPIRE Directive (which deals with the harmonization of geodata) and which is followed and implemented in the data offered and the services provided by the Spanish Cadastre.

Thus, the ENERGIS data is provided at these three different scales: the building demand information is directly calculated with the estimation engine, while for the demand in the blocks and the cadastral zones aggregation operations have been carried out in order to calculate the demand values. In order to geo-reference and be able to map this information, the geographical information retrieved in the first step will be also used.

These stored data is shown to the public through the ENERGIS online platform. The data will be presented as is reflected in the Figure 2, with the geo-referenced values and with a recognisable colour code that corresponds to the Energy Label scale used in Energy Performance Certificates.

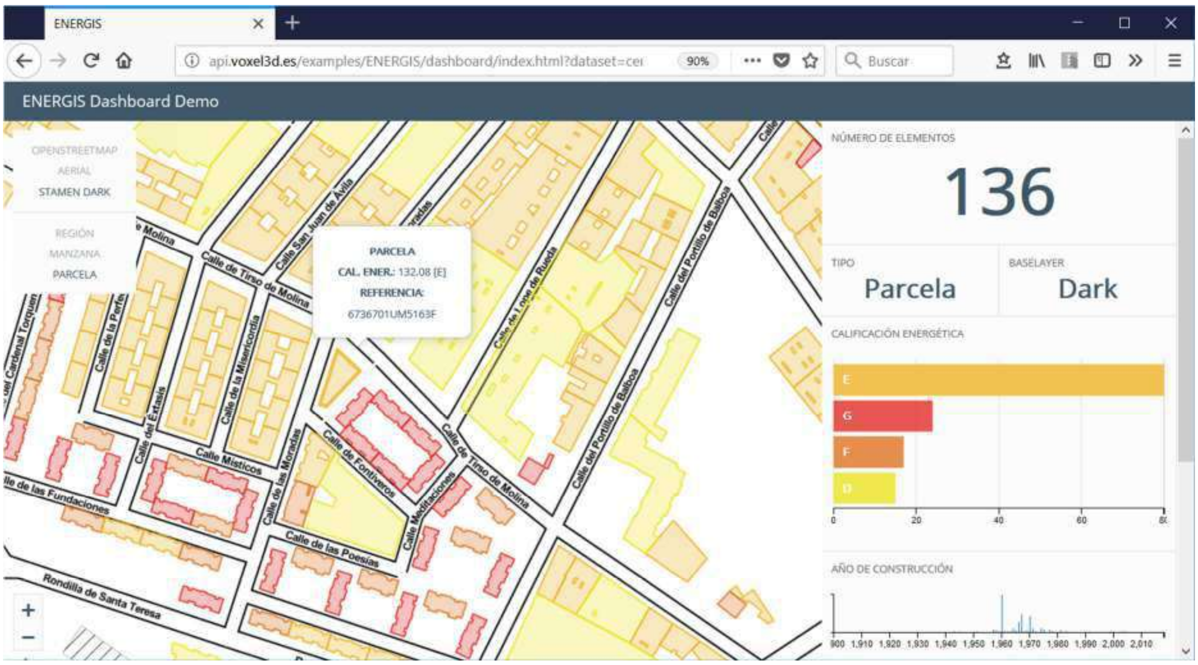

Figure 2: ENERGIS web platform

Moreover, some widgets providing more information on all the data displayed in the screen are shown in the figure in the column on the right. Using these widgets the user will be able to filter the information displayed on the screen by building type, demand label and year of construction, among others. In addition, the user will be able to move among the different scales by scrolling in the map or by using the shortcuts displayed on the top left corner of the screen. Also, there are three different base maps available for the user: openstreetmap, aerial view (ortophotography) and stamen dark (simplified black and white map, as shown in the figure).

In addition, an online web portal with further information of the platform (information about EPCs in the ENERGIS platform, instructions on how to use the tool, etc.) has been implemented in the following link: http://api.voxel3d.es/examples/ENERGIS/portal/.

7. Lessons learned

During the design and the development of the ENERGIS tool, the difficulties faced and the lessons learned were mainly related to two aspects: from the point of view of the platform development and from the point of view of energy planning and the implementation of Energy Directives.

With respect to the difficulties and lessons learned **with respect to the tool development**, the first problem faced was the absence or inaccuracies of the input data. The information provided for the cadastre was not homogeneously defined at regional and local level. Due to this heterogeneity of the information and also to the peculiarity of the different structures of the buildings, more cases than those foreseen a priori had to be taken into account. In addition all the data needed, such as, were not available in the cadastre so some hypothesis (for example dimensions of openings and lengths of thermal bridges) had to be set.

Other important challenge was tackling scalability and moving from the calculation of the energy demand of one building or district (set of buildings) to a city or regional level. The high increment of files and processing time was experienced in this proof of concept, but should be addressed in the future by means of high performance computing, big data technologies or parallel processing.

In a more general context, **from the point of view of energy planning i**t must be stated that in order for holistic and integrated approaches in the field of urban planning to succeed, based on multidisciplinary collaboration (for instance, urban planning per se and energy planning) it has been detected that it is of the utmost importance to share a common language, a common data model, and it is highly beneficial to rely on a standard. This fact has manifested in two steps in the platform development: (1) when analysing the input data coming from cadastre and (2) when analysing the inputs required for the EPC calculation tools. Standards and harmonisation efforts, such as the INSIPIRE Directive [11] (which aims at harmonising geolocation data) can prove highly effective in achieving common definitions which allow for the understanding across different fields and the ability to contrast results and methodologies: if inputs are defined and obtained in the same manner, then calculation methodologies, energy actions or policies can be aligned and contrasted.

Finally, and more focused on the applicability of the platform within energy planning process, the use of the ENERGIS platform can lead to a reduction of time and uncertainties. By automating processes or rules to analyse our real – life conditions, the efforts required in planning can be devoted to finding better solutions to the problems at hand. Therefore, not only saving money and resources, but also being able to implement more adequate measures and design better refurbishment strategies.

8. Conclusions and future work

The ENERGIS platform combines existing public data, validated calculated methodologies and GIS capabilities to offer a complete and powerful product to support energy planning. The process to define, design and develop the platform has followed several stages, which involved the analysis of data coming from public sources, working with EPC tools, the validation of results at all stages and working with GIS in order to explore its full potential. Difficulties in this process involved mainly the work with public sources of data, in particular the Spanish Cadastre. The main problem was the lack of a standardised approach in the definition of geometric data. This fact would be solved with an adequate implementation of the INSPIRE Directive, which would guarantee homogeneous information of the buildings.

The platform provides users energy planning capabilities which will aid in the decision-making process when generating energy plans, by providing with maps showing the energy demand of cities and urban settings. It will reduce uncertainties and provide a knowledge base upon which to ground decisions.

Stages 1 (development of the enforcing norm) and 2 (development of energy actions) [as explained in Section 4] within the energy planning process are covered by the platform. Future work related with this platform includes: (1) enhancing the displayed data (providing consumption estimation), (2) performing calculations at dwelling level, (3) offering new functionalities, such as capacity to introduce improvement measures and (4) offering functionalities to monitor the results obtained with the energy actions and evaluate their adequacy (stage 4). The future work scope can be seen in the figure below:

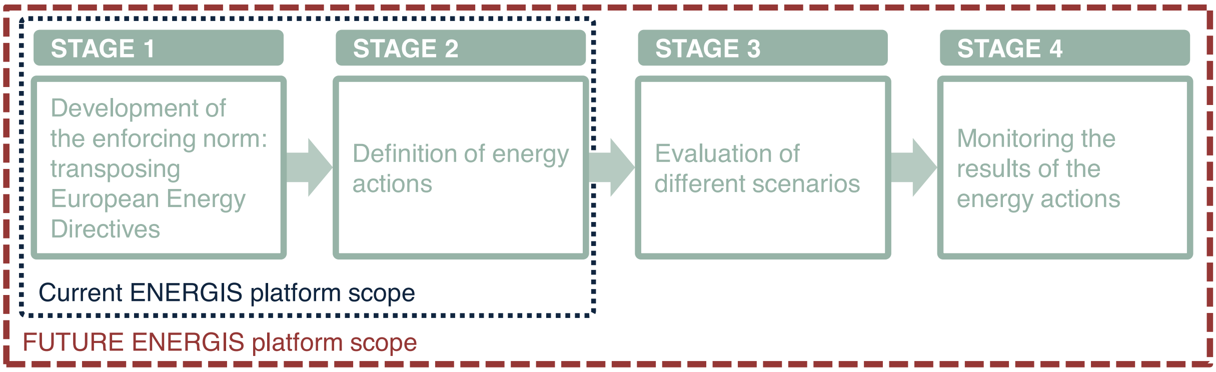

Figure 3: ENERGIS platform: current vs future scope

All in all, by supporting energy planning, the adequate allocation of resources will be fostered to comply with energy directives' objectives and thus, energy retrofitting interventions will be boosted. As a consequence, the energy consumption of buildings will be reduced, resulting in lower emission rates, which will finally contribute in the fight against climate change, advocated by the United Nations with the signature of the Paris agreement.

The achievement of these crucial energy goals should be contemplated within general urban planning processes in order to implement holistic and integrated approaches. Only with these efforts, cities, in their constant expansion and growth, will be regarded not as a major source of problems that impede the maintenance of Earth's natural environmental balance and thus as main contributors for unhealthy environments; but as sustainable opportunities for growth and development.

Acknowledgements

This platform was developed in the framework of the collaborative project 'ENERGIS' in a consortium formed by Fundación CARTIF, VOXEL 3D and SYLTEC and cofounded by the Agencia de Innovación, Financiación e Internacionalización Empresarial and FEDER funds.

Climate Protection and Environmental Impact Assessment: could climate protection be seen as an "overall public interest"?

Karin HILTGARTNER, Department of Spatial Planning, Vienna University of Technology, Austria

1. Introduction

Climate change is a fact. So is the necessity to limit global green house gas emissions. Thus, 195 states[i] have signed the Paris agreement and committed themselves to holding the increase in the global average temperature to well below 2°C above pre-industrial levels and pursuing efforts to limit the temperature increase to 1.5°C above pre-industrial levels. All member states of the European Union have signed and ratified the Paris Agreement and are therefore bound to its aim. In order to achieve the long-term temperature goal set out in the agreement parties have to aim to reach global peaking of greenhouse gas emissions as soon as possible and to undertake rapid reductions thereafter in accordance with best available science, so as to achieve a balance between anthropogenic emissions by sources and removals by sinks of greenhouse gases in the second half of this century. So far the facts, in reality many states still find it difficult to effectively cut their emissions in green house gases. At least in Europe, all states agree in principle to the goal of reducing CO_2 emissions but when it comes to deciding about new infrastructure measures or factories there seem to be very often arguments why these cases are necessary for development and thus more important than climate protection. As a result, many states do not meet their obligation under international law regarding emission reduction. However, there are raising objections to this pattern and civil society, non-governmental organizations, as well as single citizens start opposing this behavior and, among other measures, started various lawsuits trying to force governments and/or administrative bodies to respect the relevant state’s commitment to climate protection under international law.

This paper elaborates whether “climate protection” could be interpreted as an “overall public interest” within the Environmental Impact Assessment. The analysis focuses on a famous case in Austria, the enlargement of the Vienna International Airport and the respective court rulings but also compares this case with the Urgenda lawsuit in the Netherlands.

2. The case: enlargement of Vienna International Airport

Vienna International Airport is the biggest airport in Austria, with about 25 Mio passengers per year and a current growth rate of about 8 percent per year.[ii] Thus, already in 1998 the airport issued its “Masterplan 2015”, which included the decision to build a third runway in order to meet future demands.

2.1 Pre-Proceedings

Knowing that the idea to increase flights to and from the airports would lead to massive resistance from the local population, the airport managers tried to appease the relevant stakeholders by finding common solutions before starting the official administrative proceedings. So, in 2000 a mediation process was started aiming at finding a good compromise with neighbors and municipalities in question. This biggest mediation process in Europe included 50 parties and took 5 years of negotiation. In 2005 a mediation contract was signed, deciding on the exact location of the new runway and limiting night flights (between

23.30 and 5.30) to a maximum of 3.000 or about half of the former number of night flights in order to guarantee night's rest for neighbors. However, this limitation would only come into force fully, if the third runway were built until 2010. As this did not happen, the maximum amount of night flights was limited at 4.700, until a final decision on the third runway will be taken.

2.2 Environmental Impact Assessment

After this rather lengthy mediation process, the formal application to issue a permit for a third runway was started in 2007. Consequently, the developer prepared an environmental impact assessment report, consisting of 32 file folders[iii] and submitted it to the relevant authority, the Provincial State Government of Lower Austria (*Landesregierung Niederösterreich*). The Environmental Impact Assessment was *inter alia* based on the Austrian Aviation Act[iv] and of course on the Austrian Law on Environmental Impact Assessment[v]. The Austrian Aviation Act commits that permits for civil airports (which is the category applicable for Vienna International Airport) have to be issued, if the projects seem suitable from a technical point of view, the developer seems reliable and a secure management of the airport seems guaranteed, the developer has sufficient financial means to secure the payment of public obligations **and there is no contradiction to other public interests** (emphasis added). The latter clause proved to be the most discussed throughout the whole proceedings.

Finally, in 2012 the Provincial State Government issued an affirmative permit, but several parties, mainly neighbors and citizen's initiatives appealed against this decision. So, the second instance body, the Federal Administrative Court (*Bundesverwaltungsgericht*) had to decide on the case and found that the project could not be permitted, due to its effects on the environment.[vi]

2.3 Findings of the Federal Administrative Court[vii]

When deciding on the eligible legal provisions, the Federal Administrative Court ruled, that *inter alia* the Charter of Fundamental Rights of the European Union[viii] was applicable. *In concreto* it referred to Article 37, which states that, "a high level of environmental protection and the improvement of the quality of the environment must be integrated into the policies of the Union and ensured in accordance with the principle of sustainable development". The Federal Administrative Court also cited the Austrian Federal Constitutional Law on comprehensive environmental protection and sustainability[ix], saying "the Republic of Austria (Federal State, Provincial States and Municipalities) support comprehensive environmental protection". Furthermore, the Federal Administrative Court quoted the Constitution of the Province of Lower Austria[x], namely Article 4/2 that rules, "Lower Austria has to provide for the maintenance of environment, nature and landscape. Special importance has to be given to climate protection." Of course, also the Aviation Act and the Law on Environmental Impact Assessment and other legal provisions were found to be applicable.

The focus of the Federal Administrative Court's discussion was the question of the public interest. On one hand it found a public interest, stated in the Aviation Act, in having sufficient flights at Vienna International Airport and promotion of economical growth including the guarantee of existing and creation of future jobs in the region. On the other hand the Federal Administrative Court evaluated the potential rise in greenhouse gas emission, as counteracting the public interest in reducing greenhouse gas emissions and environmental protection. For the latter argument the Federal Administrative Court also referred to Austria's obligation under the Kyoto Protocol to the United Nations Framework Convention on Climate Change[xi] as well as under the Paris Agreement[xii] and of course also to national regulations on climate protection.[xiii] When contrasting these competing public interests the Federal Administrative Court found that climate protection outweighs economic growth, as Austria has obligations under international and European law to effectively cut its greenhouse gas emissions. As the building of the third runway would lead to an increase in greenhouse gas emissions of approximately two percent of Austria's total CO_2 emissions, and as Austria has not managed to significantly reduce its relevant emissions within the last years, another huge project counteracting to these obligations under international law could not be approved.

Furthermore, the Federal Administrative Court stressed the duties under the Austrian Federal Constitutional Law on comprehensive environmental protection, to provide a sustainable environment for future generations, which would also be contradicted by the project.

This judicial verdict, rendered in February 2017, was met with applause by the complainants of the case, but also by many international and Austrian environmental NGOs, citizens and administrative bodies for the protection of the environment.[xiv]

However, the developer decided to challenge this verdict and appealed to the Austrian Constitutional Court (*Verfassungsgerichtshof*), arguing for violation of the right of equality before the law. The Constitutional Court agreed, accusing the Federal Administrative Court of arbitrariness.

2.4 Findings of the Constitutional Court[xv]

In June 2017 the judges of the Constitutional Court concluded that the Federal Administrative Court had applied the Aviation Act in an incomprehensible way, interpreting the law incorrect. *In concreto* it was of the opinion that climate protection was not to be seen as a public interest under the Aviation Act and should therefore not be taken into consideration for the decision whether to grant a permit. As for the Kyoto Protocol and the Paris Agreement the Constitutional Court decided that both could not be applied directly, but only by means of implementation into national legislation. It argued further, that international aviation was excluded from the Kyoto Protocol and not explicitly mentioned in the Paris Agreement and thus was not to be seen under the obligations of national states but the United Nations respectively under its specialized agency, the International Civil Aviation Organization (ICAO).

Consequently, the Federal Administrative Court had to revise its decision on basis of the Constitutional Court's opinion and in March 2018 rendered the permit for the erection of the third runway on Vienna International Airport. [xvi]

3. Discussion of the legal arguments of the two courts

In the following chapter an analyses of the arguments taken by the two courts will be given and their content will be discussed. The case was widely debated in Austria, not only within the scientific and legal community, but also within society as such. For weeks media kept contributing to the topic and still arguments are being exchanged.[xvii] The latest developments being plans by the current government to include the target of "competitive industrial location" in the Austrian constitution, as a counter-part to the aim of "comprehensive environmental protection", as well as a new law supporting the industrial location by excluding certain "projects of overall public importance" from the necessity of an Environmental Impact Assessment. However, most of the discussion did not center on the content of the arguments, but rather on the alleged contradiction between environmental protection and industrial development and on the issue whether it was within a court's domain to decide about fulfillment of greenhouse gas reduction targets or whether this was to be seen as a mostly political decision and should thus be taken by elected bodies.

3.1.Formal arguments

First, it should be documented that the Constitutional Court issued a very sever judgment on the Federal Administrative Court's legal conclusions, defining them as arbitrary and as a violation of the right of equality before the law. Understandably, this caused a lot of discussion within the Austrian legal community as well as within society.

Second, it should be mentioned that within the duration of this special case's legal procedure a major re-organization of Austria's administrative procedure had been taking place, establishing the Federal Administrative Court as responsible second instance body for Environmental Impact Assessments. Thus, many stake-holders criticized the Federal Administrative Court simply for taking the decision of weighing these two different public interests of climate protection and economic development arguing that such decisions should be taken only by political, but not by an administrative body. In fact, the Court was absolutely acting within its domain. [xviii]

3.2.Contents of the arguments

Concerning the Aviation Act:

A central argument of the Constitutional Court focused on the definition of "public interest". It claimed that the interpretation of this term in question must lie within the interests mentioned in the relevant administrative law, in this case the Aviation Act. This act lists some public interests, but also includes a broader clause, talking about "other public interests" which must not be in contradiction to the issuance of a permit for a civil airport. According to the Constitutional Court the Federal Administrative Court was wrong to include climate protection within this clause, as it is no interest under the Aviation Act, especially as the original Aviation Act was enacted in 1957. This argument seems to be out of the ordinary, as it is undeniably a very open clause, which must be interpreted not only within the specific law, but also regarding higher-ranking legal provisions, especially regarding the Austrian Constitution. As there is an explicit constitutional law about comprehensive environmental protection and sustainability (see chapter 2.3), it must be clear that this target provision must be respected when interpreting possible "other public interests". This opinion is confirmed by the fact that the Constitutional Court has come to the same conclusion in comparable cases.[xix]

If you followed the opinion of the Constitutional Court that only public interests as defined in the Aviation Act were to be considered, this would result in the awkward situation that the broad definition within the Aviation Act of "other public interest" would not be interpreted according to the Austrian Constitution but only within a non-constitutional law, thus revising the hierarchy of legal norms.[xx]

Also, the new bill of the federal government to include the target of "competitive industrial location" in the Austrian constitution seems unnecessary, if only the relevant law and not the constitution would serve as the frame for interpretation. Noted should be further, that the province of Lower Austria soon after the judgment of the Constitutional Court altered its Constitution by including the target of "competitive industrial location". Again, this does not seem necessary, if the aim of climate protection, which had already been stated in its Constitution before, should not be used for interpretation.

As for the argument that international climate protection treaties, as Kyoto and Paris, are not directly applicable and thus should not have been taken into consideration by the Federal Administrative Court, it must be stressed, that the Federal Administrative Court did not do that. It simply included these treaties into its reflection on the importance of climate protection as a public interest, which has been done by other high courts in Austria before. [xxi]

Another argument can be found in Article 37 Charter of Fundamental Rights of the European Union, which states that, "a high level of environmental protection must be integrated and ensured with the principle of sustainable development". This Fundamental Rights catalogue is mainly directed towards the bodies of the European Union and member states courts, when interpreting cases with connection to European Union Law. One could argue, that Environmental Impact Assessment is strongly linked to European Law; however, there is an even stronger bond. In 2012 the very same Constitutional Court decided that the Charter of

Fundamental Rights has to be included in the legal norms determining the compatibility of laws with the Austrian Constitution.[xxii] How could this be reasonably be limited just because the law in question does not explicitly state environmental protection or climate change (maybe because it is simply from a time when these issues were not seen as important yet – like in the case in question) and "further public interests" mentioned in the law was not allowed to include further public interest (like even mentioned in the Constitution and the Charter of Fundamental Rights) but only further public interests specially mentioned in the respective law.

As a side note it should be clarified that the Aviation Act does indeed refer to the protection of human health. It does so not within the context of permission of airports, but within the issue of items dropping from planes, still in a broad interpretation this could be seen as a public interest stated by the law and thus as an indicator that the "other public interests" must be interpreted including human health, which certainly is affected by climate change.[xxiii]

Concerning the Law on Environmental Impact Assessments:

Surprisingly, neither the Federal Administrative Court nor the Constitutional Court did examine the case closer under the protected factors within the Austrian Law on Environmental Impact Assessments, although the proceedings for permission of the construction of the third runway were within a legal process under exactly this law. Both Courts lengthy discussed the possible interpretation of "other public interest" under the Aviation Act, but did not refer to the factors protected under the Law on Environmental Impact Assessment, without an interconnection to the Aviation Act.

When taking a closer look at this law, one finds that the aim of Environmental Impact Assessments are defined as determining, describing and assessing the direct and indirect effects of a project on listed factors.[xxiv] The factors most important for the case in questions are: human health, biodiversity and climate, but also other factors mentioned such as water, air and landscape could be affected by climate change. Undeniably, three factors listed in first place will be directly as well as indirectly affected climate change. So, as a first result, protected factors under the Austrian Law on Environmental Impact Assessment are certainly affected by the construction of a third runway at Vienna International Airport, because this construction will lead to an intended increase in flights to and from Vienna and thus to a rise in CO_2 emissions.

Of course, these protected factors are based on the EU Directive on Environmental Impact Assessment,[xxv] which lists in its Article 3, again among other, human health, biodiversity and climate, as the factors on which effects of a project must be assessed.

Under § 17 of the Austrian Law on Environmental Impact Assessment the competent authority needs to make sure that (*inter alia*) "the pressure caused by emissions is to be kept as low as possible on the protected factors. In any case emissions have to be avoided that endanger the life or health of human beings, as far as this is not already foreseen within the relevant administrative laws to be taken into consideration." So, even if one would come to the decision that "other public interests" of the Aviation Act do not have to be interpreted according to the constitutional aim of environmental protection, there would still be this paragraph of the Austrian Law on Environmental Impact Assessment to be examined.

It firstly talks about making sure that emissions posing a danger for protected factors are to be kept as low as possible, and then clarifies that in any case emissions endangering life or health of human beings have to be completely prevented. As a result, applicability of this legal clause can be argued, as climate is listed among the protected factors, which results in the obligation to keep emissions harming the climate as low as possible.

As the predicted emissions, caused by construction of a third runway will amount to 1,8%-2% of Austria's annual total greenhouse gas emissions,[xxvi] these are to be classified as significant factor within Austria's CO_2 end result.

4. The Urgenda climate law suit against The Netherlands[xxvii]

In 2015, campaign group Urgenda (for: urgent agenda) and 886 Dutch citizens sued the Dutch government in the Hague District Court for a stronger 2020 national emission target. It was the first court case in the world in which citizens tried to force their government before a court to increase its efforts against dangerous climate change.

4.1.Formal arguments

The Urgenda foundation, having its base in the Dutch Research Institute for Transition at Erasmus University Rotterdam, challenged the Dutch state to take further action against global warming by reducing the greenhouse gas emissions in the Netherlands.

The Dutch government argued that Urgenda and the citizens claiming were not entitled to sue the government because of lack of legal basis. Indeed, the Court did recognize, that individuals, such as those who Urgenda was representing, as well as Urgenda itself could not directly call on international environmental treaties relevant in the case. However, it admitted that international obligations of the state, European Union treaty provisions and guidelines could indeed play a role in filling open norms of national law. It also stressed the importance of the principle of endangerment and of equity, emphasizing that the needs of future generations must be taken into account.

Also in this case the question arose whether the matter of how much climate protection a state is supposed to provide is suited to be decided by non-elected judges. The Dutch Court argued that Dutch law doesn't know an absolute separation of powers, in this case between the executive branch and the judicial branch. It reasoned that there was rather a division of responsibilities with the goal to achieve a balance between these powers and that judges must, independently of any political agenda, restrict themselves to their domain, the application of the law. Further, it said, that in the case in question, since the severity of the danger increases the legal duty of the government, there were also fewer reasons for such restraint by the court.

4.2.Contents of the arguments

The claimants argued that the Dutch government needed to respect the findings of the Intergovernmental Panel on Climate Change (IPCC), a scientific body established by the United Nations Environmental Program, but also an intergovernmental organization, having 195 countries as member states, including the Netherlands.[xxviii] According to the IPCC, to reach the aim of the Paris agreement to control temperature increases to 2 Degrees Celsius above pre-industrial levels, the concentration of greenhouse gas emissions in the atmosphere will have to be stabilized at a level of 445-490 ppmv (parts per million by volume) CO_2 equivalents. Therefore, Annex I countries (including the Netherlands) must reduce their emissions by 80-95% compared to 1990.[xxix]

Urgenda argued that the Netherlands were a party to the United Nations Framework Convention on Climate Change and thus were obliged to reduce greenhouse gas emissions to prevent the undesired consequences of climate change. It also reasoned that the Netherlands were parties to the Kyoto Protocol as well as to the Paris agreement and therefore had to fulfill concrete reduction limits under these international law treaties.

Urgenda furthermore pointed out that the Dutch constitution reads in its Article 21 “it shall be the concern of the authorities to keep the country habitable and to protect and improve the environment”.

Its actual claim centered that the Netherlands to fulfill their duty under international, European and national climate protection law, needed to reduce its CO_2 emissions by 25% to

40%, compared to 1990, by 2020. As the Netherlands after 2010, however, took on a reduction target of 20%, which is expected to result in a total reduction of 14%-17% in 2020, Urgenda found that the Dutch reduction target was therefore below the standards deemed necessary by climate science and international climate policy. So, in principle there was no different opinion on the basis decision that CO_2 emissions needed to be reduced, but only different point of views on the level and/or timeframe of reduction.

In addition, Urgenda brought also up the international-law “no-harm-principle”, meaning that no state has the right to use its territory, to cause significant damage to other states. It also elaborated on the fact, that the sooner action preventing further greenhouse gas emissions is taken, the cheaper this counter measures are going to be.

The court followed Urgenda’s arguments and ruled that the Dutch government had a duty of care to mitigate as quickly and as much as possible. It agreed that with the current reduction level the Netherlands would not meet their reduction targets under international law and therefore the proposed reduction of 14%-17% had to be qualified as not sufficient, as the state has a duty to protect the living environment. The Court further considered that within the mentioned range of 25%-40% a decrease to the lower boundary is the minimum that is in principle required. Thus, the Netherlands had to meet a reduction target of at least 25% by 2020 compared to 1990.

As for the argument of the Dutch government that the Netherlands were only a small state that did not contribute a lot to the total increase in greenhouse gas emissions worldwide, the Court ruled that the Netherlands as Annex 1 country under the Paris Agreement should be taking a leading role in combating climate change. It focused on the fact, that climate change is a global problem and therefore requires global accountability, concluding that even if the total of the Dutch emissions is small compared to other countries, this does not affect the obligation to take precautionary measures in view of the state’s obligation to exercise care. In addition, it found that also due to the undisputable fact that the Dutch per capita emission are one of the highest in the world the Netherlands were under a more strict obligation to reduce greenhouse gas emissions.

The argument of the Dutch government that the state would risk to loose competitiveness as a business location due to a higher reduction path, was rejected by the court, indication that several neighboring states, like the United Kingdom, Denmark and Sweden, had implemented stricter national climate policies without indications that this created an unleveled playing field for business in those countries.

5. Comparison of the cases

The cases presented have been the most discussed “climate change suits” at administrative level[xxx] in Europe[xxxi], both being pioneers in their field. However, the Austrian case has been revised by the Austrian Constitutional Court, and also the Dutch case has been appealed meanwhile.

5.1.Formal arguments

From a formal point of view there are quite some differences between the cases in question.

The case in the Netherlands is a suit by a civil-society-body against the government. The Austrian case arose within an administrative proceeding that is in the process of a permission procedure. To be precise the procedure was an Environmental Impact Assessment, which is handled as an own administrative procedure in Austria, deciding about all necessary permissions for the relevant project. However, it should be noted that also within the Austrian case discussed, but also for many other Environmental Impact

Assessments in Austria, NGOs and civic associations did play a vital role in appealing against the permission for the construction of the additional the runway.[xxxii]

Both countries are highly affected by the effects of global climate change. The Netherlands because of its low-lying coastal area and Austria because of its position within the Alps, which leads to a higher temperature rise than in countries averagely affected by climate change. Obviously, this is an additional motivation for citizens to become active and challenge decisions by their governments and/or administrative bodies.

3.2.Contents of the arguments

Both cases are in a way similar concerning the argumentation of the opponents.

The dispute between Urgenda and the Dutch government did not concern the need for mitigation, but rather the pace, at which the State needed to start reducing greenhouse gas emissions. Also, in the Austrian case the amount of greenhouse gas emissions resulting from the project can be found within the main arguments of the finding of the Federal Administrative Court. So, in fact, it could be interpreted as motivating the state to set further action in combating climate change by making clear that with the current efforts being clearly not sufficient no further projects leading to significant emissions are licensable.

Both claimants stressed the importance of international climate protection treaties, mainly Kyoto und Paris and the respective states' obligation under these pacts, knowing that they did not provide for subjective rights of individuals. Still, both courts accepted these arguments. Also, in both cases a comparison between the agreed climate protection measures (mostly greenhouse gas emission reductions) and the actual efforts undertaken by the state was made and found that as these did not seem sufficient, more cautious approaches needed to be taken.

Too, the state's responsibility to ensure that activities within their jurisdiction or control do not cause damage to the environment of other states or of areas beyond the limits of national jurisdiction were mentioned in both judgments.

6. Findings

This chapter will draw conclusions, firstly, on the importance of climate protection within international and European Law and, as a second step of interpretation, for Environmental Impact Assessment procedures in Austria.

6.1. Increasing importance of climate protection in International and European Law

International law has for a long time dealt with the issue of environmental protection and climate change.[xxxiii] From the Rio Framework Convention on Climate Change 1994 to the Kyoto Protocol and then the Paris Agreement in 2016 states worldwide have understood the necessity to slow down temperature rise caused by climate change.

The European Union has a strong focus on environmental protection, mentioning this also in its founding treaties. Environmental protection as an aim of the European Union can be found in Article 3 EU Treaty. Also the Treaty on the Functioning of the European Union has a special clause clarifying the objectives of the union policy on the environment. It lists among others: preserving, protection and improving the quality of the environment, protecting human health and promoting measures at international level to deal with regional or worldwide environmental problems and in particular combating climate change. From this follows, that climate protection can be marked as having a very high importance within the EU environmental protection system, which can also be confirmed by the Union's active part in the international climate protection treaties. The European Union not only is a party to the Kyoto and Paris contracts, but also has taken an active and leading part within both instruments.

Also the Charter of Fundamental Rights of the European Union calls upon the principle of sustainability and asks for a high level of environmental protection and the improvement of the quality of the environment to be ensured.

The European Commission has declared energy policy and climate as one of its 10 priorities. As a result, the European Union has decided on an overall climate and energy package, to ensure that the EU meets its climate and energy targets for the year 2020. One of the three key targets is in close connection to the cases in discussion, as it aims at a 20% cut in greenhouse gas emissions from 1990 levels until 2020. Further aims are set as follows: By 2050, the EU should cut greenhouse gas emissions to 80% below 1990 levels. Milestones to achieve this are 40% emissions cuts by 2030 and 60% by 2040.[xxxiv]

Climate protection has generally been given increasing weight in European legislation, as can be seen by the fact, that "climate" has already been defined as protected factor by the first Environmental Impact Assessment Directive by the EU in 1985.[xxxv] This continued also with the latest revision of the Directive in 2014[xxxvi], re-defining protected factors that need to be protected by Environmental Impact Assessments.xxxvii This Directive made it obligatory to take climate change aspects into consideration much more than has been common practice hitherto. This is true in particular with regard to risks of accidents or disasters related to climate change, cli- mate protection aspects such as greenhouse gas emissions and any impacts relevant to adaptation, resulting from the projects in question.[xxxviii]

6.2. Environmental Assessment procedures in Austria: could climate protection be seen as an "overall public interest"?

Also in the international level Austria has bound itself to reduce its emission of CO_2 equivalents. It is member state to the Kyoto Protocol as well as to the Paris Agreement and of the Intergovernmental Panel on Climate Change. Under Kyoto Austria was obliged to cut its greenhouse gas emissions by 8% in comparison to the basis year 1990, but the distribution within the "Bubble" formed by the member states of the European Union bound Austria to reduce 13%.

Under the Paris agreement Austria, like all other EU countries, has committed itself to reduce its greenhouse gas emissions by 40% until 2030, again in relation to 1990 emissions level.[xxxix]

Austria is until now not able to apply to its reduction limits. In contrary, during the last year's national greenhouse gas emissions have begun to rise again. In 2016 total greenhouse gas emissions have increased at 1,3 % from 1990 levels, the sectors mainly responsible for the rise being industry and traffic. A closer look shows, that emissions from sectors not bound by the emissions-trading-system increased, in comparison to 2015 by 2,7% in 2017. Taking this into account it seems obvious that Austria should react as soon as possible to meet its reduction aims as required by European and International law.

What's more, Austria, like the Netherlands, is a country highly affected by climate change. Because of its geographical position in the middle of Europe close to the Alps, a global temperature rise of 2 degrees Celsius would lead to a local temperature increase of 2-3 times as much in Austria,[xl] leading to the effect, that Austrian population, fauna and flora, will be over proportional affective by climate change. That climate change poses sever danger to humans, animals and plants has been proven by various studies and must be considered a fact by now.[xli] As for the argument that climate change can be also tackled by adaption measures, it has to be clarified that also the IPCC reported that mitigation is generally better than adaption.[xlii]

As for the examination whether a project would have significant effects on the climate within the Environmental Impact Assessment it should be clarified that climate was from the beginning of EU legislation within the protected factors, but has gained significantly importance by Directive 2014/52/EU. This directive not only calls upon member states to ensure that environmental protection is improved and that in order to ensure a high level of the protection and human health, environmental impact assessments should take account of the impact of the whole project in question but also stresses that environmental issues like climate change have become more important and should therefore also constitute important elements in assessment and decision-making processes.[xliii] It also states clearly that climate change will continue to cause damage to the environment and compromise economic development. In the regard the Directive sees it as appropriate to assess the impact of projects on climate (for example greenhouse gas emissions) and their vulnerability to climate change.[xliv]

In fact, this is exactly what the Federal Administrative Court in Austria has done. One of its key arguments against the construction of the third runway was, that it would generate a significant amount of CO_2 emissions and was thus not licensable.

By acting like it did the Federal Administrative Court acted also in accordance with principle of sustainability, as proclaimed in the Austrian Federal Constitution, calling for decisions which should take into consideration not only needs of present, but also of future generations.

As debated in chapter 3.2., also the Austrian Constitutional Law on comprehensive environmental protection and sustainability must be taken as a means to interpret open definitions in laws on a lower hierarchical level, like the term “other public interest” in the Aviation Act. Otherwise the whole system of the Austrian legal structure would be absurd. This opinion is also confirmed by the fact that meanwhile the Province of Lower Austria has added a constitutional clause about the importance of being a competitive industrial location to the provincial constitution and the Federal Austrian government has issued a bill aiming at including a similar provision in the Austrian Federal Constitution. If the constitutions (on federal as well as provincial levels) were not to be seen as scale for interpretation of unclear legal formulations, these efforts would not have been undertaken.

As for the arguments that if certain projects were not to be permitted in a specific country, then other countries would welcome the projects and greenhouse gas emissions would still be generated, but only in another state, two things need to be clarified. Firstly, every country is responsible for its own emissions in the first place and it can hardly be seen as evident, that other countries would willingly ignore their reduction targets and take on all rejected projects from their neighboring states. Secondly, according to the general “no-harm-principle” under international law countries must refrain from supporting projects within their territory, which would lead to negative effects in other countries. So also from this point of view, projects including vast amounts of emissions should not be permitted.

Also, the dispute on the issue of competitiveness of the industrial location seems not to be too relevant in Europe. On a formal basis one can also argue with the no-harm-principle. On a more practical approach it can be stressed, that all member states of the European Union have agreed to reduce their emissions according to the EU road map and are thus in comparable situations.

In total, there seem to be many arguments that due to recent developments, climate change has to take a special role in general politics, the more within Environmental Impact Assessments. Also in view of intergenerational fairness it should hence be considered as an “overall public interest” within Environmental Impact Assessment procedures, at least in countries that are highly affected by climate change, according to the “no-harm-principle” by all countries.

xxx There have also been civil law suits against companies because of their contribution to greenhouse gas emissions and thus climate change. The most famous probably being the Case Huaraz against RWE. Huaraz is a city in Peru, represented by Mr. Saul Lliuya a farmer from Huaraz (assisted by the NGO Germanwatch). RWE is a German Energy company, claimed to be Europe's biggest energy company, responsible for about 0,47% of global greenhouse gas emissions. The claims are based on damages because of melting glaciers resulting in a thread of flooding to Mr. Huarez land. The first instance court decided that the claim was not within its filed of jurisdiction, but the second instance court (Oberlandesgericht Hamm: Az. 5 U 15/17 OLG Hamm) accepted the claim, which is still pending, in November 2017.

Actor-network analysis of transition towards urban hi-tech horticulture. A comparative study of development and adoption of urban high-tech horticultural practices in Shanghai and Amsterdam

Hosseinifarhangi, S. Mohsen; Turnavi, Margherita; Carsjens, Gerrit J.; Van der Valk, Arnold, VENEZIA, Italy, HUMMELO, Netherlands

ABSTRACT:

Urbanization, urban poverty, food insecurity, rising food prices, growing dependency on food imports and challenges posed by climate change have placed food high on the urban agenda. Advanced technology and alternative food production methods such as vertical farming and hydroponic cultivation methods support the transition of conventional food production methods to more decentralized and local production systems. The development of urban high-tech horticulture is one of the strategies for more sustainable and resilient urban food systems, being explored by cities worldwide to feed their increasing population. Although urban agriculture has been widely studied, the process and consequences of technology driven transitions on urban planning and development are hardly understood. This paper uses the theory of Multi-Level Perspective (MLP) on sustainability transitions and Actor-Network Theory (ANT) to explore this technology driven transition and its adoption in urban planning and development. MLP describes transition as a process of change of the socio-technical regime, resulting from a combination of external pressure (the landscape) and internal pressure by innovation (niches). ANT describes the relations between human and non-human entities (actants) in the process of (de)stabilizing of the regime. The circumstances of configuration and reconfiguration of actants, including horticultural technologies, policy documents, land use plans, spatial development plans and decision makers, were studied Amsterdam and Shanghai were used as case studies. A comparative approach was used to analyse the role and relations of the various actants that were involved in the development and adoption of urban high-tech horticulture technologies in both cities. Studying the implementation of similar technologies in the different socio-political context of both cities allowed to identify the losses and gains in the process of transition and identify recommendations for policymakers, industry and other actors interested in bringing about change. The data were collected though observational research, document analysis and interviews. The results show that in Shanghai, the China Academy of Agricultural Science was a focal actant that used a top-down policy implementation approach to punctualize the urban high-tech horticulture practices into the socio-technical regime. In Amsterdam, the Top Consortium for Knowledge and Innovation (TKI) was the focal actant and obligatory passage point. However, TKI focused on private public partnership and promoting bottom-up policy implementation approaches to negotiate and define the identity of government, business, knowledge institutes, innovations and spatial development plans

Construction of Green Infrastructure Based on Water Ecological Security Pattern, A case study of Songtao River Catchment in Guizhou Province, China

(Construction of Green Infrastructure Based on Water Ecological Security Pattern,

A case study of Songtao River Catchment in Guizhou Province, China)

Song LIU, Song Yao HUAI*, Hong Ting Pan, Tongji University, China

Abstract: China's rapid urbanization and climate change have led to increasingly severe water ecological security problems. The evaluation and construction of water ecological security pattern is an effective way to deal with water resources management, water environment protection and water disaster prevention. Green infrastructure strategy is considered as a sustainable land use planning emphasis on rainwater management. The method of water ecological security pattern shows good applicability to the construction and optimization of green infrastructure. The study area is Songtao river catchment located in southwest of China, which is faced with the problems including water resources shortage, water quality deterioration and frequent occurrence of floods. Based on GIS overlay method and Pressure-State-Response framework, the paper conducts comprehensive water ecological security pattern assessment from three current problems of water resources security, water environment security and water disaster risks. Then, green infrastructure hubs were further identified and prioritized through landscape connectivity index and river corridors were classified and optimized on the basis of the composite water ecological security pattern. Finally, the study draws several conclusions. (1) The water ecological security evaluation index system established by PSR framework provides a basis for the construction of regional green infrastructure. (2) Green infrastructure network of interconnected hubs and corridors can achieve the aims of water resource conservation and utilization, runoff pollution process control and floods resilience regulation.

Keywords: Green Infrastructure Construction; Water Ecological Security Pattern; Songtao River Catchment

1. Introduction

Rapid urbanization and climate change in China have exerted a profound impact on water ecological security. Water problems such as water resources shortage, water quality deterioration and frequent occurrence of floods indicate that it is an urgent challenge to ensure water security(Vörösmarty et al., 2010).

The evaluation and construction of water ecological security pattern provide an effective way to address the regional water security problems. Water ecological security pattern is the land use spatial pattern based on the goal of regional water security(Lin et al., 2016). The construction of water security pattern refers to the optimization of land use and spatial configuration of landscape elements that play a critical role in maintain and protect regional water security(Yu, 1996, Peng et al., 2016). Reasonable evaluation of regional water security can guarantee adequate water supply, reduce water pollution and minimize floods risks, which enhances the resilience and sustainability of regional water ecosystems(Gong, 2009).

Many studies illustrate the green infrastructure is closely related to sustainable water management(Ellis, 2013, Everett et al., 2015, Saygin and Ulusoy, 2011). Solving storm water problems and improving water cycle has become a primary goal of green infrastructure planning. Research show that green areas have reduced storm water runoff up to 100% during normal precipitation years and 77-88% during high precipitation years(Baker and Doneux, 2012). The linkage between green infrastructure and water ecological security are established due to the same aim of maintain water ecological security. But fewer literature focus on construction of green infrastructure based on ecological security pattern.

This paper aims to evaluate the water-oriented ecological security patterns to guide green infrastructure planning in Songtao River Catchment by GIS spatial analysis methods. Specifically, the main objectives of this study are to: 1) establish water ecological security index system based on PSR framework from three aspects of water resources security, water environment security and water disaster risk to construct a comprehensive water security pattern. 2) further identify, prioritize and optimize the hubs and corridors based on the composite water ecological security pattern through landscape connectivity index to build the interconnected green infrastructure network.

2. Study Area and Data Sources

2.1 Study Area

The Songtao River Catchment, with an area of 1563 square kilometers, is located in Songtao Miao Autonomous County of Tongren City in the northeast of Guizhou Province (Figure 1). It has a higher elevation on the sides of the east, the west and the north, but a lower terrain in the middle. The average elevation of the whole area is about 650 meters. The Songtao River Catchment is a typical subtropical monsoon climate where summer is hot and rainy while winter is cold and dry. The average annual temperature is 16.2 °C and average annual precipitation is 1186-1683mm, which mostly occurs from June to September. The imbalance distribution of precipitation often results in the frequent occurrence of drought and floods. People living there are mainly engaged in manganese mining, manganese product processing and agricultural planting. At present, Songtao river catchment is faced with the problems including water resources shortage such as degradation of river network structures and difficulty of water utilization, water quality deterioration due to point source pollution of manganese mines and non-point source pollution of agricultural chemical fertilizers, and water disaster risks such as frequent occurrence of floods.

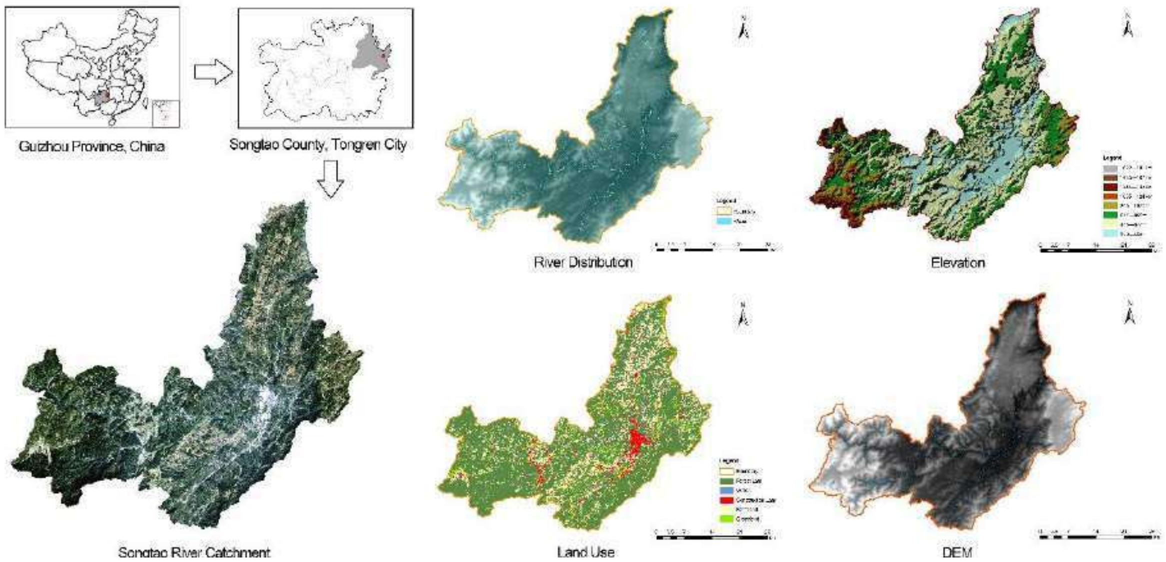

Figure 1: Location and Current Situation of Study Area

2.2 Data Sources

The data used in this study are:

(1) Elevation data was extracted from GDEM Product with a spatial resolution of 30 m from the Geospatial Data Cloud (http://www.gscloud.cn/).

(2) Land use data was interpreted through Landsat 8 images from October 8, 2013. The images were classified into five types of land use including forest land, grassland, farmland, water body and construction land.

(3) Meteorological data is obtained from the local weather station installed near the study area.

3. Methodology

3.1 General Framework

Based on GIS, the paper conducts regional water security pattern evaluation from three aspects of water resources security, water environment security and water disaster risks and puts forward the water-oriented green infrastructure construction strategies. The detailed construction steps are as follow (Figure 2)

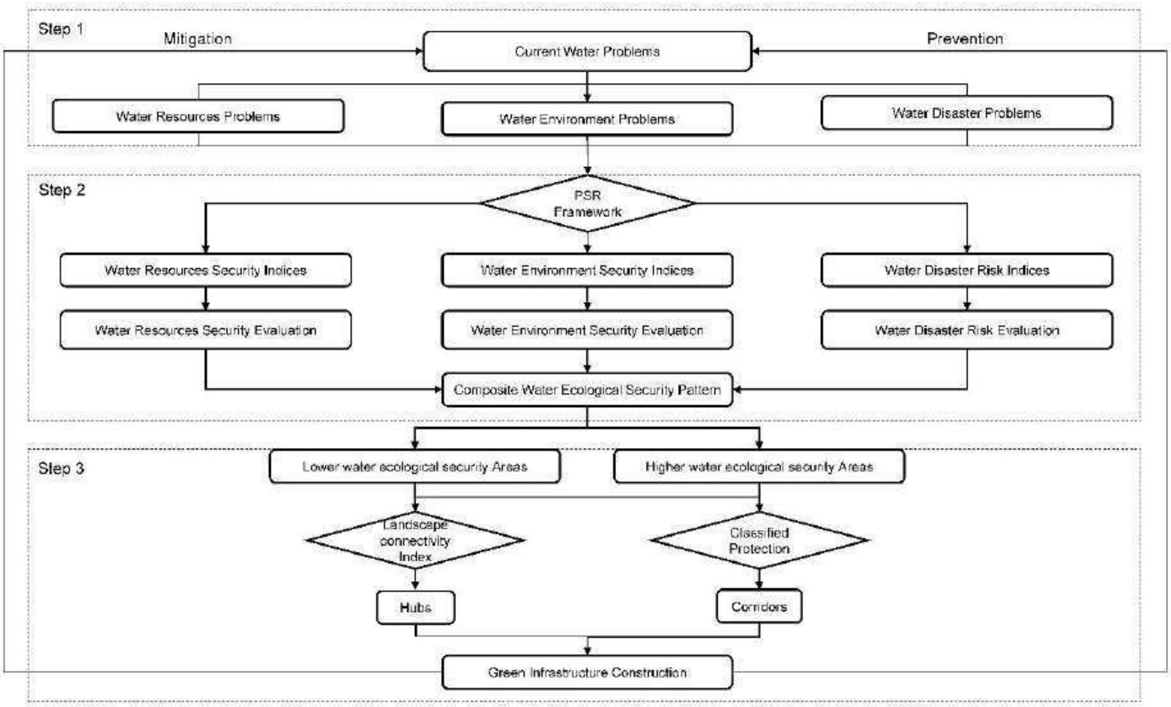

Figure 2: General Framework

3.2 Water Ecological Security Evaluation

Water ecological security evaluation is a process of mapping the water ecological problems to identify and prioritize the ecologically sensitive areas or ecologically significant areas. Areas with higher sensitivity tend to be higher significance but lower security, which are peculiarly prone to environmental problems when they are affected by intensive human activities. Through water ecological security evaluation, different levels of sensitive areas can be identified and water ecological security patterns can be constructed to provide a scientific basis for prevention and treatment of regional water security problems.

3.2.1 Water Ecological Security Indices Selection

Factors related to water ecological security are comprehensive and complex, involving natural ecosystem and socio-economic system. A systematic and logical framework is needed in water ecological security evaluation. Pressure-State-Response (PSR) framework is a conceptual framework to analyze the cause–effect relationships between society and the environment and to support decisions in response to environmental issues. It considers factors of pressures (P), states (S) and response (R), integrating the elements about natural resources and socio-economic development, which has been widely adopted in landscape assessment and environmental management(Zhang et al., 2012, Hughey et al., 2004, Wolfslehner and Vacik, 2008).

Based on the PSR framework, the paper evaluates the water ecological security in Songtao river catchment by analyzing three aspects, water resources security, water environment security and water disaster risk. According to this framework, the natural resources conditions are chosen as the state factors and the local socio-economic conditions can be regarded as pressure factors influencing the development of the catchment.

(1) Water Resources Security Indices

Water resources security refers to the state of ensuring a healthy water ecological cycle of ecosystem and maintaining sustainable living, industrial and agricultural water supply for human society. It mainly includes water source conservation, soil and water holding and water system support and allocation capability. Factors influencing these capabilities are included in the evaluation indices (Table 1).

Table 1 Water Resources Security Indices

Indices	Parameters	Extremely sensitive	Highly sensitive	Moderately sensitive	Lowly sensitive
State Indices	Distance from Rivers	0-30m	30-100m	100-200m	Above 200m
	Elevation	306-550m	550-750m	750-950m	950-1612m
	Soil Thickness	120-150cm	90-120cm	30-90cm	2-30cm
Pressure Indices	Water Facilities	6-8	4-6	2-4	0-2
	Land Use	Water Bodies	Forest Land, Grassland	Farmland	Construction Land
Value		7	5	3	1

(2) Water Environment Security Indices

Water environment security refers to the reduction of point source pollution and non-point source pollution in the river basin to ensure water quality safety. In Songtao River Catchment, the sensitivity of the area affected by point source pollution is mainly measured by the manganese mines density. However, there is no specific source of non-point source pollution, which is mainly discharged through the surface runoff into the nearby rivers randomly. Surface runoff provides quick transport mechanism for potential pollutants between the landscape and surface water bodies(Walter et al., 2000). Therefore, identifying areas that are more susceptible to producing surface runoff, that is hydrologically sensitive areas (HSA's), helps to minimize contamination into rivers and mitigate water quality risk by effective measures. Topographic index, widely applied in hydrological studies(Rousseau et al., 2004, Page et al., 2005), is chosen to identify hydrologically sensitive areas and to estimate runoff distribution to control the transport of pollutants. It is given by the following expression:

$$\lambda = \ln\left(\frac{\alpha}{\tan(\beta)K_s D}\right)$$

where α are the catchment areas, $\tan(\beta)$ is the gradient, K_sD is average soil permeability rate(Woods et al., 1997).

Other factors influencing water environment security, such as precipitation, distance from rivers, land use, are also included in the evaluation indices (Table 2).

Table 2 Water Environment Security Indices

Indices	Parameters	Extremely sensitive	Highly sensitive	Moderately sensitive	Lowly sensitive
State Indices	Topographic Index	10-47	-6-10	-9-6	-17--9
	Precipitation	1550-1650mm	1450-1550mm	1350-1450mm	1250-1350mm
	Distance from Rivers	0-30m	30-100m	100-200m	Above 200m
Pressure Indices	Mine Density	70-130	35-70	15-35	0-15
	Land Use	Farmland	Construction Land	Forest Land, Grassland	Water Bodies
Value		7	5	3	1

(3) Water Disaster Risk Indices

Water disaster risk refers to the possibility of floods occurrence. It is generally understood as an interaction of hazard, exposure and vulnerability(Kaźmierczak and Cavan, 2011). The hazard can be defined as frequency and severity of damage and threats to people, property, and systems, which usually depends on geographical and meteorological factors. Areas with intense rainfall, lower terrain, dense river networks, and poor soil permeability are more susceptible to floods. The exposure is closely related to all social, economic and natural ecosystems that may be threatened by disasters. Vulnerability comprehensively reflects the extent of damage to all property present in a given area due to potential risk. The factors influencing the hazard, exposure and vulnerability are listed as follow (Table 3).

Table 3 Water Disaster Risk Indices

Indices	Parameters	Extremely sensitive	Highly sensitive	Moderately sensitive	Lowly sensitive
State Indices	Precipitation	1550-16509mm	1450-1550mm	1350-1450mm	1250-1350mm
	Flow Accumulation	7146656-15444045	3512763-7146656	1150732-3512763	0-1150732
	Topographic Index	10-47	-6-10	-9-6	-17--9
	Elevation	306-550m	550-750m	750-950m	950-1612m
	Vegetation Rate	0-0.25	0.25-0.5	0.5-0.75	0.75-1
Pressure Indices	Population Density	399-560	326-399	225-326	159-225
	Agricultural Production Value	1.15-1.65	0.95-1.15	0.57-0.95	0.55-0.57
	Water Facilities	1	2-4	4-6	6-8
Value		7	5	3	1

3.2.2 Water Ecological Security Indices Weight determination

Based on the three water ecological security indices mentioned above, the global weights of group indices and local weights of individual parameters were further determined using the Analytic Hierarchy Process (AHP) and the expert scoring method. Water ecological security index system was established as follows. (Table 4). Multiple evaluation indices can be combined through GIS overlay method to map different water ecological security levels.

Table 4 Water Ecological Security Index System

Object	Group Indices	Global Weight	Pressure-State Indices	Parameters	Global Weight
Water ecological security	Water Resources Security	0.2	State Indices	Distance from Rivers	0.0623
				Elevation	0.0240
				Soil Thickness	0.0137
			Pressure Indices	Water Facilities	0.0670
				Land Use	0.0330
	Water Environment Security	0.2	State Indices	Topographic Index	0.0556
				Precipitation	0.0122
				Distance from Rivers	0.0322
			Pressure Indices	Mine Density	0.0500
				Land Use	0.0500
	Water Disaster Prevention	0.6	State Indices	Topographic Index	0.2055
				Flow Accumulation	0.1245
				Precipitation	0.0854
				Elevation	0.0399
				Vegetation Rate	0.0249
			Pressure Indices	Population Density	0.0381
				Agricultural Production Value	0.0450
				Water Facilities	0.0367

3.3 Green Infrastructure Identification and Prioritization Based on Landscape Connectivity

Green infrastructure is a comprehensive network of interconnected hubs and corridors. The hubs are defined as ecologically significant natural areas that provide an origin or destination for ecological processes moving to or through it. Corridors are the connections that tie the system together and enable green infrastructure networks to work(Benedict and Mcmahon, 2002). Connectivity between them is a critical feature to maintain vital ecological processes and services. In addition to water ecological security evaluation, further identification and prioritization of green infrastructure space should be based on landscape connectivity.

3.3.1 Identification and Prioritization of Hubs

Probability of connectivity Index (PC) was applied in areas with lower water ecological security levels to identify and prioritize the hubs. It is defined as the probability of dispersal from one patch to another patch, which reflects the potentiality and significance of landscape connectivity. It is given by the following expression:

$$\mathrm{PC} = \frac{\sum_{i=1}^{n}\sum_{j=1}^{n} a_i a_j p_{ij}}{A_L^2}$$

where $a_i$and a_j are the areas of the patches i and j, and A_L^2 is the total landscape area. p_{ij} is defined as the maximum product probability of all possible paths between patches i and j(Saura and Pascual-Hortal, 2007). The higher PC value indicates the better landscape connectivity and more dominant role in hubs. Probability of connectivity Index (PC) was calculated and classified through Conefor Sensinode 2.2 among the areas with lower water ecological security levels.

4. Results

4.1 Water Ecological Security Pattern

4.1.1 Individual Water Ecological Security Pattern

(1) Water Resources Security Pattern

Fig. 3 shows the security levels and evaluation values for the water resources security of the Songtao catchment, ranging from higher security to lower security (0.2-1.32). The higher value indicates the higher sensitivity and the lower security of water resources. Areas with lowest water resources security are mainly located close to reservoirs, the river sources and dense river network in the north and in the middle of Songtao River Catchment, which covers 2.40% of total area with 37.47km^2 . In the future planning, it is necessary to enhance the protection of water source and build suitable buffer zone to ensure the safety of water resources. In addition, water facilities such as reservoirs should be improved or enlarged to satisfy the needs of rainwater sustainable utilization.

(2) Water Environment Security Pattern

Fig. 3 shows the security levels and evaluation values for the water environment security of the Songtao catchment, ranging from higher security to lower security (0.2-1.35). Regions of high mines density tend to suffer from point source pollution while farmland and construction land are of highly risk to non-point source pollution. Hydrologically sensitive areas with lower terrain are prone to generating and transporting runoff pollution to water bodies. These areas are in lowest water environment security levels, which are mainly distributed in the southeast of Songtao River, accounting for 5.78% of total area with 903.41km^2 . High security level and medium security level lie in forest land and grassland, which occupy the most area of the catchment. In the future planning, it is essential to control the impact of human activities on the water source and maximize the role of green space in contaminants interception and reduction.

(3) Water Disaster Risk Pattern

Fig. 3 shows the security levels and evaluation values for the water disaster risk of the Songtao catchment, ranging from higher security to lower security (0.68-3.86). Areas with higher construction intensity, lower terrain and lower vegetation coverage in the basin have higher flood risk, most of which are concentrated in the river valleys. It covers 3.45% of total catchment area with 53.92km^2 . Most of sensitive and low-sensitive areas are mainly located in forest land and grassland.

4.1.2 Composite Water Ecological Security Pattern

Through GIS overlay of three patterns by individual weight, composite water ecological security pattern can be constructed (Figure 3). Areas with lower water ecological security level are mainly distributed close to the main stream of Songtao River, which are the top priority areas for protection.

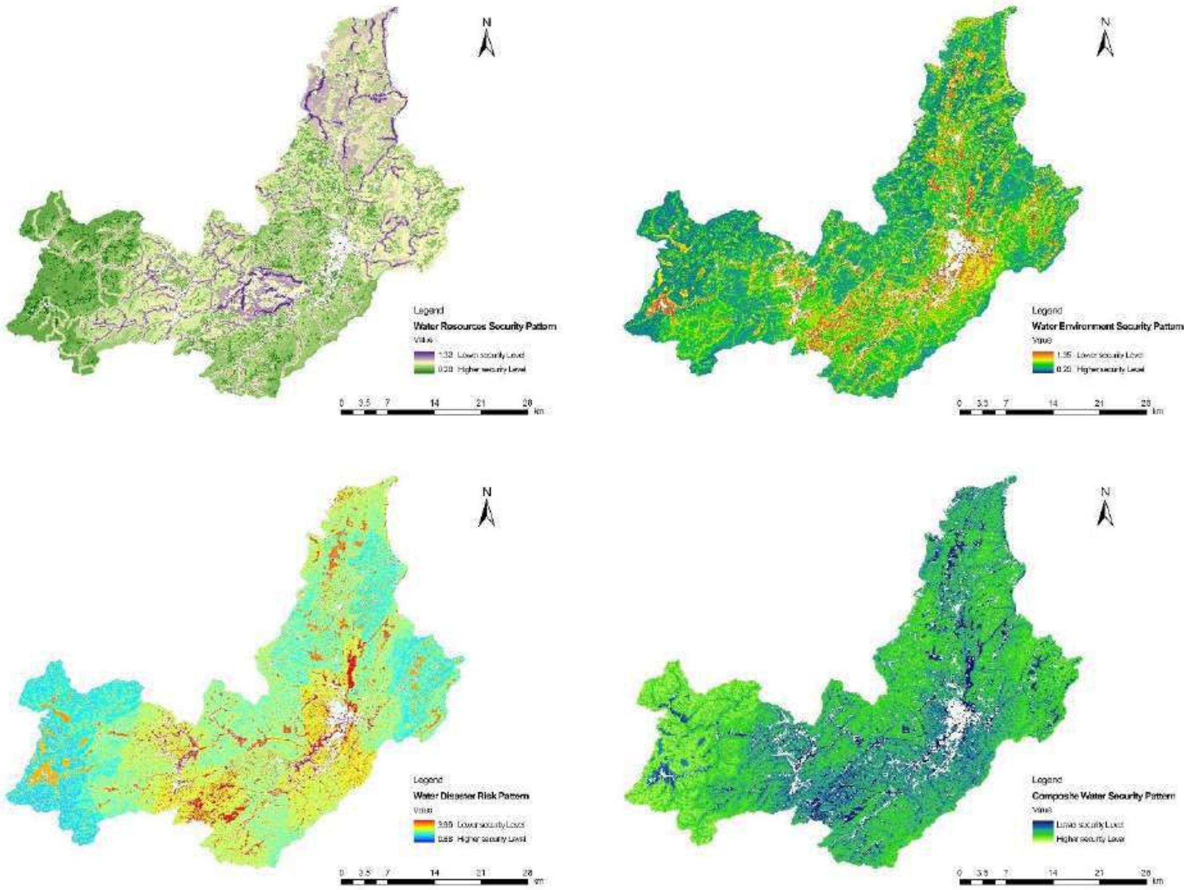

Figure 3: Individual and Composite Water Ecological Security Pattern Results

4.2 *Green Infrastructure Construction*

4.2.1 Hubs

Probability of connectivity Index (PC) was calculated and classified through Conefor Sensinode 2.2 into three categories: PC<0.04、 0.04≤PC≤0.4、PC>0.4, which represent the extremely important hubs with best connectivity, important hubs with good connectivity and slightly important hubs with moderate connectivity. All three categories were included in the green infrastructure hubs (Figure 4).

4.2.2 River Corridors

Based on the composite water ecological security pattern, the river corridors are classified into three levels of protection and optimization (Figure 4). The first level of rivers refers to the main stream of Songtao river system with the purpose of decreasing the floods risk. It is necessary to add additional wetlands, reservoirs and detention ponds to link with main stream to build blue and green flood passages. The second level of rivers are the branches of main stream in the whole catchment, whose function is to prevent contaminants from discharging into the rivers. Some buffer zones of different width can be delimited according to local ecological situation. The third level of rivers are the potential runoffs determined by topographic and soil data, which can collect the storm water and connect with the branches to facilitate the storage and usage of water resources.

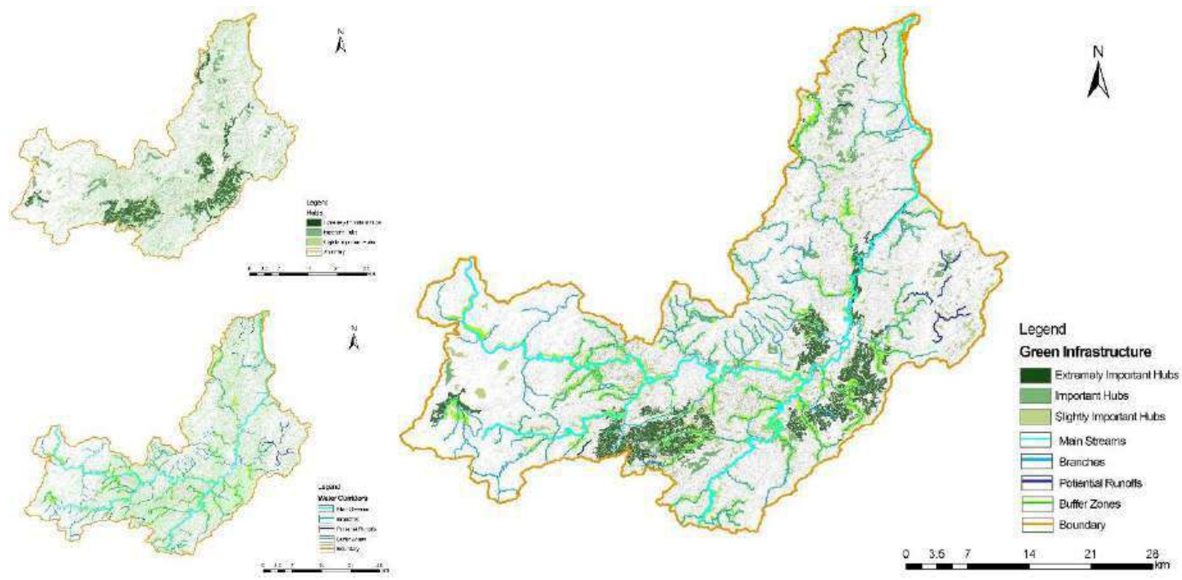

Figure 4: Green Infrastructure Construction Results

5. Discussion

5.1 Methodological Advantages

Based on the understanding of current water security problems, the research expanded the traditional concept of water security pattern by analyzing the cause–effect relationships between human society and environment and including the socio-economic dimension into PSR indices system. In addition, considering the process of water ecological cycle and the typical attributes of green infrastructure, the research made further identification and prioritization of hubs according to the probability of connectivity index to produce a more precise outcome.

5.2 Limitations and future research direction

In the process of indices weight determination, although expert scoring method is feasible, it couldn't fully reflect the influence degree of each index on water security problems. The evaluation results need to be continuously improved in accuracy. As green infrastructure is a multifunctional land use planning method, future studies may involve multi-objective orientated evaluation process.

6. Conclusion

Taking Songtao River Catchment as a study area, this study identified the water ecological security patterns based on the PSR framework from three aspects of water resources security, water environment security and water disaster risk. Then, on the basis of the composite pattern, we applied the further prioritization of green infrastructure space through landscape connectivity index. The hubs were graded into three categories of extremely important, important and slightly important. The river corridors were also classified into three categories of main streams, branches and potential runoffs. The interconnected green infrastructure was constructed combining the hubs and corridors. The construction of green infrastructure is conducive to healthy water cycle and can facilitate adequate water resources supply, water pollution reduction and floods risks resilient regulation.

Cool Planner: place-based adaptation solutions for South African settlements

Moderators: IVKOVIC, Milena (Vice President ISOCARP and Director Blok74 Rotterdam); NIEL, Lena (Urban and landscape designer, Deltares, Delft)

ABSTRACT:

Cities are facing new types of challenges, because of the effects of climate change and densification in cities. The Sendai Framework, Sustainable development goals and The New Urban Agenda are trying to address these challenges for cities. Cities have to become inclusive, climateproof and economic hubs. Hence, the city is approached as an urban ecosystem instead of a blue print that exists of different layers and flows. Only a truly resilient and inclusive city could be achieved if one understands the functioning of this system. This shift of planning and design also asks a new type of urban planner and designer. But what is exactly this new role of urban planning and design to achieve these climate-proof cities in line with these frameworks?
The aim of this session is to explore furthermore what is the role of urban planning and design within global resilience frameworks. As a preparation of this session, ISOCARP Dutch National Delegation will hold an experts workshop in July 2018. The focus of the session will be on the importance water as the resilience factor. During the workshop, the special water envoy of the Netherlands will discuss the role of planners and designers within these resilience frameworks together with the Dutch ISOCARP members and other Dutch planning societies. Design offices, municipalities, knowledge institutes and consultants will participate in this discussion.

Consequently, this session proposal is divided in two parts. In the first part, the results from discussions amongst the Dutch part of ISOCARP will be presented by a Dutch delegate. In the second part, an international panel of experts on urban resilience will reflect and discuss the role of urban planning and design for the design of resilient cities according to global frameworks. The aim is to come up with several statements that both the panel and the public can reflect on. To conclude, this session is a platform within the ISOCARP conference where both experts and planning professionals can discuss the role of urban planning and design within global resilience frameworks. To keep this discussion on-going is necessary to ensure the design of truly resilient cities in the future.

“Heat!” – testing design approaches to mitigate excessive heat exposure for vulnerable populations in Toronto apartment buildings

George Thomas KAPELOS
Professor, Department of Architectural Science,
Ryerson University, Toronto (Ontario) Canada

Synopsis

As climate changes, excessive summer heat will impact Torontonians, especially residents in older, high-rise buildings. Toronto Public Health proposes outdoor cooling centres as a strategy for heat mitigation. To assist municipal policy development, researchers documented issues on film, students designed cooling centre prototypes, and community members provided feedback on design proposals.

From Toronto Public Health, 2012 …
“Toronto can expect an almost five-fold increase in three-day heat waves and an increased risk of more severe or prolonged heat events by 2050, as a result of climate change. It is estimated that current heat conditions contribute to an average of 120 premature deaths per year in Toronto. Average annual heat-related deaths could double by 2050 and triple by 2080.”
(Toronto Environment Office, 2012.)

From CBC Radio, August 2016 …
Interviewer: “You did mention the fact that the federal government is developing a national housing strategy to look at affordable housing. How specifically would you like to see tenants' cooling needs addressed in that strategy?
Tracy Heffernan: “Well, I think as soon as you talk about the right to adequate housing, you're talking about the right to live in housing that is habitable. If people are dying, or their health is being compromised, this is not habitable housing.
(Robyn Bresnahan, ‘Air Conditioning as a human right?’ *The Current,* CBC Radio One. 22 August 2016.)

1. Introduction: Toronto’s high-rise landscape in the face of climate change

Toronto’s post-war landscape changed dramatically with the construction of modern high-rise residential apartment towers across the city in the period from the early 1950s into the 1970s. As a consequence, Toronto contains the second highest number of high-rises in North America (defined as a building of 12 stories and higher). (Stewart 2016) Many of these towers are found in Toronto’s inner suburbs. Home to diverse communities, these towers are located in neighbourhoods that show trends towards increased poverty, isolation, lack of economic opportunity, social need and health risks. (United Way Toronto 2018) Most of these towers lack centralized cooling plants and during periods of extreme heat in the summer, residents experience inordinate discomfort. Outdoor cooling centres offer the possibility of providing residents respite during periods of extreme heat. A research project undertaken by Ryerson University in association with Toronto Public Health explored the potential of outdoor cooling to address this issue. This paper presents findings and opportunities arising from this research.

2. Context and Background

2.1 Climate change, extreme heat and public health

The World Health Organisation estimates that the warming and precipitation trends due to anthropogenic climate change of the past 30 years have already claimed over 150,000 lives annually. (Patz et al. 2005) In the USA, since 1998, heat waves have resulted in more weather-related fatalities annually than any other natural disasters, estimated at 400 deaths per year. (United States Department of Commerce, n.d.) Heat wave effects may increase in the near future as the result of global climate change. (Cubasch et al. 2001) There has been an extensive review of the potential health effects of climate change. (Haines et al., 2004; Patz et al. 2005; Patz et al. 2006; McMichael et al. 2006; Haines et al. 2006, Ebi et al. 2006) The effects of heat, include benign disorders (fainting, sweating or hyperventilation), more acute responses (nausea, vomiting or weakness) and, most serious, heat-stroke, which can lead to renal failure and profound physiologic derangements, with a high fatality rate. (Frumkin et al. 2008) Risk factors for developing heat stroke or dying during a heat wave, including being elderly, having certain diseases, and living on upper floors. (Kilbourne et al. 1982) Poverty and minority race or ethnicity are also risk markers. (Semenza et al. 1996)

While heat-related mortality has historically been important, it remains an underestimated public health problem. (Bernard and McGeehin, 2004, p. 1520) Public health practitioners advocate the necessity of a public health approach to climate change. They argue that proactive measures need to be taken to address the impact of climate change on health.(Frumkin et al. 2008) Principal concerns include illness and fatalities related to severe weather events and heat waves, and require both primary and secondary prevention measures. Mitigation and adaptation are key to this approach. Public health practitioners are mobilizing community partnerships and actions to address this issue, developing policies and plans to support their efforts and engaging with other disciplines to research and develop innovative solutions to health problems related to climate change. (Frumkin et al. 2008) Health professionals are turning to planners, urban designers, architects and landscape architects, who can play a leading role in this matter.

Greater collaboration between architect, planners and health promoters would support the overall improvement of the health of the public in the face of climate change. This paper addresses the question of mitigating the impacts of excessive heat through architectural and site planning measures, aided by policies that are embedded in both coordinated planning and public health initiatives in order to adapt our environments to anticipate heat stress resulting from excessive heat and long-duration heat waves. Specifically, activities in Toronto point to ways in which collaboration between public health practitioners and design and planning professionals can climate-proof urban environments.

2.2 The vulnerability of urban landscapes with climate change / the urban heat island

On warm days, urban areas can be 3 – 4 ºC warmer than surrounding areas. Dark surfaces such as pavement and rooftops that absorb heat from sunlight and reradiate it, and the absence of significant areas of vegetation, especially trees and green spaces, are causes for the urban heat island. As cities expand, the heat island increases in both scale and intensity. Continued urbanization further aggravates the heat island effect. (Frumkin 2002) The sprawling regional metropolis becomes vulnerable, where the urban heat island effect could intensify extreme climatic events. (Patz et al. 2005)

2.3 Toronto's Changing Climate

The Greater Toronto Area (GTA), a region encompassing the City of Toronto and four regional municipalities that surround it (Durham, Halton, Peel and York), is Canada's most populous metropolitan area. With a population of 6.4 million, it is home to 20% of the Canadian population. (Statistics Canada 2018) As a result of climate change, the region is experiencing an increase in extreme weather conditions. In 2013, Toronto suffered two severe weather events – a winter ice storm and a summer flood – that gave residents a taste of what climate change will bring. The cost was over $CAD1.3 billion, the equivalent to a one-time 51% residential property tax increase. (Toronto Environmental Alliance n.d.) In 2012, Toronto recorded its earliest ever official heatwave from June 19 – 21. This summer, as of writing in July 2018, the City has issued three extended heat warmings (temperatures greater than 31 ºC). (Toronto Public Health 2018)

Climate change prompted Toronto to undertake a review of the implications of severe weather, beginning in the early 2000s. In February 2013, Toronto City Council received the outcomes of the study, *Toronto's Future Climate*, and directed the Board of Health (BoH) to review and consider the social and health impacts as a result of increased health and extreme weather conditions. The background report indicated that between the date of the report (2013) and into the next 30 years (2040-2049), average temperatures in Toronto will increase by 4.2 ºC. Average summer temperature are predicted to increase by 2.0 ºC, and the extreme daily maximum will increase by 9.2 ºC. The report indicated that the maximum daily temperature will rise from 33 ºC to 44 ºC. The number of days greater than 33 ºC will triple from 20 to 66, and the number of heat waves (three or more consecutive days with temperatures greater than 32 ºC) will increase five-fold (from .57 to 2.53). The report addressed the impact on the City and articulated adaptation responsibilities. With regard to extreme heat, the increased summer temperatures would impact energy consumption six-fold. (Toronto Public Health, 2012)

2.4 Addressing climate change health risks for Toronto Residents

Toronto's changing climate poses health risks to Toronto residents. Particular concern is directed toward the city's older high-rise apartment buildings, constructed during the first post-war residential boom of the 1960s and 1970s.

Beginning in the early 2000s, architectural and heritage researchers drew attention to this unique architectural heritage of Toronto. Under appreciated and misunderstood, Toronto's concrete architecture represents an exciting era of cultural investment, city building, and design innovation. (McClelland & Stewart 2007) The stock of over 2000 buildings, containing 30,000 apartment units, house a significant portion of the city's population at densities as high as 350 units per hectare. (Tower Renewal Partnership 2007, *Fact Sheet*) In 2008, the reinvigoration of these buildings and their sites became an initiative of Toronto's Mayor and brought attention to the social, economic and architectural renewal of apartment neighbourhoods. (Tower Renewal Partnership 2007, *The Tower Renewal Opportunities Book*). Out of this, a collaboration of designers, planners, stakeholders, building owners, academics and interested citizens came together to form the Tower Renewal Partnership (TRP) with the objective of revalorizing Toronto's high-rise heritage. A key focus of this renewal is the development of amenities, community services and facilities, lacking in many of the apartment neighbourhoods. (McClelland et al. 2011)

In 2011, Toronto Public Health (TPH) launched *Healthy Toronto by Design,* an initiative that sought to address the major impacts of urbanization and city design on health in order to highlight and strengthen the role local governments may take in creating healthy, liveable and prosperous cities. (Toronto Public Health 2011b). As part of these explorations between health and design, TPH reported on the health of Toronto's apartment neighbourhoods. In their study, *Toward Healthier Apartment Neighbourhoods,* TPH considered how Toronto's several hundred clusters of post-war high-rise apartment buildings – labelled as apartment neighbourhoods – could better support the health of their residents and people living in the surrounding communities. Improvements to building settings – including natural environments and places for people to gather – as well as improvements to lighting and security, and programs and facilities for physical fitness were investigated. (Toronto Public Health and Centre for Urban Growth and Renewal, 2012) This initiative has led to several positive outcomes.

First, Toronto established new zoning regulations for apartment neighbourhoods. The recently-adopted Residential Apartment Commercial Zone (RAC) (City of Toronto By-law

No. 572-2014) breaks down traditional single-use zoning that historically characterized these communities. Toronto's new zoning allows for a mix of uses to complement the apartment towers, allowing for broadening uses, mixing scales of development, and permitting the development of new amenities and services. It is anticipated that these new regulations will allow for these neighbourhoods to evolve as economically diverse and lively places. (Hug et al. 2013; Stewart 2018) The impact of this bylaw has yet to be fully realized. However, it holds promise for effecting needed change in apartment neighbourhoods.

Second, detailed attention was paid to the energy consumption of these inner suburb apartment buildings. Opportunities for sustainability through retrofit, including building envelope performance, air conditioning, passive conditioning through envelope renewals, and proposals for best practices are being explored. (Tower Renewal Partnership 2007.*Thermal Comfort and Cooling in Apartment Towers*)

Third, close attention was paid to the linkages between extreme heat and attendant health risks to residents in these apartment neighbourhoods in units that do not have air conditioning. A process to explore detailed options began. (Toronto Public Health 2015b). While the City of Toronto sets minimum heat requirements in rental housing during winter months, there are currently no provisions for maximum temperatures in summer months. The City considered establishing standards for maximum heat in apartment buildings. The report, *Protecting Vulnerable People from Health Impacts of Extreme Heat,* revealed that the idea of creating regulations that would legislate a maximum heat standard presented complex challenges, including reticence on the part of apartment building owners, who believed that a majority of apartment dwellers chose not to have air conditioning and also chose not to use existing indoor cooling rooms. Further, they expressed concern that such standards would have profound negative environmental consequences in terms of exacerbating the heat island effect, as well as severely straining existing electrical systems within buildings and the local electrical grid. (Toronto Public Health 2011a) (Correspondence, GTAA to BoH, 27 November 2015)

Consequently, the City pursued alternate strategies that permit property owners to meet a maximum heat standard through the provision, at minimum, of a cool location where building occupants can go during hot weather. At the direction of the Toronto BoH, TPH worked with City departments to explore strategies to mitigate extreme heat such as onsite indoor and outside cooling spaces in and near apartment buildings. A 2015 workshop, *Extreme Heat in Multi-unit Residential Buildings,* considered potential strategies to reduce the risk from extreme heat. The creation of on-site indoor and outdoor cooling centres became one strategy that was pursued. The benefits of such centres were identified, including their potential to create positive relationships among tenants, the potential of access by multiple users at various times of the day, and the ways such spaces, if situated out-of-doors, could relate to underutilized or undeveloped green spaces adjacent to existing apartment buildings. It was contended that these cooling centres would have multiple, long-term benefits, including reduction in heat island effect and improvement of community cohesiveness and interaction. Many apartment buildings already have locations on their properties which would be ideally suited for outdoor cooling use, and residents and owners were ready to act. (Toronto Public Health 2015a, Toronto Public Health 2015b)

The creation of these on-site cooling centres also would address concerns previously identified by TPH. A 2011 survey explored the relationship of Toronto residents to extreme heat. It found that many people without air conditioning often chose to stay home, even though there was a cool place nearby, citing lack of transportation (10%) or being "too far" (14%)or the perception that such places were inaccessible at night (11%), worries about personal safety (4%) or inaccessibility for disabled persons (5%). (Toronto Public Health 2011a)

A strategy of access to cooling on site was pursued by TPH. In order to explore the design of outdoor cooling centres, in 2016 TPH partnered with Ryerson University's Department of Architectural Science to undertake a pilot study to design prototypes for outdoor cooling centres, and receive community input on design proposals.

3. Ryerson University's Pilot Study to Investigate Outdoor Cooling Centre Design

In late 2010, the TRP undertook a community design charrette on one property to explore practical design strategies in and around the public space of the two apartment buildings on the site that would support long-term planning of the apartment neighbourhood. (Tower Renewal Partnership 2007, *Kipling Towers Community Design Charrette)* The project engaged residents to identify opportunities for property renewal. Attention focused on public spaces, services, security and wayfinding, but the specific question of heat mitigation were not addressed. The outcomes of this charrette formed the starting point for Ryerson University's engagement.

The project's goal was to undertake design research on behalf of TPH. This research would aid in their work with apartment building owners and community residents to address issues of energy planning and costs through creating alternate strategies for cooling in periods of extreme heat. The pilot project was viewed as part of the larger question of infrastructure renewal aimed at high-rise housing. Mitigating impacts of extreme heat through thoughtful and considered design became a key component of the pilot project. Here is how the project unfolded.

4. Heat! Cooling spaces for high-rise places

The pilot project took place from 2016 – 2018. It focused on sites identified by TPH as case studies where prototype design interventions were to be proposed. Interventions were developed by undergraduate students in Ryerson University's Department of Architectural Science (DAS) program in their annual Collaborative Exercise in 2017 (CEx17). Design interventions were presented to focus groups comprising building residents to elicit responses on proposed design interventions. It was anticipated that the study's outcome would form the basis of a larger investigation leading to the development of design standards and approaches for heat mitigation in Toronto's high-rise apartment towers. A component of the study included a documentary film on the impact of excessive heat on the quality of life of occupants in high-rise buildings. The film was conceived to provide student designers and focus group participants with an overview of the issue and featured interviews with key stakeholders and typical residents.

4.1 Ethics Approvals, Owners' Consent, Project Funding and Research Support

Prior to the commencement of research involving human subjects (filmed interviews and community focus groups) the project underwent research ethics review. Ryerson University's Research Ethics Board (REB) approved the film (Ryerson REB 2016-225, approved 24 June 2016) and focus groups (Ryerson REB 2016-351, approved 28 October 2016). TPH REB approved the focus group (TPH REB 2016-10, approved 17 February 2017). The owners of the apartment buildings on whose sites where prototypes were developed and where focus groups were to be held gave their consent to the use of their properties and facilities. Prior to project commencement, the author, the project's Principal Investigator (PI) secured funding for portions of the project from the Ryerson University Centre for Urban Research and Land Development (CURLD). TPH supported the project, but was unable to provide any financial support. Funding provided support for a Research Assistant (RA) and a documentary filmmaker, a graduate student in the Ryerson University School of Image Arts (SIA), where a faculty member also assisted to advise on the film.

4.2 Site Selection

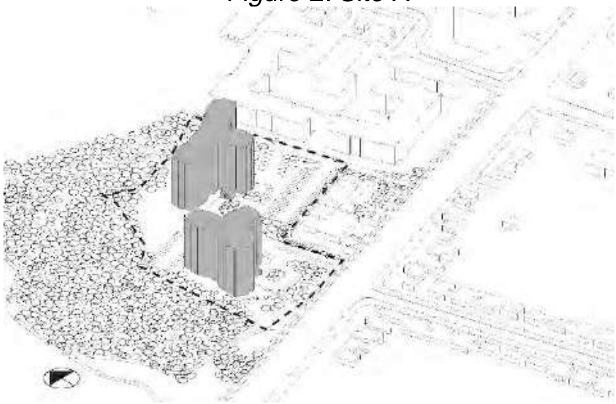
In the spring of 2016, the PI consulted with staff of the Healthy Public Policy Directorate of TPH who identified seven sites within the City as potential candidates for the development of prototypes for outdoor cooling centres. Prior to the commencement of the project, the owners and managers of buildings of these sites had expressed interest in addressing issues of extreme heat and had been actively involved with TPH. Community residents had also been active in working with the owners and building managers on this issue. TPH advised the PI that these groups would assist, as appropriate, in the implementation of the project. The sites were typical of apartment neighbourhoods located across the city. The PI researched proposed sites and obtained detailed architectural, landscape and site design information. The PI selected three sites as locations for the study based on specific criteria, including the configuration and orientation of buildings on the sites, and the availability of locations on each site for outdoor cooling centres. The property owners confirmed agreement to utilize these sites for this study. For reasons of privacy and out of respect for the residents of these sites, the addresses of these sites are not identified. (Figure 1)

Figure 1: A view of the apartment towers on one of the candidate sites (Site A)

This apartment neighbourhood located in an inner suburb of east Toronto is typical of the high-rise neighbourhoods that were part of the pilot project.
Credit: Christopher Marleau

Site A comprises two Y-shaped high-rise 14-storey apartment towers containing 168 units in a mix of types with both on-site and below-grade parking for residents. All units are rented at market rates. Site A is located on the north side of a major arterial road. The site is bordered by a ravine on the west and north, and a local community “hub” and low-rise commercial district on the south and east. Given the configuration of the towers, apartments face all four directions and, consequently, residents experience a range of sun exposure during the summer months. A small convenience store is located on the ground level of one of the apartment towers. The site borders Toronto’s ravine system to the north, an area protected by the Toronto Region Conservation Authority. (Figure 2)

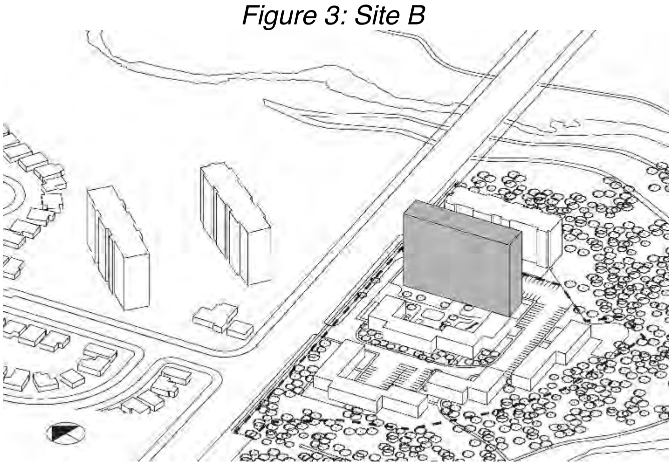
Figure 2: Site A



Site A comprises two Y-shaped high-rise 14-storey apartment towers containing 168 units in a mix of types with both on-site and below-grade parking for residents.
Credit: Drawing by Joe Ball.

Site B consists of one 19-storey slab-type apartment tower containing 192 units in a mix of types. All units are rented, some at market rates and other subsidized through housing assistance. The tower is oriented north-south and located on the south side of a major east-west arterial road. A series of three-storey townhouses sit adjacent to the east and south. A lower, high-rise apartment tower is located on the west. The site contains on-grade parking and amenity areas for outdoor recreation. The site borders Toronto's ravine system to the south, an area protected by the Toronto Region Conservation Authority. (Figure 3)

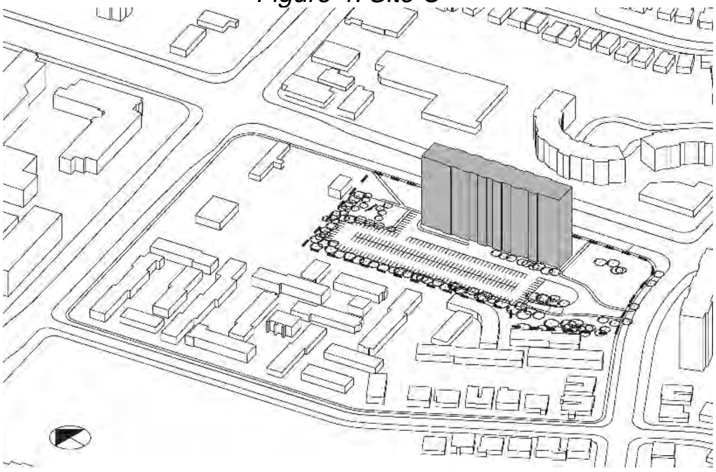
Figure 3: Site B



Site B consists of a 19-storey slab-type apartment tower, oriented north-south and surrounded by low-rise townhouses on the east and a lower apartment building on the west.
Credit: Drawing by Joe Ball.

Site C consists of a 20-storey slab-type apartment tower, oriented north-south. All units are rented at market rates. The site is located on a major north-south arterial road, close to a major east-west road and neighbourhood commercial area. The site is flanked on the west by a parking lot and a low-rise residential single-family neighbourhood beyond. A major commercial area is across the street, on the east, and there is a high-rise tower currently under construction in this location. The site is a five-minute walk from a community centre. A community day-care is operated on the ground floor of the apartment tower, the entrance of which is located on the tower's north face. The building main entrance is situated on the building's east side, although access is provided to the parking lot on the western side of the building through a lobby that bisects the ground floor from east to west. (Figure 4)

Figure 4: Site C



Site C consists of a 20-storey slab-type apartment tower, oriented north-south, with parking along the western side of the property.
Credit: Drawing by Joe Ball.

All sites are served by public transport. The sites were documented in film, still image and digital mapping.

4.3 Film, "Heat! cooling spaces for highrise places"

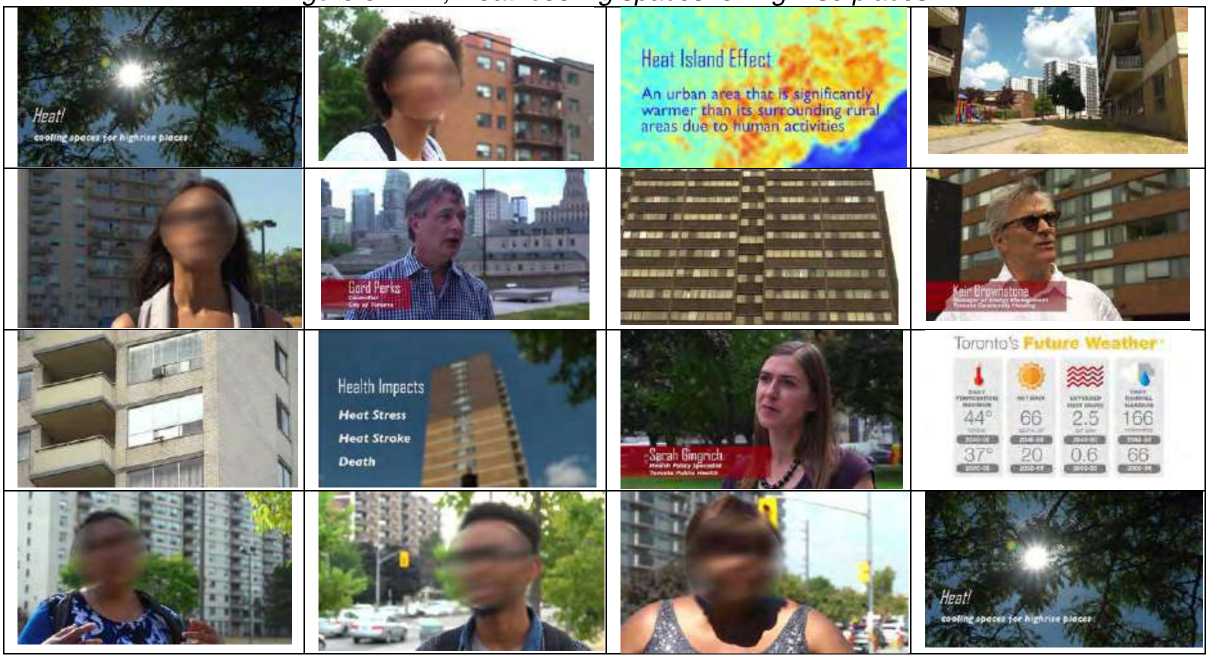
During the summer of 2016, which was reported as Toronto's hottest to date, the filmmaker and RA conducted and filmed interviews in the vicinity of the three sites. They recorded interviews with approximately 15 residents in these communities. Positioning themselves on public property, the RA presented the project to potential interviewees and requested an interview, describing the project and its objectives. Subjects were selected randomly. Each subject confirmed that they lived in a high-rise building in the neighborhood, were in residence there during the summer (i.e. they did not have access to another summer location, such as another residence or a summer home), and did not have air conditioning in their unit. All interviewees provided consent as per REB requirements.

The RA followed a standard set of questions querying the interviewee's response to Toronto's summer heat, how they kept cool during the summer heat, and what measures they took, either in their unit or away from it, to keep cool. Filming took approximately 20 minutes per interview. Water was made available to interviewees and, as much as possible, all interviews were conducted in the shade.

The PI identified a number of experts on heat, heat island, climate change, building management, architecture and public health. The REB approved specific questions for each expert. Each expert agreed to an on-camera interview and signed a release form permitting their name and affiliation to be included in the film. The researcher interviewed six interviews and their observations were filmed.

The documentary filmmaker and researcher completed the collection of film interviews in the late summer of 2016. The filmmaker and PI reviewed film footage and prepared a film treatment. Editing of filmed interviews and review of the rough-cut of the film took place in the fall of 2016. The PI secured a composer to compose music to accompany the film. In late fall 2016 the PI and the SIA faculty advisor reviewed the final rough cut of the film and the final version was completed in January 2017. (Figure 5)

Figure 5: Film, Heat! cooling spaces for highrise places



Still images from the film, Heat! cooling spaces for highrise places. Faces of residents interviewed have been blurred to protect their identity.
Credit: Peter Conrad, filmmaker.

The PI screened the sixteen-minute film, "*Heat! cooling spaces for highrise places"*, during the CEx17, where the filmmaker and SIA faculty advisor discussed the role of film-making in architectural research and documentation. Following the completion of the film, the PI oversaw the production of a film transcript containing still images of the film; images of residents are blurred to protect their identities. A copy of the film transcript is available on request from the PI. The film was made available for screening at each of the focus groups. An abbreviated version of the film of approximately 9 minutes duration is available for screening during academic presentations of this research.

4.4 Prototype Design – The 2017 DAS Collaborative Exercise

The Ryerson DAS runs the Collaborative Exercise (CEx) annually at the start of the winter term. All DAS undergraduate students participate for a pass-fail credit. DAS graduate students provide support to the CEx and DAS faculty members participate as advisors to the undergraduate student design teams. The PI was the Instructor for the DAS Collaborative Exercise in January 2017. The focus of CEx17, entitled Design approaches for outdoor Cooling Centres, was to address ways to mitigate excessive heat exposure for vulnerable populations in Toronto high-rise apartment buildings through on-site cooling centres.

CEx17 asked students to address the following questions:

> "What effective passive design interventions can be created to provide outdoor Cooling Centres on sites adjacent to older inner-suburban high-rise buildings in Toronto?" and "How can architects contribute to the design of these outdoor Cooling Centres to provide places that provide comfort and relief in periods of extreme heat, and are well designed, safe, inviting to a wide variety of users, and have a low-energy impact?"

Approximately 425 DAS students participated in CEx17, under the guidance of 12 graduate students and an equal number of DAS faculty members. During the five days of CEx17, students followed a rigorous agenda and developed designs for outdoor cooling centres. Students completed final designs and produced posters of their designs that were displayed for a two-week period in January 2017 at the CEx17 conclusion in the Ryerson University

Paul H. Cocker Gallery located in the Architecture Building. The DAS CEx is seen as a way to start the winter term with a bang and energize students for the term ahead. For CEx17, each day was given a different name, to reflect the build-up of the week's work: Monday: "Heat Alert", Tuesday: "Heat Exchange", Wednesday: "Heat Wave", Thursday: "Making Cooling Outcomes" and Friday: "Show your stuff". Experts who were interviewed in the film spoke at a panel during Tuesday's "Heat Exchange". The filmmaker discussed his work on the same day. Six invited jurors drawn from health, design and the community, reviewed submissions and identified a number of noteworthy designs. The week ended with a celebration and all-school party on Friday evening.

The Instructor and PI oversaw a publication, *Heat!, Cooling spaces for highrise places* that documented CEx17 activities and design project outcomes. The publication was completed in 2018 and is available through the Ryerson University and Archives digital portal, https://library.ryerson.ca/. (Figure 6)

5. The Collaborative Exercise 2017 – Creating Cooling Centre Prototypes

Continuing in the tradition of past Collaborative Exercises, which addressed a number of important topics related to architectural issues and the public interest, including 'Civility' (2013), 'Identity' (2014), and 'Water' (2016), CEx17 addressed the topic of 'Heat'. The focus was the creation of prototypes for outdoor cooling centres. The PI, a professor in the Ryerson University DAS, was the Instructor for the CEx17, responsible for course conception, development and delivery. He developed the parameters for CEx17, which follow.

5.1 The sites

The design of outdoor cooling centres in CEx17 focused on three high-rise residential sites located in Toronto's inner suburbs (Sites A, B and C). The exact addresses and locations of these sites were not relevant to CEx17, as the three sites were chosen as typical of the approximately 2,000 high-rise sites where outdoor cooling centres may be located.

Table 1: Typical locations and location requirements and / or restrictions

	Name / location type	***Requirements / restrictions***
Typical location 1	**PARKING** Within an existing paved parking area	Must address the question of heat buildup on pavement and may require a raised platform. No excavation allowed into the pavement for plantings or water features. Must be accommodated within the existing flow of vehicular traffic and not block emergency routes. Plant and / or water features must be constructed on the platform and / or at grade. Must provide for a raised, well-drained area in the event of inclement weather.

Typical location 2	**GRASSY** On a grassy area which may have the potential to be enhanced with tree plantings	Some excavation of the site is allowed. Trees and other vegetation can be planted in the ground. Must provide for a raised, well-drained area in the event of inclement weather.
Typical location 3	**STREET** Adjacent to a major public thoroughfare and visible from the street	Some excavation of the site is allowed. Trees and other vegetation can be planted in the ground. Some form of enclosure is to be provided separating the cooling centre from the adjacent street / public walkway and providing privacy from the street. No obstruction of public pathways / emergency routes is allowed. Must provide for a raised, well-drained area in the event of inclement weather.
Typical location 4	**REAR** At the rear of the property, away from a major public street.	Some excavation of the site is allowed if this area is on grass or earth. Trees and other vegetation can be planted in the ground if the area is on grass or earth. Clear lines of sight into the cooling centre, ensuring surveillance of the facility from outside the cooling centre must be provided. Must provide for a raised, well-drained area in the event of inclement weather.

The sites display characteristics typical of older high-rise buildings located in the inner suburbs. The high-rise buildings contain from 200 – 300 residential units in a mix of bachelor, one-, two- and three-bedroom units. Typically these are rental buildings. The instructor secured the permission of the owners of these properties to utilize these sites for CEx17. However, as there were issues of privacy and respect for the residents, the instructor did not disclose the exact locations of these sites. Adequate information on each site was provided on D2L, the Ryerson University digital learning portal. Each of the high-rise building sites presented four typical locations where an outdoor cooling centre could be placed. Students were to assume that all locations at each site had access to power and water. The typical locations with requirements and / or restrictions are described in Table 1.

Figure 7: Site A

Site A, showing typical locations for outdoor cooling centres.
Credit: Saman Soleimani-Deilamani

Student teams were assigned one of the three sites (Site A, Site B or Site C). Within each site, teams were assigned one of the four location types (Type 1, Type 2, Type 3 or Type 4).

No changes were permitted. Typical locations for the cooling centre designs were identified on site materials posted on the D2L site. The sites and locations are indicated in Figures 7, 8 and 9.

5.2 Project Description – Heat: Creating Outdoor Cooling Centres

CEx17 took its cues from the growing concern about climate change and the ways in which episodes of extreme heat will impact Torontonians.

CEx17 invited students to design an outdoor cooling centre on a specific type of location on one of the three typical high-rise sites found in Toronto's inner suburbs. The cooling centres were to be designed in such a way to provide a range of residents of high-rise buildings the opportunity to seek respite during periods of extreme heat in the summertime in Toronto.

The cooling centre was to provide basic amenities to users that would provide them comfort during a heat alert. It was recommended that the cooling centre be open 24 hours / day, 7 days / week, and be accessible to building residents on a priority basis. Other residents in the surrounding community might also access the cooling centre. Student design teams therefore were also to address questions of security, round-the-clock use and the implications of mixing user types in the centre's design.

The cooling centres were to cater to a wide range of individuals representing the spectrum of high-rise apartment dwellers in Toronto. Therefore and to focus the design, four specific user groups were identified. Each team was assigned one prime user group, but would have to consider at least two other user groups as secondary users. Students were asked to address the question of sensitivity between different types of users and potential conflicts that might arise when the site is programmed for a mix of users. In all cases, there might be a mix of ethnic groups and a range of abilities within these groups. Students were to be mindful of these issues as they developed their designs. Table 2 identifies the proposed user groups.

Table 2: Proposed user groups:

User Group 1	Parents with young children (i.e. children under 12 years of age)
User Group 2	Teenagers
User Group 3	Adults
User Group 4	The elderly

5.3 Project Drivers

A major thrust of this project was to seek ways in which to explore ideas of passive cooling and the use of water, plant materials and shade (either natural or constructed) as elements in the design of the cooling centres. Each cooling centre would have access to water and electricity but was not to be energy dependent for cooling. These were not to be designed as "air conditioned" rooms but rather as places that provided comfort and respite during periods of extreme heat through natural means.

Therefore, as a means for participants in CEx17 to explore the potential for passive cooling in these outdoor cooling centres, each team was asked to consider encapsulating passive cooling, which would provide thermal comfort to cooling centre users with low or nil energy consumption.

5.4 Design Considerations

Students were advised that these were to be unique facilities that would bring together a variety of people who might have common needs but not necessarily share similar values, beliefs, backgrounds or interests. Students therefore were to be mindful of providing privacy and a range of spaces within the cooling centre to address the diversity of the populations and their individual requirements.

The cooling centre might accommodate a cross-section of users, from individuals to small groups to large gatherings, of all ages and demographics. Therefore, the cooling centre might have within it a variety of zones from the intimate to the public. Therefore, the design was to be considered at three scales: the cooling centre, its immediate context (e.g. an area within 20 meters of its focus), and its larger context (e.g. extended vistas, views from within the site and from the larger urban context).

5.5 Design Objectives and Parameters

Each team was tasked to design an outdoor cooling centre that would provide comfort to a range of residents during periods of extreme heat. Different groups might have different needs and these needs were to be accommodated. For each cooling centre, students were to consider nine design issues. These are described in Table 3.

Table 3: Design issues

Access and welcome	For the cooling centres to be used by residents, the designs must demonstrate that they are accessible and welcoming places.
Comfort	Thermal comfort is important in these centres. As they are not to be "air conditioned" and are to use passive means of cooling, using low to no energy, students must demonstrate that comfort is achieved in their proposed design.
Security	Create a space where users may feel secure and welcome. If the decision is taken that the cooling centre may be in operation 24 hours per day, students must address the question of security of users around-the-clock.
Recreation	Create a space where users may engage in recreational activities, either individually or collectively. This may be in the form of quiet reading or group activities, including engaging with water recreationally, or other activities requiring more exertion. Different age groups may have different recreational needs and students should be mindful of this.
Culture and Ethnicity	Be capable of accommodating the needs of diverse cultural and ethnic groups and communities.
Function	Provide basic functional needs such as seating, resting/relaxing and toileting. Other activities may be incorporated, such as information functions, capacity to access internet, public telephone or charge individual portable computer devices or telephones. The facility may include a shower for individual bathing as appropriate.
Privacy	Provide the opportunity for individuals to find comfort and privacy, albeit in a public or quasi-public setting.
Sociability	Provide the opportunity for people to undertake sociable activities in small groups.
Information	Provide information to users on possible heat-related or public-service related issues.

5.6 Project Scope and Considerations

Table 4 identifies dimensional and area considerations each cooling centre design. Table 5 lists program considerations.

Table 4: Cooling centre dimensional and area considerations

- A space of approximately 100 m2 which will form the core of the cooling centre, capable of accommodating 15 – 20 people.
- If 24 hour use is proposed, present ways the space may be secured at night to permit possible overnight sleeping by residents during periods of extreme heat.
- It must be shaded and provide coverage in inclement weather.
- If students believe that this area is too small or too large, they may contract or expand the area and provide a rationale for their decision.
- If the area is enlarged, it must not exceed the area of 200 m^2 as discussed below.
- A larger space of approximately 200 m^2 which may extend the area of influence of the cooling centre into the larger location.
- The cooling centre may be a one- or two-storey structure. Be mindful of accessibility requirements. The maximum height of the built area is to be no more than 8 metres.

Table 5: Cooling centre program considerations

- The underlying premise of CEx17 is to create safe, comfortable, accessible and secure cooling centres that provide comfort to residents during periods of extreme heat.
- Each cooling centre will have common program elements.
- Specific program elements will be required for specific user groups and students may propose additional elements and incorporate these into their designs.
- Passive cooling is to be the main means of cooling. Energy consumption for cooling is to be low or nil.
- The tectonics of the cooling centre should be explored and clearly developed. The form and materiality of the cooling centre may seek to reinforce the idea of cooling. The tectonic, therefore, should consider both construction and how the choice of materials, assemblage and construction raises the architecture of the cooling centre to a higher meaning beyond the functional, allowing the design and object to have a significant presence.
- The cooling centre must have weather-protected / shaded and open / outdoor components.

- The cooling centre is to function from late spring through early fall. Its use, function and operation may change with time (daily or seasonally). - The cooling centre may be a permanent or temporary facility. If permanent, provision must be made for its enclosure / security in the season when it is not in use. If temporary, the design must demonstrate how it may be demounted and stored for reassembly and use in future summer seasons. - The cooling centre should accommodate a multiplicity of purposes and activities that may change over time.

5.7 Program elements and design requirements

Each cooling centre was to include common elements for any type of user and specific user-related elements. Table 6 lists common program elements and design requirements. Table 7 lists program elements and requirements for specific user groups.

Table 6: Common Program Elements and Common Design Requirements

Common Program Elements
− Water and electricity are provided
− Water: pools either need 24 hour surveillance (e.g. a lifeguard) or need to be drained when there is no surveillance
    - Must be wading pool or splash pad (wading pools are 0.75m or less in depth)
    - Misting station
    - Drinking water fountains
    - Two unisex bathrooms equipped with toilet / sink and a changing station; one may include a shower
− Shading: natural and constructed
− Area: $100m^2$ secured area, $200m^2$ maximum footprint
− An area for a person who will operate / supervise the cooling centre (including locked storage)
− Lighting: dependant on the program (sleeping, activities, etc.)
− Cooking space, including a barbeque, sink area
− Garbage disposal
− Assume even grading for the site
− Vending machine for cool drinks
− Ice machine
− Refrigerator for storage of cool/cold items
− Night activity permitted
    - Said activity to be determined by the group (active or passive)
− Students must address what happens to the site during the other seasons

Common Design Requirements − Barrier free design − Charging stations − Information panel − First aid station − Location for a Public Health worker or community volunteer to attend the Centre on an occasional basis − Digital component (audio, visual, etc.) − Storage space − A public address system − Possibility of public event area / public gathering area − Area for quiet relaxation, reading, listening to music (on earphones), lounging, resting − Picnic area − Universal activity tables

Table 7: Program Elements and Requirements for Specific User Groups

Parents with young children (i.e. children under 12 years of age)	− Easy visibility of children − Spaces must allow for adults to interact with their children − Park / play structure − + other uses as determined by student team
Teenagers	− Gathering space

	− Study space+ other uses as determined by student team
Adults	− No special uses other than those presented above − + other uses as determined by student team
The Elderly	− No special uses other than those presented above − + other uses as determined by student team

6. Design Prototypes

In CEx17, ten designs were prepared for each of the three sites, comprising a total of thirty different designs. Each design was the product of a team of students in the four-year Ryerson University DAS undergraduate B. Arch. Sci. program. Students in each group worked as a team in a four-day charrette.

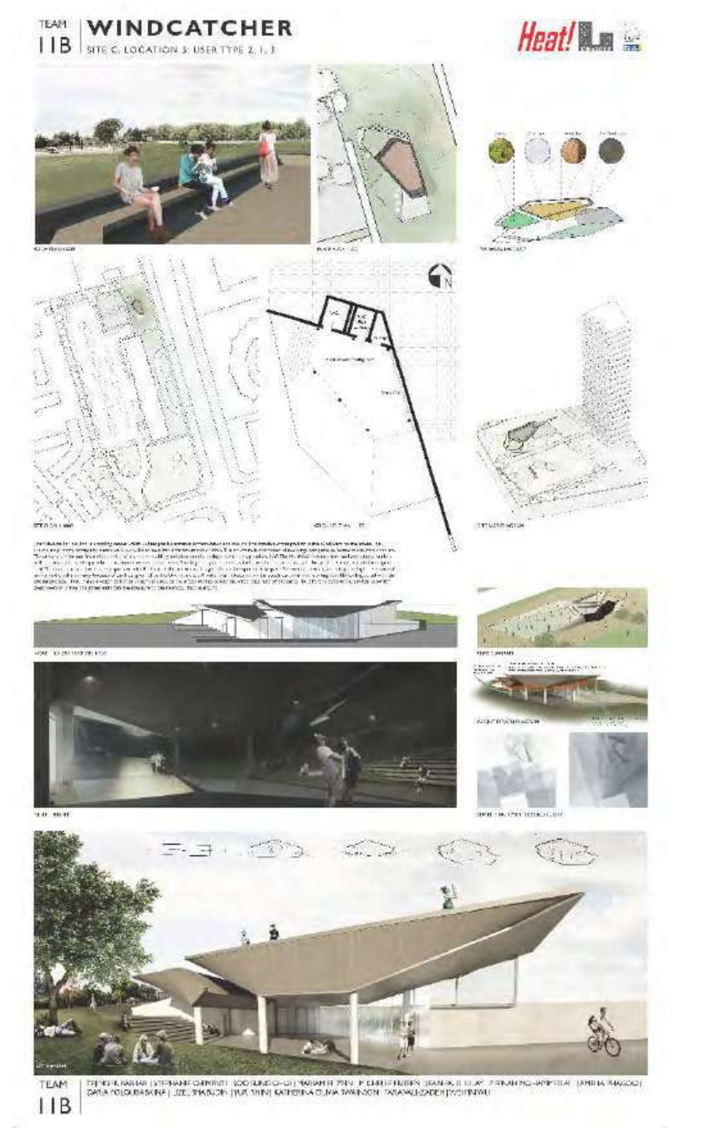
For the focus groups, four projects were selected for discussion and feed-back by focus group participants at Sites A and C. The projects were chosen to represent a range of design approaches for the four locational conditions and age-group focus of specific users. Table 8 lists design parameters for each prototype reviewed.

Table 8: Prototype names, on-site location and primary/secondary user

	Team number and Project Name	Location on site	Primary User	Secondary Users
Site C	11B Windcatcher	street	teenagers	adults parents with children under supervision
Site C	12B Heat: It's lit	rear	senior citizens	adults parents with children under supervision
Site C	13B Cool	parking	teenagers	adults parents with children under supervision
Site C	14B Cross Shade	grass	senior citizens	adults parents with children under supervision
Site A	6A Cool-Haus	grass	parents with children under supervision	adults teenagers
Site A	7A Sombra	street	adults	seniors parents with children under supervision
Site A	8B River and Chill	rear	teenagers	adults seniors
Site A	9A Chill Out	parking	adults	teenagers seniors

Each student team chose a name for their design and provided a brief description. The complete range of work is available through the Ryerson University Library and Archives digital portal, https://library.ryerson.ca/. The design prototypes present consistent themes of passive cooling, relaxation and sensitivity to the surrounding natural and built environment. Figures 10 – 17 present student designs and brief descriptions prepared as part of the student submission. These descriptions have been revised and edited for consistency and are provided as captions to each of the figures.

Figure 10: Site C – Team 11B, "Windcatcher"



The Windcatcher pavilion is a cooling centre which utilizes passive systems for ventilation and cooling. The structure is composed of two large compressive masses and its form is derived from the intersection of the street, building and playground, creating a place to stop and cool off.

The north-west wind direction flows along a sunken path to create a versatile space for relaxation, events or activities. The larger suspended space is to be used as a patio space and the small, as a climbable green roof.

The manipulation of wind is incorporated into the pavilion form, as air is drawn into the open activity space. A water wall is featured on the south-east entrance, creating sensible cooling for pavilion users. The different levels of the pavilion allow for great views to adjacent playground.

Figure 11: Site C – Team 12B, "Heat: It's Lit"

The aspirations of this project culminated in a minimal impact cooling pavilion, providing various cooling effects to the immediate community, with specific focus on the elderly.

The pavilion is divided into three distinct zones: an air zone, a water zone and a comfort zone. By incorporating passive air movement and providing a live wall that will catch the wind, the pavilion can provide more-than-adequate cooling on even the hottest of summer days. The inclusion of an interactive misting station provides opportunities for children to play. A small kiosk provides additional benefits to users, offering cold beverages when needed. A seating area in the comfort zone is geared towards the elderly, allowing places for rest and socializing.

The inspiration behind the form and tectonics is drawn from the adjacent apartment slab tower, as well as the less-is-more minimalist approach of Mies van der Rohe. Ideally, the pavilion acts to engage fully with the community and solve the issue of extreme heat during the summer by means of passive cooling strategies involving air and water.

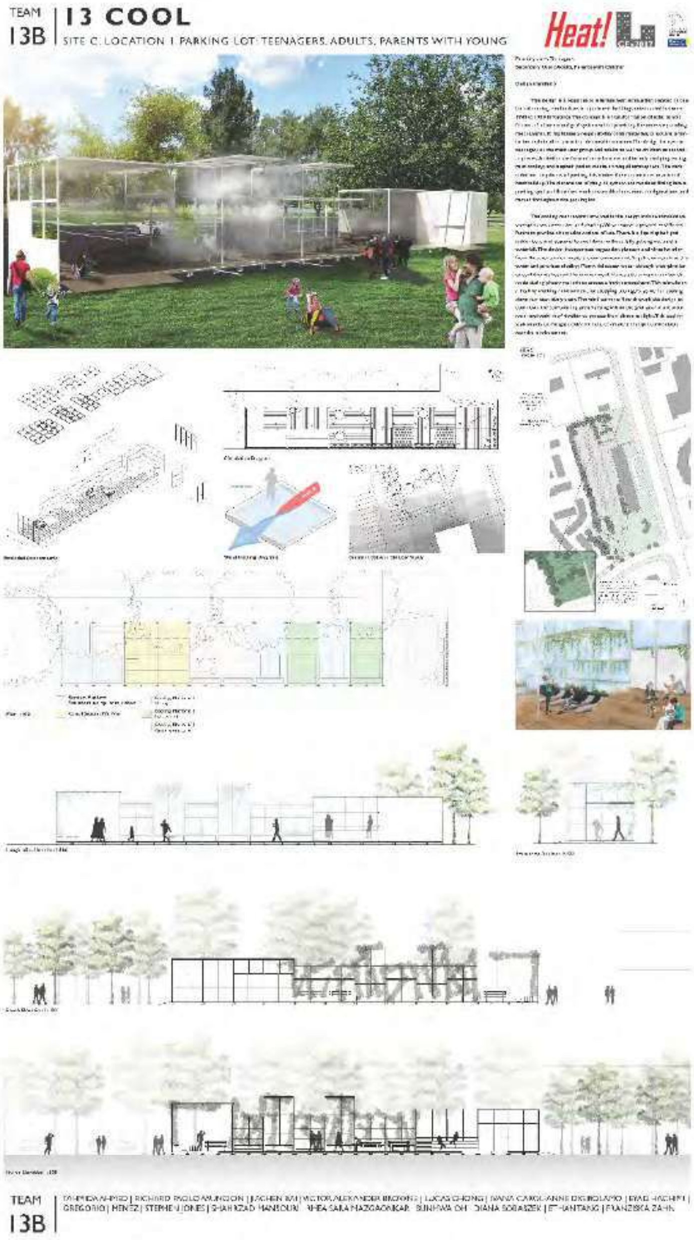
Figure 12: Site C – Team 13B, "Cool"



The design concept is the transformation of solid-to-void to fit into a three-dimensional grid while at the same time providing mechanisms for cooling. Materials, structure and orientation are brought together to provide a pleasurable summer experience for users. Teenagers are the prime user group with activities focused on relaxation, eating and studying. Mist cooling and a splash pad create a tranquil atmosphere. The lines demarcating parking spaces create the scheme's modules, which can be assembled in various configurations and moved in a number of locations on the parking lot.

Cooling is brought about through conduction, transpiration, convection and shading. Water in various forms – vapor, mist or liquid – provide options for cooling. There is a splash pad for wading, misting stations for cooling, and a waterfall for visual pleasure. Hanging vines and planters emphasize the coolness of this place and provide shading and cooling through transpiration and carbon transfer. The presence of water and vegetation stimulates a healthy working environment for teenagers who wish to study. Winds moving through the pavilion cool the surrounding area. Shading devices protect users from harmful UV. The cooling station acts to mitigate extreme heat through the creation of a tranquil and comfortable exterior environment.

Credit: F Ahmed, R P Asuncion, J Bai, V A Browne, L Chong, I C-A Digirolamo, E Hachemi, G Jimenez, S Jones, S Mansouri, R S Mazgaonkar, S Oh, D Sobaszek, E Tang, F Zahn.

Figure 13: Site C – Team 14B, “Cross / Shade”

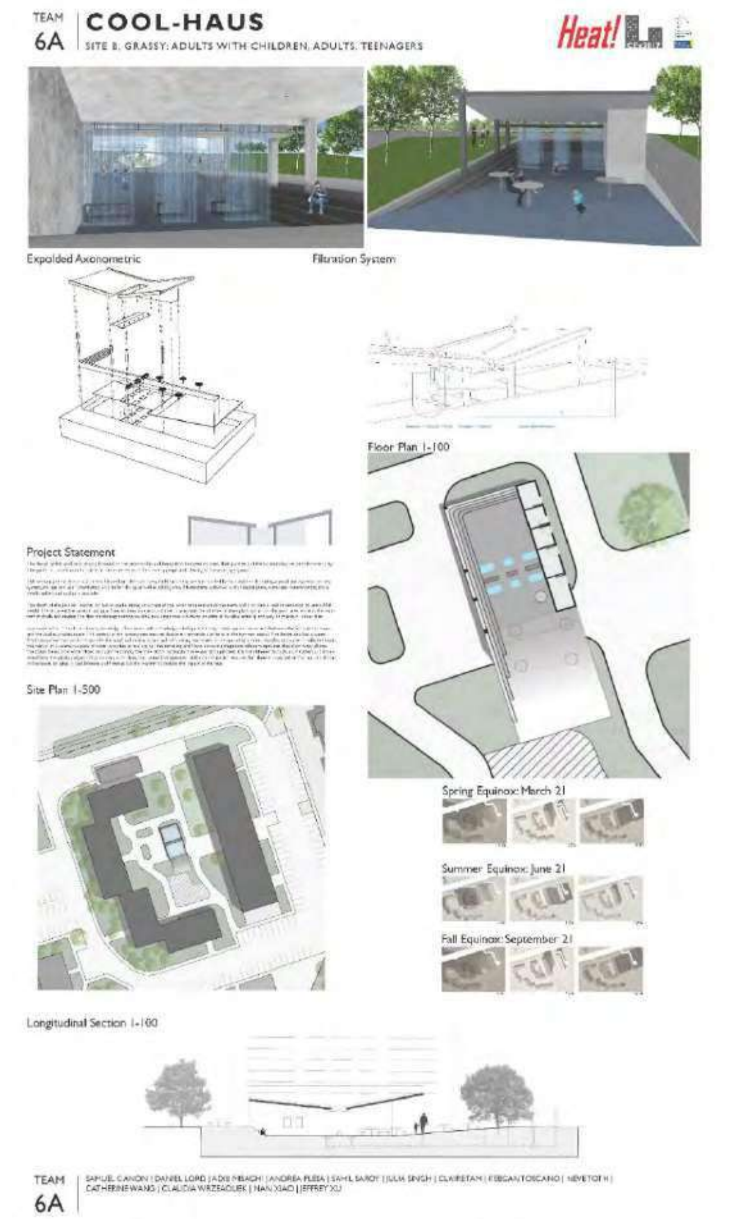
The goal of this project is to create a communal cooling system for elderly residents. The centre provides a refuge in heat wave and a lively recreation space. The design features four spaces, each with a specific purpose, all unified by an overhead lattice structure housing a misting station and branching from the central area to connect with other spaces.

A decked seating area is located in the centre of the site, furnished with patio tables and chairs and sitting over a narrow extension of the adjacent wading pool. Three existing trees shade the area and a small structure houses a small kitchen, washrooms and storage is located adjacent to the seating area. The wading pool (that can become a winter skating pond) is part of a larger water system across the site and provides a space for children to play.

Another seating area is designed, closer to the apartment building, intended for elderly users. Set off from the other areas, this is a quiet space, separated from the more active areas for users to enjoy board games, conversation or reading. The lattice structure extends to cover all areas of the site, unifying the composition.

Credit: S Adnan, D Ahmad, Y Arboleda, A Brenna, M Breteon-Honeyman, J Cavliere, G Chalabi, L Crichton, V Chow, E Doucette, B Esuan, S Elangko, J Hache, I Jeong, V Paningbatan-Cerez.

Figure 14: Site A – Team 6A, "Cool-Haus"



The design of the pavilion is focused on the interaction between children, their parents and their neighbourhood. The goal is to unite fun and comfort in the experience of the space. The versatile and fully accessible pavilion offers an open multipurpose space, seating, waterfall cooling, amenities, a BBQ cooking area, with a nearby splash pad and small park. The pavilion floor sits 1 m below grade, creating a cool environment. This grade differential allows for parent supervision beyond the enclosed area.

A shaded roofed space offers users a place for easy transition between hot exposes outdoor spaces and cooler, shaded spaces. A water filtration system and rainwater collection mechanism provides water to the pool and a constant flow of water, supplemented with municipal water, flows down the slope falling into the ponds below. A UV system filters water for use in the splash pad, all while cooling the overall area.

The openness of the structure ensures there is a constant airflow and through ventilation. Cool breezes reduce the impact of summer heat.

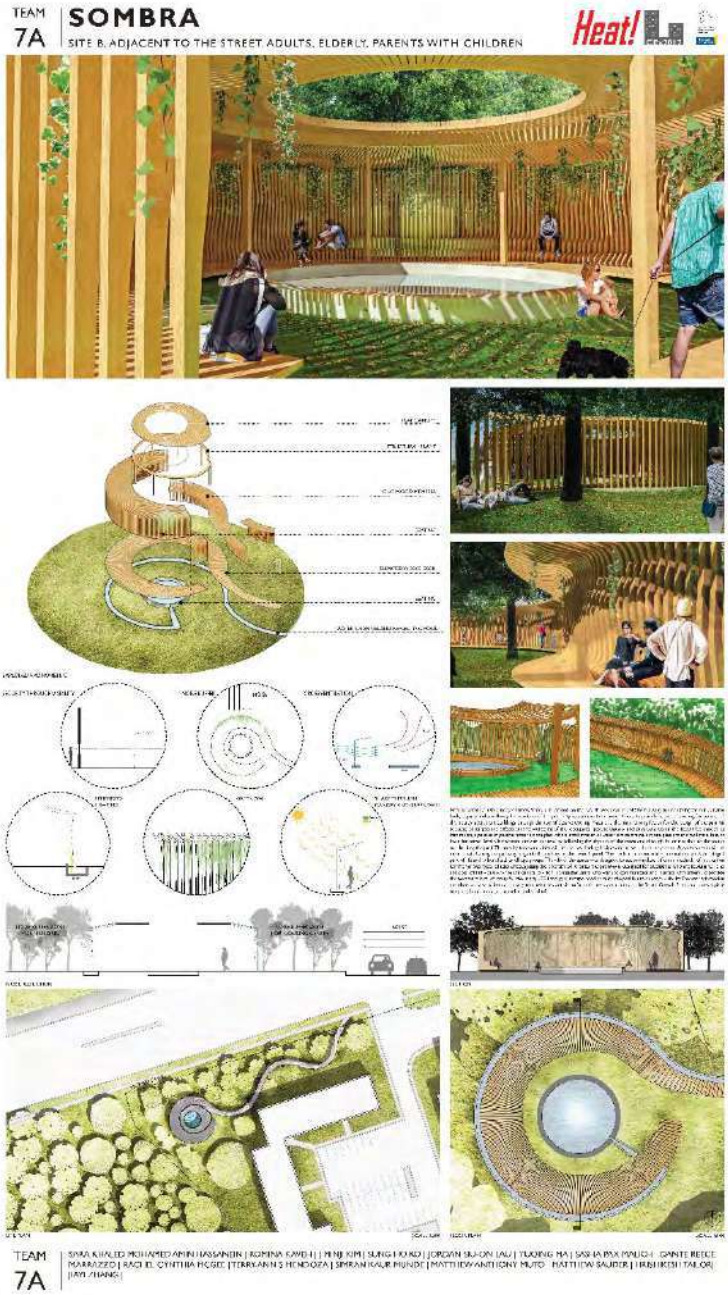
Figure 15: Site A – Team 7A, "Sombra"



Nestled within a lush canopy of trees, an undulating form denotes a space and a walkway for residents to call as their own. The design aims to provide respite to residents through passive cooling. Nature is the main driving factor of the pavilion because of its positive effects on the wellbeing of occupants, psychologically and physically.

Using the local tree canopy as inspiration, a palette of natural materials together with a small stream of water aim to create a pleasant microclimate that helps lower a user's stress. The design that overlooks the park respects the site context, following the rhythm of the trees. Nearby, vegetation provide shade and noise reduction.

The pavilion accommodates meditation, as it is an integral part of the natural world and provides benefits to users of all ages. The pathway provides space for people who seek relaxation and cooling relief, while the central pavilion is larger for users to interact and engage with each other. To provide necessary levels of safety for users, LED lighting is incorporated in the design to enhance visibility. The vertical wooden members are oriented to allow constant views to the south.

Overall, Sombra creates a place to take a break in nature, to relax and cool off.

Figure 16: Site A – Team 8B, "River and Chill"

The earth's climate is changing. Recent warming trends are significant as they are the result of human activity. Toronto will experience the impact of climate change.

Cooling stations may help prepare us for future heat waves. Ideally these cooling stations should utilize passive cooling that takes advantage of local climate and site conditions to maintain a comfortable environment, minimizing the impact on the environment. A building built for passive cooling may be no building at all but rather an intervention that is integrated within nature and uses no energy.

Our proposal therefore guides users to a river adjacent to the site. This waterway has the potential to be fantastic cooling amenity for residents from the adjacent building. Modules designed for specific activities frame the path that brings users through the forest to the river. These spaces will allow users to relax on their own, gather in groups and enjoy activities together, such as an outdoor meal. The modules are passively shaded by the surrounding dense foliage, ensuring that users remain cool at all times.

Figure 17: Site A – Team 9A, "Chill Out"

Chill Out is a proposal for a cost-effective modular cooling station. Designed to occupy the vast outdoor parking spaces surrounding apartment towers, the modular unit is derived from the size of a typical parking spot. Using a combination of semi-enclosed and open units, a variety of configurations are made possible, allowing for future expansion and use in other places.

Passive cooling is achieved by creating a module that is devoid of any solid walls, allowing for a constant breeze to pass through the space. In addition, shading is provided by the solid roof element and through vegetation and vines that grow around the cables and planers. Active cooling is achieved through a misting bar found at the entrance of every module that generates a mist when someone walks through the entrance. Electricity is generated through photovoltaic panels found on the roof or the modules. Additionally, the roof is designed to collect rainwater that provides a constant supply for misting.

To accommodate the activities of users, a variety of leisure, work and gathering spaces are provided. Each module is subdivided into three zones: intimate relaxation, circulation, and a multi-use active space.

The construction of the modules is made cost-efficient by using dimensioned lumber and steel cables as the main structural elements for the cooling stations.

7. Community Focus Groups

The project anticipated three focus groups, one on each site. The protocol called for a random selection of up to 12 residents from each site to discuss the outdoor cooling centre prototype designs. The protocol anticipated focus groups would take no more than two hours.

In planning the focus groups, the PI recognized that it would be unlikely that focus group participants would have an in-depth knowledge of architecture. The PI also determined that presenting all the designs for each site could overwhelm participants and extend discussion beyond the focus-group's two-hour limit. Therefore, the PI in consultation with the focus group facilitator identified four designs per site to take to each focus group and posters were prepared. These are presented in Figures 9 – 16, above. The graphics contained architectural plans, descriptive texts and colour renderings of the spaces of the proposed cooling centres. An architecture student presented these design ideas at the start of each focus group, so participants could better comment on the architectural drawings presented to them.

In recruitment and organizing the focus groups, three issues arose.

First, due to delays in receiving REB approval for the focus groups (received in mid-February 2017), implementation of the focus groups was delayed to late winter / early spring of 2017.

Second, late in the process, a community group involved with one of the sites advised the PI that this group would not support Ryerson's engagement with that community, believing that the community had been "studied enough". This news came as a surprise to both the PI and TPH who had received permission from the property owners and community representatives for the focus groups. Consequently, the PI organized focus groups on the two remaining sites, B and C. Depending upon recruitment, the PI planned to hold up to three focus groups on the remaining two sites.

Third, agreed recruitment protocols – postering in the buildings and distributing flyers to building residents – yielded no participants, even after several attempts. Given constraints of budget, timing and availability of all personnel, the PI decided to approach recruitment with a more concerted effort and in a targeted manner. On the day that each focus group was scheduled, the RA and focus group assistants arrived early at each building. By going door to door and also waiting in the buildings' lobbies, they were able to recruit six participants at each site who met the participation criteria. In consultation with the PI, the facilitator proceeded to undertake the focus group utilizing each group as a convenience sample of users.

The first focus group was held on Saturday 22 April 2017 in a meeting room dedicated for community discussions, located in one of the low-rise buildings at Site B, the first of the two remaining sites. This focus group had three male and three female participants of various ages. One participant is active on the tenant council. All participants could communicate in English, as required, and also appeared able to follow the design presentations made. However, one participant seemed less comfortable participating than the others, and another participant made multiple efforts to divert the conversation to his personal interests about the housing complex. In general, the participants had great familiarity with their own site. When asked about personal cooling strategies, they all talked about going somewhere else: air-conditioned mall, park, or city beach. With respect to their own apartment building site, they gave detailed responses to their preferences about the best location on the property for an outdoor cooling centre. They were also very sensitive to issues of safety, security and vandalism of property, as well as the role of a property manager to support tenants' needs. Participants were not discerning about the specifics of design details other than the relationship of material choices and construction to property management and maintenance issues. The group was extremely interested in a design that would enable a wide range of residents to assemble and use a cooling centre, whether all at once or at varying times of the day.

The second focus group was held on Sunday 23 April 2017 in a meeting room in the high-rise building on Site C, the second of the two remaining sites. This focus group consisted of three male and three female participants. All participants could communicate in English, as required, and also appeared able to follow the design presentations made by one of the student focus group assistants. At this site, the participants all identified strategies of personal cooling in hot weather rather than going off-site. These included finding shade, wearing light-weight and light-coloured clothing, and staying hydrated. When assessing the student designs, these residents demonstrated a good knowledge of their own site. They indicated that the large open green space to the south is used from time to time for building-wide events but also that this area is both the hottest part of the site and the least convenient for assembling residents. Participants focused on the specific location of an outdoor cooling centre. They were mindful of the potential costs of constructing a centre. Participants expressed interest in modular designs that could be erected quickly, re-arranged and / or replicated to meet a variety of needs and conditions. When asked about property management issues, vandalism and security, the participants in the focus group described their building as well-managed and therefore had few concerns about these issues. The participants in the second focus group expressed interest in the social aspects of a cooling centre and offered support to those designs that would continue to facilitate wide use and social interaction of residents beyond periods of extreme heat.

8. Project Findings and Observations

This research project required the unfolding of a series of events and activities, with specific deliverables over a limited timeframe, in order to present to TPH and potential cooling centre users prototype designs for consideration and evaluation. The requirements of the multiple players added to the complexity of the project and led to delays in implementation of aspects of the project and a delay in project completion from early 2017 to late 2018. Nonetheless, the multiplicity of stakeholders reflects both the complexity of this issue and the necessity of a multi-valent approach to the question of addressing heat mitigation through outdoor cooling in apartment neighbourhoods. The following are presented as project findings and personal observations by the PI.

8.1 The development of design prototypes for outdoor cooling centres and the value of student engagement

This research project centred on architecture and the utilization of design-as-research as a means to explore an issue in the domains of public health, urban design and city planning. The use of actual sites, with real site constraints, obliged student designers to engage in creative and collaborative problem-solving. Specific locations within the given sites, further required consideration of both typical and unique conditions that would shape design decisions and outcomes for given sites and locations. The development of design objectives and parameters, the identification of potential user types and the articulation of design issues, and their application to the design problem, challenged students to meet all aspects of these real-world constraints, conditions and obligations in their design proposals.

The short time-frame for decision making and project execution in within a team of a dozen student called for all participants to negotiate decisions in a constructive and positive way, in order to achieve the objective of a coherent and considered design prototype. Foregrounding user comfort in extreme heat, sustainable design practices and passive cooling brought students into the contemporary exigencies of design praxis.

Engaging students with practitioners in multiple disciplines, exposed them to the complexities of design in the world beyond the academy. Presenting designs in focus group settings brought students into the reality of client engagement and feedback, necessary for effecting successful, engaging and useable design outcomes. Notwithstanding these multiple factors, constraints, issues and obligations, students produced a range of prototype designs that provide a spectrum of possibilities potential for the creation of outdoor cooling centres.

The outcomes of this pilot project demonstrates the potential of design to reveal possibilities and imagine different and otherwise unimagined futures

8.2 Utilization of focus groups for design feedback and community "buy-in"

Focus groups can be an effective way to elicit user feedback on a design proposal. In these particular focus groups, engaging architecture students in the development of designs, the presentation of design outcomes in focus group settings and hearing the community members' response to discuss proposals, provide student assistants a one of a kind opportunity to experience user feedback to design work.

For reasons of time and cost, the material presented to the residents in the focus groups at the apartment sites was in the form of reduced scale reproductions of the students' presentation panels, produced at the end of CEx17. These panels contained a lot of information and were presented in a variety of formats. The lack of uniformity and the relative lack of capacity among focus group participants to engage with architectural drawings and renderings may have made it more difficult for lay users to understand design concepts. A different process, such as providing more time or making designs available prior to focus groups, or more simplified and consistent presentation, may have made it easier for residents to quickly understand and then assess each proposal.

Focus groups depend upon participation. The absence of a significant financial incentive for participation (as a result of ethics considerations) and the timing and location of focus groups (and possibly the underlying issue of community residents believing that they had been "surveyed enough" without any long-term perceived benefits or outcomes) appears to have inhibited large-number participation in the focus groups. The low number of participants in the focus groups was disappointing. Although promised, community support for the project did not materialize that resulted in low turnout. Broadening recruitment to residents outside those on the subject sites may have yielded greater numbers. Nonetheless, the convenience sample of users at the two sites provides useful feedback on design proposals.

The positive response to cooling centres in both focus groups indicated a support for outdoor cooling as a potential to address one aspect of excessive heat for apartment dwellers in Toronto's summer. Based on comments received, designing for such facilities must anticipate a wide range of users, extensive use over all times of day, and support for use of these facilities outside of periods of extreme heat.

Securing the buy-in of stakeholder groups is essential. Early in the process, the project anticipated engaging with building owners and managers, but this was not pursued, due to time constraints, changes in project personnel and limitations of resources. Sensitivity to community needs and closer work with community groups may facilitate broader participation and deepen project findings.

8.3 A complex issue takes time

As the research content and background information to this paper indicates, the issue of the impact of climate change on human health, in this case in relation to extreme heat for vulnerable populations living in highrise buildings without air-conditioning, has been developing over a long time. Evidence-based and conclusive research has provided considerable data for practitioners in health and planning.

The paucity of design-based research points to opportunities for architects, urban designers and physical planners to develop expand the field of knowledge and add their voices to those of the scientist, health promoter or policy maker. Continued investment in design-based research is called for in expanding this field of knowledge.

8.4 The power of film media to convey ideas and present issues in context

The production of a film on the impact of excessive summer heat, shown to architecture students in mid-winter, contributed positively to the CEx17. Capturing the voices and thoughts of residents in times of extreme heat (participants were filmed in the summer of 2016, Toronto's hottest summer to that time) provided viewers with insights into the issue, that otherwise would have been difficult to convey. The Image Arts graduate student filmmaker is to be commended for his insightful development of this film and his work together with the RA to capture the essence of being in an overheated city in summertime.

The successful use of this medium to communicate a set of architectural issues is evident and worth continued pursuit. The showing of this film to a wider audience – perhaps through public libraries or community recreation centres or other community facilities – may prompt a broader discussion of this issue. The impact of film – and its current capacity to be easily accessible and user-friendly – may prompt architects, urban designers and city planners to engage in this aspect of research and documentation to support the advancement of their respective disciplines and professions.

8.5 The creation of permanent record of the project and project dissemination

The publication of the CEx17 outcomes allows for a wider distribution of this material and provides opportunities for further focus group or other user feedback. The opportunity to present findings at academic conferences and public events further supports discussion of the seminal ideas of the project, feedback and knowledge transfer.

8.6 The complexity of inter-disciplinary and inter-sectoral research and the potential of positive synergies between multiple stakeholders

In the design and planning disciplines, engagement with multiple stakeholders, listening, responding and acting, are keys to successful practice.

This project originated with conversations between the PI and staff at TPH, who were interested in advancing ideas about outdoor cooling centres that were coming out of their research and stakeholder engagement on the issue of climate change. As the project developed and was implemented, others were drawn into the process, including a filmmaker, building science researchers, academics in many disciplines, health promoters, building owners and managers, landscape architects, tenant representatives and their associations, climate change experts, housing providers, municipal politicians, community leaders as well as collaborators in the Tower Renewal Partnership and others. In all this, the exigencies of time, the responsibilities and obligations of participants to their individual organizations created unforeseen challenges as well as unanticipated revelations. Nonetheless, common goals and shared aspirations for successful outcomes continued to propel the work of this project.

Addressing solutions to climate change is both time-consuming and challenging. As we all know, good things take time to develop and be realized. Inter-disciplinary and inter-sectoral work has the potential to yield fruitful outcomes for multiple benefits.

8.7 Further work

Funding from Ryerson's CURLD provided for three focus groups, of which only two took place. Additional focus groups may provide further and more extensive feedback on the issue of cooling centre designs.

Seeking a broader audience for this issue, through showing the film then effecting a focus group, may prompt greater participation and elicit a broader range of opinion.

Since the conclusion of the project, staff at TPH has changed and priorities shifted. In light of a newly appointed Medical Officer of Health and new staff appointments, a full presentation of prototype proposals, a discussion of their designs and implications for future work to support concept of heat mitigation through outdoor cooling centres is warranted.

9. Conclusions

Vulnerable populations will face greater challenges to test their resilience in the face of climate change. Concerns about climate change, urbanization, heat island effects and concomitant impacts on the quality of life and the health and well-being of residents have been on the minds of planners, health promoters, designers and municipal leaders for decades. These concerns are not new. They echo the voices of early planners and putlic health practitioners that sought to ensure the health and well-being of all citizens through investment in urban infrastructures and attention to the design for health of urban places.

The push to re-valorize Toronto's aging inner-suburb apartment neighbourhoods is a process of continual evolution. The new DAS zoning promises to promote the introduction of new uses, and the recreation of these monolithic neighbourhoods into vibrant and multi-faceted new places. The work of the Tower Renewal Partnership demonstrates leadership and vision. It is hoped the activities and findings of this pilot project may support their ongoing work.

Cooling centres and environmental awareness of design interventions promote a holistic view toward the design and renewal of buildings and their settings for the benefit of all residents, regardless of means, stage in life, backgrounds or abilities. The City of Toronto, through its agencies, boards, commissions and divisions is in a position to work collaboratively to address holistic issues of climate change, public health and resilience in order to mitigate effects of climate change, adapt to changing conditions and equitably seek solutions to address the diverse needs of Toronto residents.

Toronto's comprehensive approach to “cool planning" (the theme of the 54th ISOCARP Congress 2018), reflects a responsible and considered approach to climate-proofing vulnerable citizens in Canada's largest metropolitan region.

Project Participants
Principal Investigator: George Thomas Kapelos, Professor, Department of Architectural Science, Ryerson University. Co-Investigator: Umberto Berardi, Associate Professor, Department of Architectural Science, Ryerson University. Image Arts Advisor: Gerda Cammaer, Associate Professor, School of Image Arts. Research Assistants: Christopher Marleau, Peter Conrad. Focus Group Facilitator: Karen Chisvin, Architect. Focus Group Graduate Assistants: Hussain Patwary, Patrick Ritsma, Daniel Petrocelli, Carleen Lawson, Brandon Bortoluzzi, Adrian Man. Toronto Public Health Representatives: Carol Mee, Sarah Gingrich, Kelly Sabaliauskas. Collaborative Exercise 2017 Coordinators: Joseph Ball, M. Arch. 1, Isabelle Gunn, M. Arch. 1, Ishan Patel, M. Arch. 1. Film: George Thomas Kapelos, Executive Producer, Writer, Narrator; Peter Conrad, Producer, Director, Photographer Editor; Gerda Cammaer, Associate Producer; Christopher Marleau, Researcher Editor; Composer, John Kapelos. Department of Architectural Science Faculty: Jurij Leshchyshyn, Interim Chair (to June 2017), Mark Gorgolewski, Chair (after 2017), John Cirka, Director, Master of

Architecture Program, Russell Richman, Director, Master of Building Science Program, Vera Straka, Undergraduate Program Director.

Project Funding, Support, and Acknowledgements
The project was funded by a grant from the Ryerson University Centre for Urban Research and Land Development (CURLD). Other, non-financial support was received from the Ryerson University Department of Architectural Science, the Yeates School of Graduate Studies, the Ryerson School of Image Arts and the Healthy Public Policy Directorate of Toronto Public Health. The PI gratefully acknowledges and appreciates this support. A number of individuals participated in the film, film interviews and focus groups, including Lloyd Alter (Architect, retired), Keir Brownstone (Toronto Community Housing), Tanzina Mohsin (University of Toronto), Gord Perks (Councillor, City of Toronto) and Sarah Gingrich (Toronto Public Health), as well as the City of Toronto residents who shared their views on dealing with excessive heat in high-rise apartment buildings and designing appropriate cooling spaces.

For further information
Further information on this project and to obtain a transcript of the film, *Heat! Cooling spaces for highrise places,* please contact the author, George Thomas Kapelos, Ryerson University, 350 Victoria Street, Toronto Ontario Canada. T: 416 979 5000 x 6510. E:gkapelos@ryerson.ca.

A framework to identify risk level of areas for the formation of evacuation zones during cyclones

Amarjeet Kumar, Indian Institute of Technology, Kharagpur, India
Saikat Kumar Paul, Indian Institute of Technology, Kharagpur, India

Abstract

India has 7516km long coastline, close to 5700km is prone to cyclones and tsunamis. Approximately 250 million people lived within 50km from the coast in the year 2010. Major cities like Mumbai, Chennai, Surat, Vadodara, Vishakhapatnam, Pondicherry etc. lie along these coasts. The rapidly growing urban population in these coastal zones and the increase in severe weather events have magnified risk in these areas. On an average, nine cyclonic and severe cyclonic storms are formed over north Indian ocean per year. Evacuation during cyclones is one of the most effective strategies to reduce human loss. The purpose of this work is to propose criterions for defining the risk level of different zones that will help in the management of phased evacuation. In this study, an approach is proposed to identify the risk level of zones in hazard impact area based on parameters related to hazard, vulnerability and exposure. The hazard frequency is considered for measuring the proneness of a block to the cyclone. The level of vulnerability is determined using social and economic parameters. The exposure component is a combination of physical susceptibility and response infrastructure of an area. The spatial pattern of these three components is mapped on the GIS platform to understand the distribution of risk. The proposed approach will help emergency managers understand about the disaster impacts and the response needed to counter them. This will also help in the efficient utilization of resources during an evacuation process and will improve the total evacuation time.

Keywords: Disasters, Evacuation zoning, Risk assessment

1. Introduction

Human developments from their nature of location, activities and other factors are susceptible to natural and man-made disasters. The impacts are generally in the form of capital and human losses. According to the Centre for Research on the Epidemiology of Disasters (CRED) global database, the hydrological, meteorological and geophysical hazards have respectively contributed to the maximum number of disasters across continents in the past decade. The increasing number of Hydro-meteorological (climatological, hydrological and meteorological) disasters are linked to climate change and its related impact. Studies have shown that developed countries generally face high capital losses while the number of victims is more in the case of developing nations. Although the capital losses in the case of developing countries appear to be small in absolute terms as compared to developed countries, they correspond to a significant percentage of their GDP.

An estimate from the global database of CRED between the year 1900 to 2009 shows that the maximum number of disaster events and deaths in India have resulted from Hydro-meteorological hazards. These hazards together contributed to 78.4% of the events and 47.94% of the deaths over the period of 1900-2009 (Government of India, 2011). India is second among the countries with a large share of the population living in low elevation coastal zones (LECZ) and among the top ten countries according to the land area under LECZ exposed to coastal hazards (McGranahan, Balk and Anderson, 2007). Based on scenarios predicted by Neumann et al. (2015), Indian coasts are likely to show rapid population growth in the future, putting it among the countries with the highest population exposed to storm surge following China. The socio-economic condition in developing country like India adds to the vulnerability of the exposed population and amplifies the disaster. This configuration of population equates to the concentration of risk and disaster affecting these areas have compounding impact with a par to the population and infrastructure density of the place. Since urbanization and economic development are unavoidable, disaster mitigation

clearly has an important role in managing the disaster. Identifying and measuring risk and vulnerabilities are essential tasks in mitigating the effect of a disaster. In pre-disaster conditions, these assessments help in communicating and managing disaster operations and after disaster these help in the reconstruction process (Joern Birkmann, 2007).
Studies related to risk mapping of threat from cyclones in India generate risk profiles of area based on hazard characteristics and physical characteristics of place. Currently, zoning for evacuation during cyclones is based on personal judgment to some degree. The risk maps are used for ordering evacuation without defining manageable zones corresponding to the risk-levels, thus leading to inefficient utilization of resources. Such ad hoc planning of evacuation hinders estimation of priorities during an evacuation and results in unsuccessful evacuation from high-risk areas.
The purpose of this study is to develop block level indicators to prioritize evacuation based on exposure, vulnerability and coping capacity of communities. Local level analysis of vulnerability has not been attempted in this study. The study looks into factors which lead to the spatial variability of the risk of communities in coastal areas. The damaging agents of the cyclonic storm are considered for identifying the type of threats they impose on settlements in the coastal region. It also focuses on the socio-economic condition which adds to the vulnerability of the exposed population and amplifies the disaster in developing countries like India, Philippines. The study is based on block level analysis of a district highly vulnerable to cyclones in the east coast of India. It attempts to identify the risk levels of different blocks in a hazard (cyclone) prone area by considering factors related to hazard, vulnerability and exposure of population in an area to map risk. The hazard component is studied using the historical data on cyclones. The difference in exposure and socio-economic vulnerability gives the variability in block level impacts. The spatial variability of risk at the block level is demonstrated on the GIS platform.
In the first section, the existing body of work on the components of risk and its dimensions like hazard, exposure, vulnerability etc. have been reviewed. It is followed by a brief explanation of concepts of these dimensions from the previous studies. The list of indicators is finalized from the existing literature. The next section of the paper gives a broad framework for the valuation of these indicators into a risk index. Furthermore, the framework is implemented in the study area and the results are discussed in the next section. The implications of the study are discussed in the final section.

2. Literature review

The familiarity of systems, that interact to produce a disaster, is necessary for any disaster-related study. The system characteristic influences the level of impact, suitable responses and recovery period in a disaster. Some study considers disaster to be the result of interaction between the following three systems: the hazard system, the geophysical system and the social system (Chakraborty, Tobin, & Montz, 2005). The hazard system looks at the characteristics of a hazard over space and time. The Geophysical and social systems are occasionally combined together to give place-based vulnerability as described in the hazard of place model (Susan L Cutter, 1996). The exposure, susceptibility and coping capacity of communities vary over space and time depending on the characteristics of their geophysical and social systems. The social system differs from location to location and is modified by changes brought over time in subsystems, like economic, political and institutional. The weaknesses in any of these systems can lead to enormous loss of human life and damage to property.

2.1 Theoretical concepts: Risk, Hazard, Exposure and Vulnerability

Risk as a theoretical concept that does not have an established universal definition. Risk of an area depends on its exposure to hazard and vulnerability of the elements exposed. It has always been estimated based on functions built on components like the probability of a hazard, vulnerability, exposure, coping capacity, resilience etc. The risk is conceptualized in many ways mainly as a function of hazard and vulnerability (ISDR,2004) with its other dimensions like elements at risk (Alexander, 2000), Deficiencies in Preparedness (Villagran,2001), exposure (Dilley et al; 2005), exposure and coping capacity (Hahn, 2003). Risk of a place increases with simultaneous increase in the severity of the hazard and increased vulnerability. Combination of these hazard and vulnerability characteristic gives distinct risk profile of a region over different points in time and spatial distribution of risk across regions. The importance of risk mapping lies in the function that it serves while estimating the level of risk and evacuee population from a zone. The higher the risk level of a zone, the more population is likely to evacuate from that zone.

For the purpose of this study the definition of risk given by UNISDR (2015) is adopted which considers the risk to be "a function of hazard, exposure and vulnerability. It is normally expressed as a probability of loss of life, injury or destroyed or damaged assets which could occur to a system, society or a community in a specific period of time".

Hazard

Hazard is a phenomenon that has the potential to cause severe adverse effects and can either result in emergency, disaster or catastrophe. Hazards involve more complex patterns of onset (instantaneous or slow), frequency (frequent and infrequent) and impact (small-scale and large scale), and can last for months, years or intermittently even for centuries.

The hazard potential is either moderated or enhanced by the place-based vulnerability i.e. interaction of biophysical and social configuration of a place (Susan L Cutter, Boruff, & Shirley, 2003). In order to quantify hazard, each magnitude is tied to a specific return period or its inverse, frequency. The magnitude-frequency relationship of a particular hazard is locality or region-specific (Thywissen, 2006).

Exposure

Exposure is one of the preconditions for a disaster other than vulnerability and hazard. Exposure is a measure of the number of physical units (Number of households, number of health and education facilities, livestock, length of road, the extent of irrigated agricultural areas, the number and capacity of electricity, water supply and sanitation systems, etc) that can get affected by a hazard. Exposure of an inhabited place is also dynamic and is based on the demographics of that place over time. Exposure is considered as a component in defining vulnerability as given by Jörn Birkmann & Wisner (2006). Exposure is defined as elements (People, property, systems, or functions) at risk of loss that are exposed to a hazard (UNISDR, 2004). While exposure is also used to include the characteristic of the hazardous process ('biophysical vulnerability) (S. Cutter, Mitchell, & Scott, 2000). Exposure has been used as an indicator of the spatiotemporal distribution of an 'element at risk', rather than 'just' an account of what is potentially harmed by natural hazards (Hollenstein, 2005). This comprehension of exposure does not imply an influence on vulnerability as such but represents an additional component of risk. The elements, which do not fall, in the region of hazard impact area, have zero exposure for that particular hazard. Measures of exposure can include the number of people or types of assets in an area. These can be combined with the specific vulnerability of the exposed elements to any particular hazard to estimate the quantitative risks associated with that hazard in the area of interest.

Vulnerability

The vulnerability is a function of exposure (who or what is at risk) and sensitivity of a system (the degree to which people and places can be harmed) (Adger, 2006; Susan L Cutter, 1996) along with the coping capacity of the affected entities (Joern Birkmann, 2007).

The complexity of vulnerability is not only given by its multiple dimensions but also by the fact that it is site-specific and that its parameters change with geographic scale. The parameters that determine vulnerability are different on the household, community, and country level. Vulnerability is a dynamic process, but for measurement, purposes are often viewed as static phenomena (Susan L. Cutter et al., 2008). While Kelman (2007) suggests that for a more comprehensive understanding and analysis of vulnerability one should also consider that vulnerability is qualitative, subjective, proportional and contextual. Although the theory is important in defining and understanding the concepts clearly, the data-driven approach is

mostly used in making policy decisions. The need for identifying and assessing vulnerability has been emphasized in international declarations (The Hyogo framework for action; Jörn Birkmann & Wisner, 2006). It can be operationally defined by providing a method for mapping theoretical concepts to operational concepts. The process of providing operational definition to vulnerability concept is generally called as a methodology for vulnerability assessment (Hinkel, 2011).
The UNISDR (2009) terminology for vulnerability i.e. "the characteristics and circumstances of a community, system or asset that make it susceptible to the damaging effects of a hazard" are followed in this study.

Researchers have considered various criteria's for establishing evacuation zones. A notable work which attempted to establish criteria and procedure for determining the delineated hurricane evacuation zone was done by C. Wilmot & Meduri (2005). Few works following this have been carried out for delineating evacuation zones by considering only the hazard characteristics and zone formation criteria, but they did not cover the social and economic dimensions which generate varying evacuation demand during disasters (Hsu and Peeta,2014; Lim et al.2016). Studies defining a method based on social vulnerability to identify the population that would need evacuation during a disaster are fewer in number. Chakraborty et al. (2005) provide one such method for calculating evacuation assistance need index by combining the geophysical risk and social vulnerability indices. This study attempts to assess the differential risk faced by blocks during the tropical cyclone and thereby defining the appropriate evacuation zones.

2.2 Indicators for measuring spatial variability of risk for evacuation need assistance

Disaster vulnerability is socially constructed i.e. it arises out of the social and economic circumstances of everyday living. Morrow (1999) identifies that certain categories of people such as the poor, the elderly, women-headed households and recent residents, are at greater risk throughout the disaster response process. Identifying the concentration of these vulnerable communities can be useful for effective response during disasters(Morrow, 1999).
A list of indicators for the estimation of geophysical, social vulnerability and economic vulnerability have been identified from the literature review and are discussed under following components
The initial list of parameters identified for measuring vulnerability is categorized into five components: social, economic, housing, physical and response capacity. Studies have shown that the young children and the old people have higher risk of death than the rest of the population (equal among genders). People other than children and old, it is observed that the female population is at higher risk of mortality than men. One of the key risk factors found for high mortality of women was their inability to swim. The proximity to the sea is also found to be a very significant factor for contribution to the risk of mortality People living with mental or physical disabilities are less able to respond effectively to disasters and require additional assistance in preparing for and recovering from disasters (McGuire et al. 2007). Emergency managers need to target areas with high concentrations of disabled people, particularly in group-living quarters, for early evacuation and other preparatory measures (Morrow 2008)
Social inequities and limited availability and unequal distribution of resources make people vulnerable to disasters. Some social aspects of vulnerability are beyond quantification (Jörn Birkmann & Wisner, 2006).

The residential units with semi-permanent or temporary construction type are highly vulnerable. Temporary houses in coastal areas lying outside the evacuation zones are also vulnerable to events like overturning in strong wind, windblown objects and falling trees can penetrate their exteriors (Baker, 1991). The response infrastructure includes parameters like proximity to medical services, proximity to transport infrastructure, the density of road network, coastal defense structures (natural and artificial) and availability of cyclone shelter, unavailability of these response systems can lead to loss of life (Cutter, Boruff, & Shirley, 2003).

	Parameters / factors	Indicators	Description	Source
Social / Demographic	**Population Density**	Persons per sq.km	Population density is measured in a number of persons living in per square kilometre of a zone. Higher the population density of a zone, more traffic will be generated from that zone.	Turner et al 2003a; Chandra Sekhar Bahinipati 2014;S Maiti,2015;M mahapatra 2017
	Female population	Percentage of Female Population	Women are considered more vulnerable than men at the time of disasters and during the recovery period	Cutter, Boruff, & Shirley, 2003
	Children	Percentage of children(<6 years)	Extremes of the age spectrum affect the movement out of harm's way, Need more care during the evacuation process	Cutter, Boruff, & Shirley, 2003; Mazumdar & Paul, 2016
	Old People	Percentage of Old People(>60years)		
	Special Needs Population (Institutional HH+ Houseless)	Percentage of Special Needs Population	Special needs populations will require mobility assistance for evacuation.	Chakraborty et al., 2005 , Mazumdar & Paul, 2016
	Demographic Pressure	Population Growth Rate (decadal growth rate)	Rapid population growth would create demand for more shelters, social services network and often results in unpredictable demand of relief supplies during disasters	Cardona, IDEA (2005), Bollin and Hidajat, 2006
	Disabled	Percentage of disabled Population	They need special care as they face constraints in terms of information gathering and mobility during the evacuation	Cutter, Boruff, & Shirley, 2003;Mazumdar & Paul, 2016
	Literacy rate	Percentage of illiterate Population	Literacy level influences the ability to understand warning and information related to evacuation measures.	Cutter, Boruff, & Shirley, 2003;Mazumdar & Paul, 2016
	Poverty Level	Percentage of people below the poverty level	Households below the poverty line are more vulnerable	Bollin and Hidajat, 2006
Economic / Access to resources	**Vehicle Ownership**	Percentage of Households having a vehicle	Vehicles help in mobilization during evacuation and recovery. In absence of any vehicle, families may have to travel by foot or public transport to reach the nearest shelter	Mazumdar & Paul, 2016, Devendra K. Yadav and Akhilesh Barve (2017)
	Information devices	Percentage of houses with television, radio, mobile phone	These devices act as a source of information on hazard conditions, warnings, evacuation notice and guidance.	Joerin et al. 2012;Mazumdar & Paul, 2016
Location / Physical	**Elevation**	Percentage of low lying area	Low lying areas are susceptible to inundation	R. Prerna et.al 2014, Arun Kumar 2012, S das 2012, Jana 2016, Parthasarathy and natesan 2015
	Land use/Land cover	Percentage of built-up area in a zone	Type of activity in a zone will give the size of the population present in a zone at a particular time.	V Poompavai , 2013,R. Prerna et.al 2014
	Proximity to cyclone track	Distance from cyclone track	The distance from the path of the cyclone is an indicator of the level of risk. More the distance from the centre of the cyclone the safer is a zone.	V Poompavai, 2013
	Proximity to landfall	Distance from landfall (Surge)	The distance from landfall decides the impact of the surge in an area. If the zones are away from the landfall point they will receive relatively less damage	V Poompavai, 2013
	Proximity to sea/coast	Distance from coast	The effect of damaging agents on houses and assets decreases with increasing distances from the coast	V Poompavai, 2013

	Proximity to the major river	Distance from a major river	Major rivers have large carrying capacity, carry away surge water and help in reducing the surge velocity to flooding. Nearness to the major river should reduce death	S das, 2012
	Proximity to the minor river	Distance from a minor river	Minor rivers get inflated and bring in more water to interior areas during the storm surge and can cause more death in nearby areas	S das, 2012
	Hazardous facilities (factories, power plants)	Distance from a hazardous facility	Households living near hazardous facility are vulnerable to the damage from the breakdown of these facilities	
	Distribution (Built Density)	Number of Households per sq.km of a zone	Evacuation demand depends on the number of HH in an area.	Chakraborty et al. 2005
	Critical road connections	No of bridges and culverts	The failure of these elements can lead to a loss in evacuation route for the people in risk zones and will increase the pressure of re-routing and management on managers	
Housing Condition	**Construction Material or type of Dwelling**	Percentage of Semi Pucca Houses	Pucca house can resist high-speed winds during cyclones while thatched/mud houses are less resilient to cyclones	Devendra K. Yadav and Akhilesh Barve (2017)
		Percentage of Kutcha Houses		Cutter, Boruff, & Shirley, 2003; Mazumdar & Paul, 2016
	The condition of the dwelling unit	Percentage of dilapidated units	The condition of a structure decides its resilience to disaster. Weak structure are prone to damage from cyclones	Cutter, Boruff, & Shirley, 2003
Response capacity	**Medical Services**	Number of Healthcare Centres	The lack of proximity to medical services effects immediate relief and longer-term recovery from disasters. Delay in medical attention may lead to an increase in fatalities	Cutter, Boruff, & Shirley, 2003, Devendra K. Yadav and Akhilesh Barve (2017)
	Transport Infrastructure	Distance to a paved road	Inadequate transportation infrastructure leads to difficulties in access to evacuation route and relief supply resources	Cutter, Boruff, & Shirley, 2003, D K. Yadav and A Barve (2017)
	Road Network	Road density per sq.km	The road density shows the level of accessibility to the population of that area. Higher road density provides more alternatives to people during the evacuation.	Upasna Sharma and Anand Patwardhan(2008)
	Coastal defense structures (natural and artificial)	Length or density of coastal defense structures (Mangrove(sq.km), Sand Dunes(km), length of rocky coast(km))	Coastal defense structure reduces the impact of the cyclone by acting as barriers against strong winds, flood water and decreasing the energy of storm surge when they pass through the defenses.	Cutter 2008,M Mahapatra et.al 2017
	Cyclone shelters	Number of cyclone shelters	Availability of shelters in the local area will reduce the travel distance and distributed demand	Devendra K. Yadav and Akhilesh Barve (2017)

3. Study Area

India has 7,516 km long coastline, close to 5,700 km is prone to cyclones and tsunamis. Approximately 250 million people lived along the coastline in India in the year 2010. The Indian coast is subject to severe weather events, such as cyclones and super-cyclones at an average of nine cyclones per year (ICZMP 2010).

3.1 *Tropical cyclones over the Indian Ocean*

Cyclones form over seven basins worldwide out of which the North Indian Ocean(NIO) basin provides favourable conditions for cyclone landfall over India. The NIO basin is divided into two areas: The Bay of Bengal and The Arabian sea and they receive cyclones averagely in the ratio of 4:1. The breeding season for the storm over NIO are generally pre and post-monsoon period i.e. periods from April to May and October to December are the months during which most of the cyclonic storms occur in the Bay of Bengal(BoB) and Arabian Sea(AS) as shown in Figure 1.

The probability of Genesis and intensification is less in the Arabian sea as compared to the Bay of Bengal due to the relative difference in their Sea surface temperature(SST). The sea surface temperature of AS is about 1-2ºC lower than that of BoB.

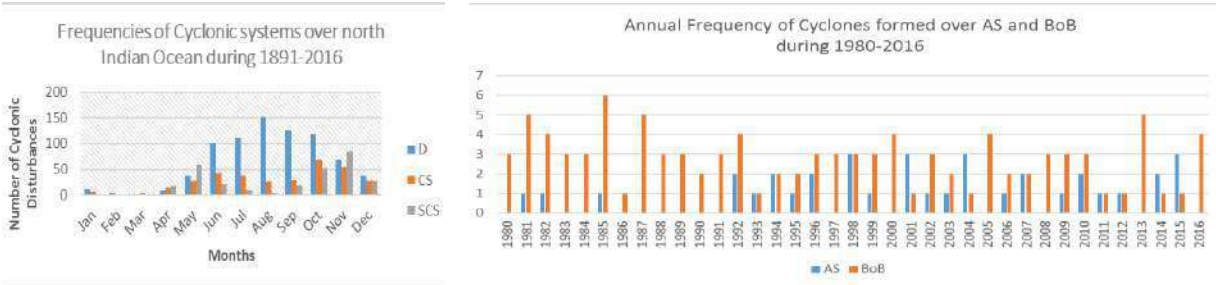

Figure 1: *Frequency of cyclones formed over NIO during 1980-2016*

The effect of cyclone is amplified in the north Indian Ocean (NIO) due to shallow depth of the Bay of Bengal and low flat coastal terrain which produces larger storm surges and takes heavy toll of life (India Meteorological Department, 2013) and the concavity of the bay and its estuaries produce further amplification (Dube et al., 1982).

The study area selected i.e East Medinipur district, it came into existence after bifurcation of erstwhile Midnapur on and from 1.1.2002. The district is located in the southern part of West Bengal adjoining Bay of Bengal. According to the 2011 census, East Medinipur district has a population of 5,094,238 and ranks 20th out of 640 districts in India. The decadal growth rate of the population of the district is 15.36% which is higher when compared to the decadal growth rate of the population of the state i.e.13.9 %.

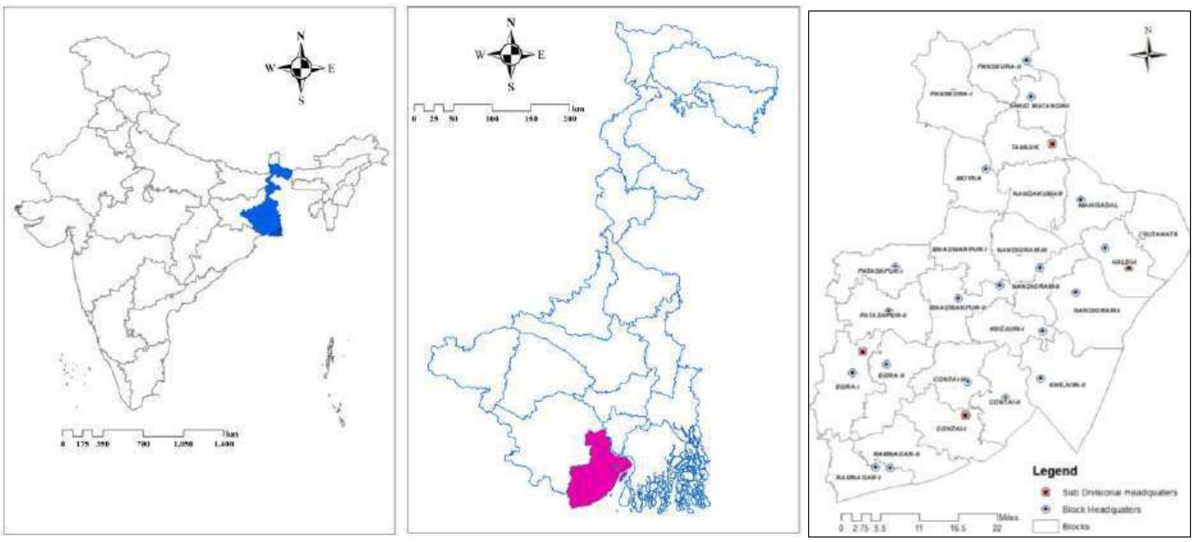

Figure 2: *Study Area*

East-Midnapur district is highly susceptible to floods and cyclones and it falls under 'Very High Damage Risk Zone' according to the vulnerability atlas of India. The major portion of the study area falls under low elevation coastal zone (LECZ). The probable maximum storm surge height in the study area is 12m according to the vulnerability atlas prepared by the Building Materials and Technology Promotion Council (BMPTC), India. The elevation map (see figure 3) prepared using digital elevation model (DEM) image obtained from USGS shows that the Major part of the district falls in low elevation coastal zone (LECZ). In the past, this region has experienced a number of storms which were very destructive and have created tremendous damage. In Last 100 years, 34 Cyclones have occurred over this coast and three of them (1942, 1974 &1976) is in Severe Cyclones list.

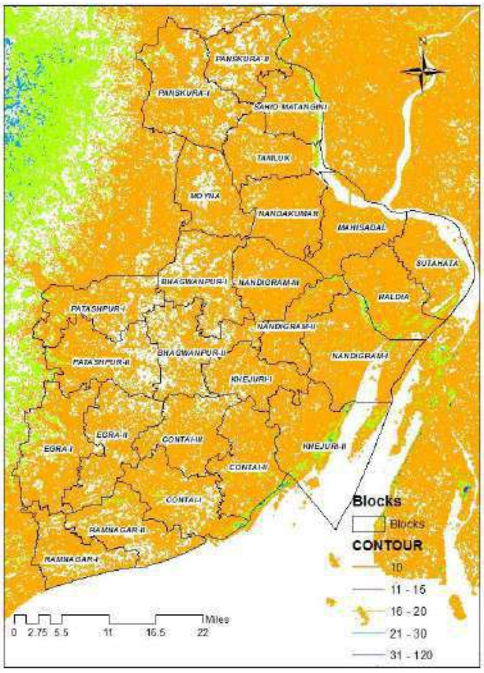

Figure 3: Elevation profile of East Midnapur

3.2 *Data collection*

The data is collected from secondary sources, mainly the source of data is the census of India, 2011, district census handbook district disaster management reports and flood reports. The data used to describe the current vulnerability of Community Development blocks of East Medinipur district include: *Hazard data*: frequency of cyclones; *Demographic data*: Female Population, Children below 6years, decadal growth rate; *Economic data*: Households owning mobile phones, motorized vehicles; *Housing data*: Number of Temporary and Semi-permanent households; *Physical Location Data:* Proximity to coastline, Flood Prone Area; *Response capacity data*: Population served by medical facilities, transport and communication and pucca roads.

3.3 *Methodology*

Disaster management in India had undergone a first paradigm shift from 'response and relief'' approach to 'prevention, mitigation and preparedness' centric approach. Efforts through 'hazard-vulnerability and environment' centric approach focused on disaster risk reduction strategies in various sectors is seen as a second paradigm shift for a holistic understanding of the vulnerability of communities to hazards.

In India, studies on vulnerability assessment of coastal area have mostly focused on hazard and physical characteristics of the area with some recent analyses accounting for socio-economic characteristics (Das, 2012; Bahinipati, 2014; Maiti et al., 2015; Mazumdar & Paul, 2016; Yadav & Barve, 2017). Although most of these studies compared vulnerability at the district level, few measured it at the block (Yadav & Barve, 2017) and the village level (Das, 2012). The method employed in this study integrates hazard characteristics with the vulnerability characteristics and geophysical(exposure) characteristics to form risk indices at the block level.

Indicators are formed based on a function which maps the theoretical concepts to an operational or observable variable. Based on the number of variables needed to make concepts operational, there can be scalar, composite and vector-valued indicators. However, there are challenges in making theoretical concepts operational like the vague definition of theoretical concepts and how they are combined. The broad steps in the development of vulnerability indicators are to define what is to be indicated, selection of indicating variables and aggregation of the indicating variables(Hinkel, 2011).

Index based study to relate the mortality has been done in the past using vulnerability indicators in climate change and Disaster risk reduction domains (Brooks, Adger, & Kelly, 2005; Chakraborty, Tobin, & Montz, 2005). The index method has been used in several studies in Indian context to assess vulnerability in case of tropical cyclones (Dube, Mazumder, & Das, 2006; Bahinipati, 2014; Yadav & Barve, 2017). Use of Indicators for measuring vulnerability at the local scales has been found appropriate for identifying vulnerable people, communities and regions (Hinkel, 2011).

The hazard component in determining risk considers frequency and probability of hazard in its measure. A set of indicators of exposure, vulnerability and response capacity to adapt to a disaster is derived from the literature using a deductive approach. Indicators used to assess vulnerability in case of the study area is based on ease in availing data from the census or other secondary sources. The effect of an indicator on the index value is important to calculate all the indices on the same scale. For example, indicators taking into account the age of children below 6 years and of the old person above 60 years, the higher number of old person and children will indicate high vulnerability.

3.4 *Index Calculation*

The study assigns equal weight to each indicator since the weight of indicators can change for the different study area(Hinkel, 2011). The indicators considered for analysis follow different dimension, in order to use them in the same function, the data was normalized(Dube, Mazumder and Das, 2006). The indicators or variables have been brought to an increasing scale (0 to 1) i.e the higher value of the variable corresponds to the high level of risk. Depending on the relation of the indicator to the risk index the data was converted into decreasing or increasing form.

$$\textit{Index}\ (X_I) = \frac{X - X_{min}}{X_{max} - X_{min}}$$

X_i = the Index value of ith Block, X is the value of the indicator for ith Block

Following are the indicating variables used for the purpose of this study:

Components	***Parameters***	***Indicator Data***	***Effect***
Exposure	Flood Prone Area	Indicates Low lying Area (1-yes, 0-No)	Increases
	Proximity to sea/coast	Distance from coast	Decreases
Population Structure	Population Density	Persons per sq.km	Increases
	Female population	Percentage of Female Population	Increases
	Children population	Percentage of children(<6 years)	Increases
	Demographic Pressure	Population Growth Rate (decadal growth rate of the population)	Increases
Access to Resources	Vehicle Ownership	Percentage of Households having a motorized vehicle	Decreases
	Information devices	Percentage of houses with mobile phones	Decreases
Housing Condition	Building type	Percentage of Semi Pucca Houses	Increases
		Percentage of Kutcha Houses	Increases
Response Infrastructure	Medical Services	Percentage of population with access to Healthcare	Decreases
	Transportation service	Percentage of population with access to Transportation Services	Decreases
	Transport Infrastructure	Percentage of population with access to paved roads	Decreases

Rather than simply summing the standardized variables, values were averaged yielding aggregate index (Exposure and Vulnerability) normalized between zero and one.

$$F = (X_1+X_2.... +X_n)/n$$

The risk Index is calculated based on the following function:

Risk = Hazard x Exposure x Vulnerability

This study considers the frequency of cyclones in each block over the past for estimating the level of impact faced by a community from a hazard.

Hazard incidence probability of the Blocks

The Probability Density Function for describing cyclone arrivals during a specified period follows the Poisson's Distribution (Dube, Mazumder and Das, 2006).

$$F(\mathbf{x}) = \frac{1}{ARI} * e^{-X/ARI})$$

Intervals between successive arrivals follow Negative Exponential Distribution The distribution of time 'x' between successive arrivals of a random event is given by:

$$\mathbf{AEP} = = (1- e^{-1/ARI})$$

***ARI** = Annual Reoccurrence interval, **AEP**= Annual Exceedance Probability*

Hazard Analysis

The cyclones considered for hazard analysis combine both severe cyclonic storm and cyclonic storm data from 1890-2013.

Block	ARI	AEP	Block	ARI	AEP
Panskura	61.5	1.61	Haldia	0	0.00
olaghat	61.5	1.61	Nandigram - I	20.5	4.76
Tamluk	30.75	3.20	Nandigram - II	20.5	4.76
Sahid Matangini	0	0.00	Khejuri - I	61.50	1.61
Nanda Kumar	24.6	3.98	Khejuri - II	30.75	3.20
Mahisadal	41	2.41	Contai - I	17.57	5.53
Moyna	123	0.81	Deshopran	15.38	6.30
Potashpur - I	13.67	7.06	Contai - III	13.67	7.06
Potashpur - II	11.18	8.55	Egra - I	13.67	7.06
Bhagawanpur - II	20.50	4.76	Egra - II	10.25	9.30
Bhagawanpur - I	30.75	3.20	Ramnagar - I	15.38	6.30
Chandipur	30.75	3.20	Ramnagar - II	11.18	8.55
Sutahata	24.6	3.98			

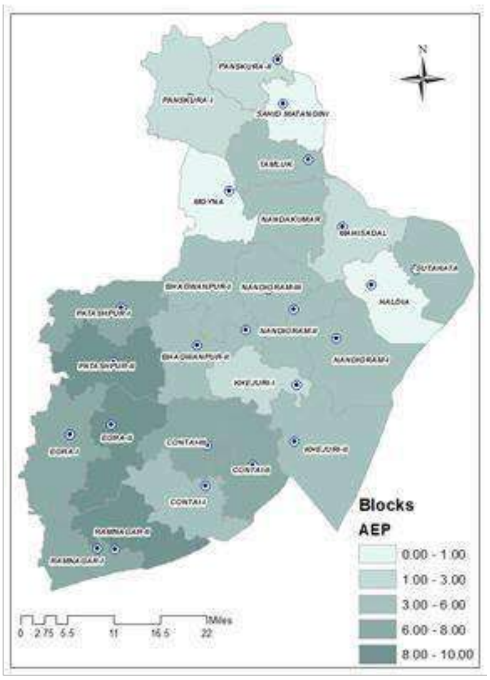

Figure 4: Annual Exceedance Probability of Cyclones

4. Results

The risk index showed that the blocks which had higher number of cyclones passing through them, thus more Annual Exceedance Probability (AEP), face high level of risk. The result shows that the blocks Ramnagar-II, Egra-II and Potashpur-II are at very high risk. Ramnagar-II and Egra-II are at high risk largely due to their exposure while Potashpur-II block ranks second highest in vulnerability. The blocks under high risk are Contai – I, Potashpur – I, Deshopran, Egra – I and Contai – III. Haldia and Shahid Matangini ranked lowest as no cyclones have crossed over these blocks in the past. They had the least probability of receiving a tropical cyclones and are relatively protected from danger.

As risk index mainly presents those blocks as high-risk areas which have had a high occurrence of cyclones in past, thus it is important to compare the exposure and vulnerability of population in a block while preparing for cyclones and for identifying a population that needs to be evacuated in a future hazard. The impact highly depends on the level of exposure and the vulnerability of population exposed.

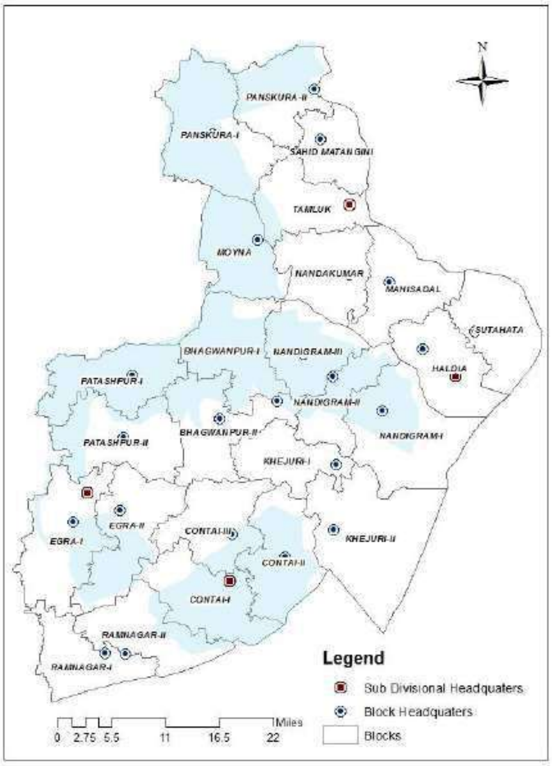

Figure 5: Flood-Prone Areas

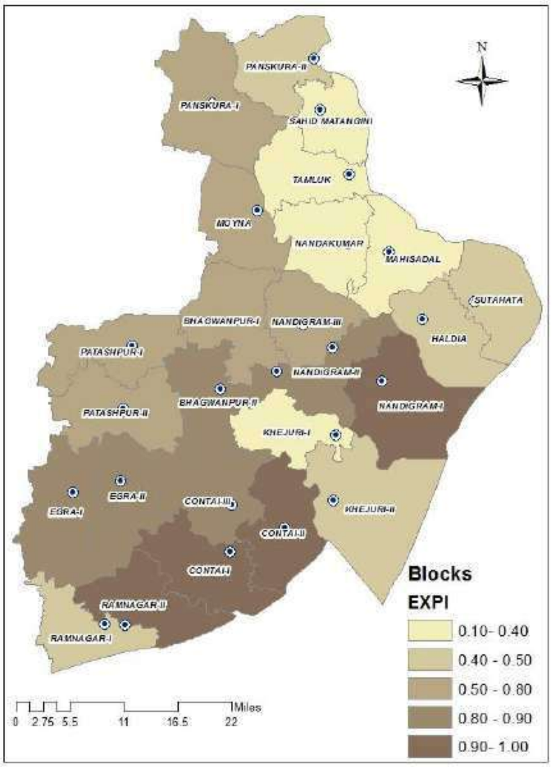

Figure 6: Exposure Index

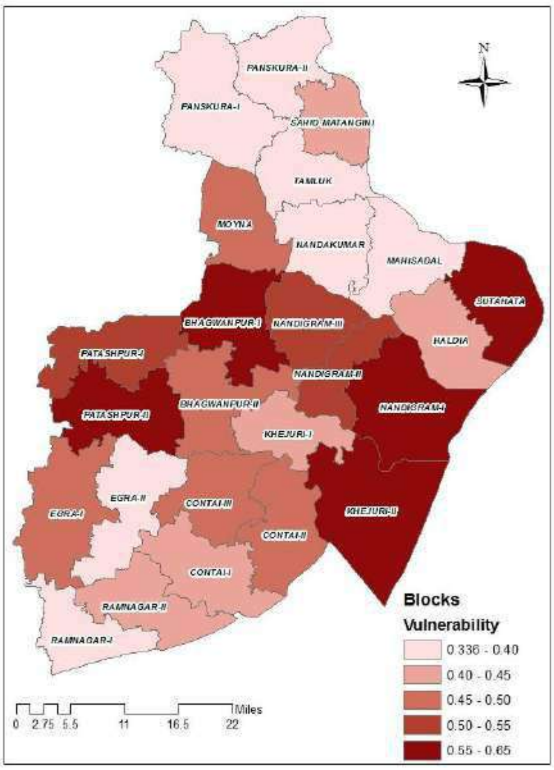

Figure 7: Vulnerability Index

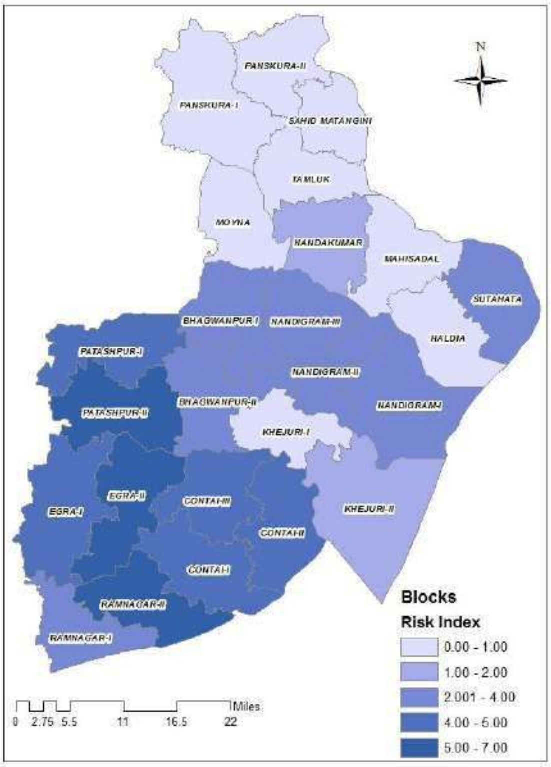

Figure 8: Risk Index

This analysis indicates that reduction in mortality can be achieved by addressing factors of the vulnerability of communities in highly exposed areas. The more complex processes that lead to high mortality can be better understood by examining the local level risks using given indicators.

5. Conclusion

The selected indicators cover dimensions like exposure, vulnerability and response capacities to identify the relative risk of development blocks. It will help us understand how the risks are distributed over geographical space and how it changes over time. In long run, it will help us identify the important factors which are responsible for these changes. These factors could be a good measure to check the effectiveness of the implementation of programs and guiding policies. The level of vulnerability of different blocks will help in decision making in prioritizing the allocation of capital and other resources for pre and post-disaster activities.

In case of evacuation during cyclones, origin zones are concentrated in threatened coastal areas and destination zones are spread inland to neighbouring areas and states. The risk identification can probably indicate the area that is risk-free and could accommodate evacuees from risk areas. The method would help in determining evacuation zones and their risk levels for prioritizing block-wise evacuation. The organization of evacuation according to these risk levels will lead to efficient utilization of resources, personnel and improved traffic management.

Mitigating the Effects of Climate Change in Strategic Development: the Ibadan City Masterplan

Yann LECLERCQ, MRTPI, United Kingdom

Abstract

Nigeria's third largest city, Ibadan, is today a bustling centre focused on commerce and markets. Estimated at 6 million in 2017, the city is projected to grow to a population of over 13 million by 2036.

Sprawling urbanisation has resulted in deforestation on the city's outskirts. The resulting decrease in soil permeability has caused an increased rate of water runoff from rainfall, which has affected the city's drainage channels and river system. Coupled with the indiscriminate disposal of waste into the city's river system, bridges and culverts that have been built at too small a capacity, and development of infrastructure that has not kept up with the pace of the city's growth, the result is a city that suffers from regular flooding of increasing intensity.

Upon the initiative of the Oyo State government, the World Bank was brought onboard to support the process to find solutions to resolve the issue of flooding. The outcome was the commissioning of three masterplans to address the issues: a solid waste masterplan, a drainage masterplan, and a land use city masterplan.

Completing the Ibadan City Masterplan in 2018 (the land use city masterplan), Consultant Dar Al-Handasah worked closely with the Oyo State Government throughout the project's progress. An in-depth stakeholder engagement process brought support and knowledge from the local communities, with all responses and comments taken on board in developing the masterplan.

A detailed diagnostic of Ibadan's context was undertaken to form the evidence-base to developing the strategy. The masterplan sets out a policy framework for implementation over the next 20 years. It identifies the direction of growth to accommodate the city's population increase, supported by an adequate provision of infrastructure. It proposes detailed responses on how to address the impact of flooding, including demarcating and protecting flood-prone land from encroachment.

The masterplan is the first city-wide strategic planning framework for Ibadan. If the city is to avoid future potential catastrophic floods and other impacts of a changing climate, it is critical that the masterplan is implemented and delivered.

1 The Rapid Rise of Ibadan

Ibadan (along with Kano and Kumasi (Ghana)) is one of the few major pre-colonial sub-Saharan cities to retain its importance as an urban centre today.

The earliest recording of a settlement in present day Ibadan is an Egba village, which from the 1820s grew because of displaced people from the wider region escaping internal conflict within the Yoruba Empire and exogenous aggression. The location close to the edge of the savannah had the advantage of hills for protection plentiful access to water and good quality agricultural land.

The population later swelled with the arrival of immigrants across what is now western Nigeria. Ibadan grew extensively into a popular hub of commerce and also dominated the political and military scene in Yoruba, filling the vacuum created by the fallen Oyo Empire. People displaced by war saw Ibadan as a sanctuary because of its location, economy and military power.

In 1893, the area became a British Protectorate, by which time the population had grown to 120,000. The city formed the centre for colonial administration of the Western Region, which reinforced the position of the city as a focal point for trade, commerce and fashion. Post-independence Ibadan retained its administrative and political importance as the capital of the Western Region and today as the capital of Oyo state.

Ibadan is defined as the area that includes 11 Local Government Areas, with a land area that covers 3,145.97sqkm. As of 2017, 546sqkm comprises the Ibadan built up area (17.4%) with a further 164.78sqkm of built development within the rural part of Ibadan. The undeveloped area (agricultural land, forests, and open space) totals 2,435sqkm (74.5%).

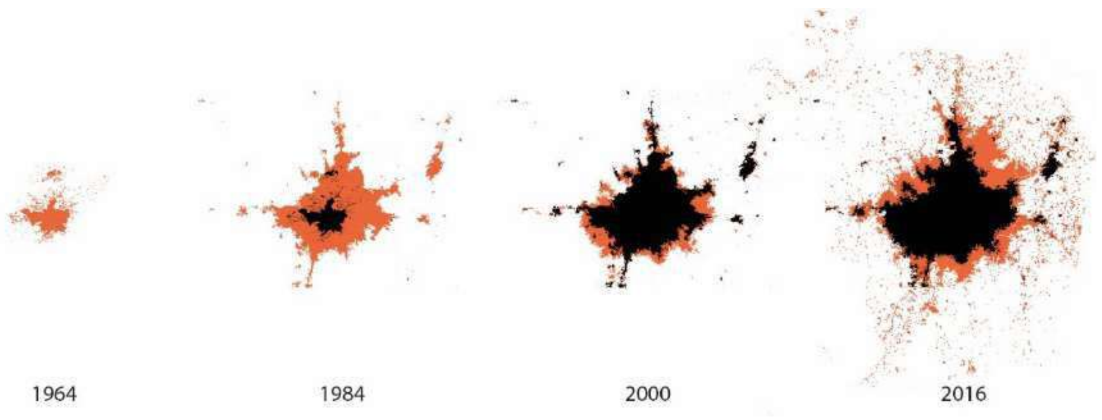

Figure 1.1 Growth stages for Ibadan 1964-2016

Population and spatial growth have been rapid, with a noticeable slowdown during the years of the IMF-World Bank Structural Adjustment Programme in the 1970s, although it has since grown again and now reaches 3.5% per annum.

Expansion of the built-up area has been driven by an increase in population caused by both in-migration (1.3% per annum) and rapid natural population growth (2.2% per annum) resulting from declining death rates and consistently high birth rates.

Ibadan is a rapidly growing city that continues to expand in all directions. In the absence of any strategic plan or official development management strategy for the city, its expansion is taking place in an ad-hoc organic manner.

2 The Effects of Climate Change

Ibadan has a distinctive wet season which starts around the third week of March and ends around mid-October. The rainiest month is June when the average rainfall reaches about 200.6 mm. Average rainfall reaches around 1,340 mm annually.

A major impact of sprawl is loss of forest cover, which means that when it rains, the ability for the water to seep naturally into the ground is decreased. Vegetated cover has better retention abilities.

Decreased forest cover also means there is less time for moisture to be absorbed into the atmosphere, which creates an imbalance of CO_2.

The greater the expanse of urban areas, the greater the volumes of water build up on the ground. Greater volumes subsequently flow at an increased velocity. The drainage system that has developed naturally over time is inevitably affected: greater volumes of water flowing at faster rates have an impact on the profile of the rivers, which erode and therefore change the landscape. This has inevitable consequences as the volumes of water affect the existing built-up areas of the city further downstream. There is increasing evidence of this happening as damage to historic buildings are testament to the severity of flooding impacts.

Figure 2.1 Historic buildings are increasingly at risk of erosion from neighbouring river corridors

It is predicted that the impact of climate change will increase by 1 to 2 days the levels by which extreme rainfall is experienced over most of Nigeria for B1 (low) and A2 (high) emissions scenarios by middle (2046-2065) and late (2081-2100) century. Sudden flood events are therefore increasingly likely to negatively affect Ibadan.

It is worth noting that the river basins that cross the city lie largely within the boundaries of the city region, and the impact of flooding is therefore a localised issue, that can and must also be addressed locally. The topography of the city means that water drains naturally from the higher ground in the north, with water flowing south through the built-up areas of the city. Downpours regularly result in sudden swelling of the rivers, which the majority of the time only contain small flow levels.

The incidence of flooding in Ibadan is not new. Floods have been recorded over many decades. However, as the city grows, and as the pressures on the city increase, the volumes and intensity of the water inevitably has impacts that are more widely felt.

Adding further pressures to the established drainage channels is encroachment of informal settlements in the drainage channels and flood plains. This further reduces the space available for drainage, which increases the potential for flooding.

Figure 2.2 The build-up of waste in the river system is an issue in Ibadan

Another critical issue is the indiscriminate disposal of waste across the city. Rivers are traditionally used to dispose of waste as the water pushes it downstream. However, in a city of over 6 million, the impacts of these actions are exacerbated. To date, the refuse collection services have been unable to effectively remedy the issue, and the three existing dumpsites in the city have reached capacity. The character of the city’s traditional Core Areas, with their densely packed buildings, means that many areas are also difficult to access.

The impact of waste disposal in the drainage system is it accumulates and ends up blocking the channels: the bridges and culverts are not built to the capacity needs of the rivers and streams, with waste build-up frequently leading to blockage.

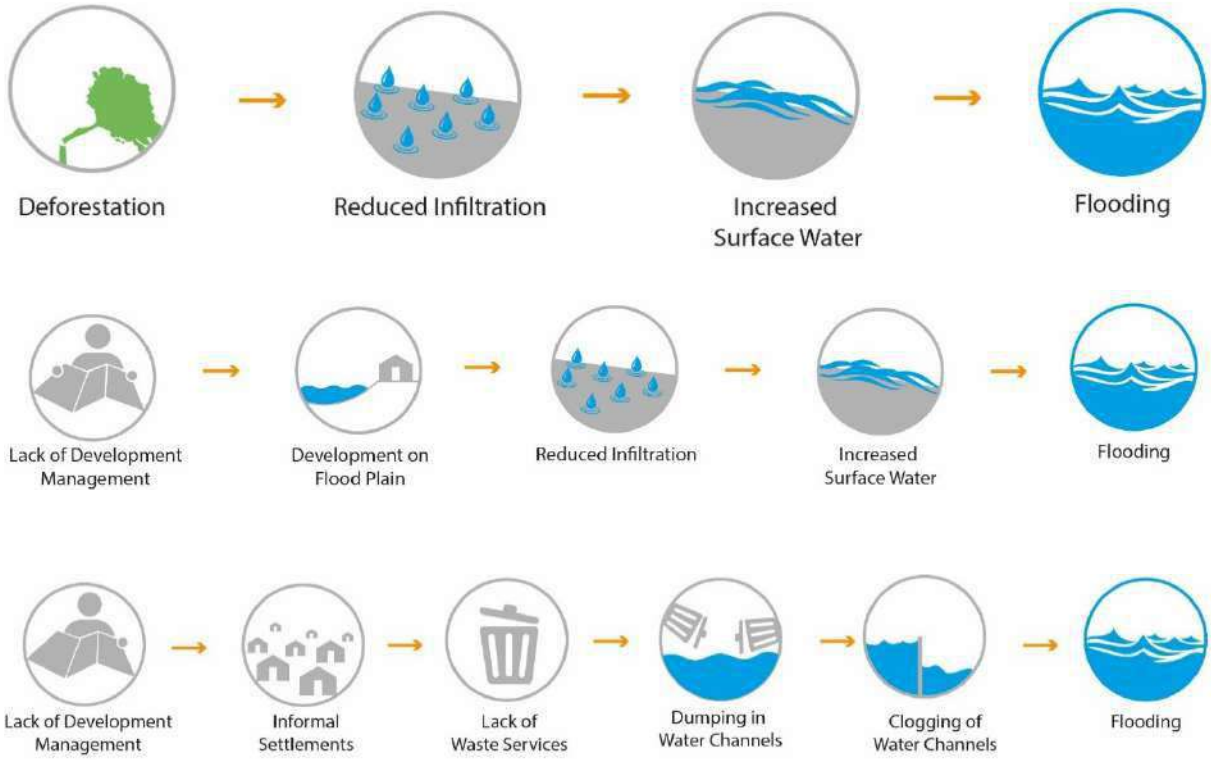

Figure 2.3 The causes of flooding in Ibadan

The absence of a formal spatial planning framework for the city has numerous impacts, together which result in urban stresses. Figure 2.4 illustrates how these factors are interconnected and how many impacts have ongoing repercussions. The longer these issues are left, the more difficult and complex it gets to eventually resolve them.

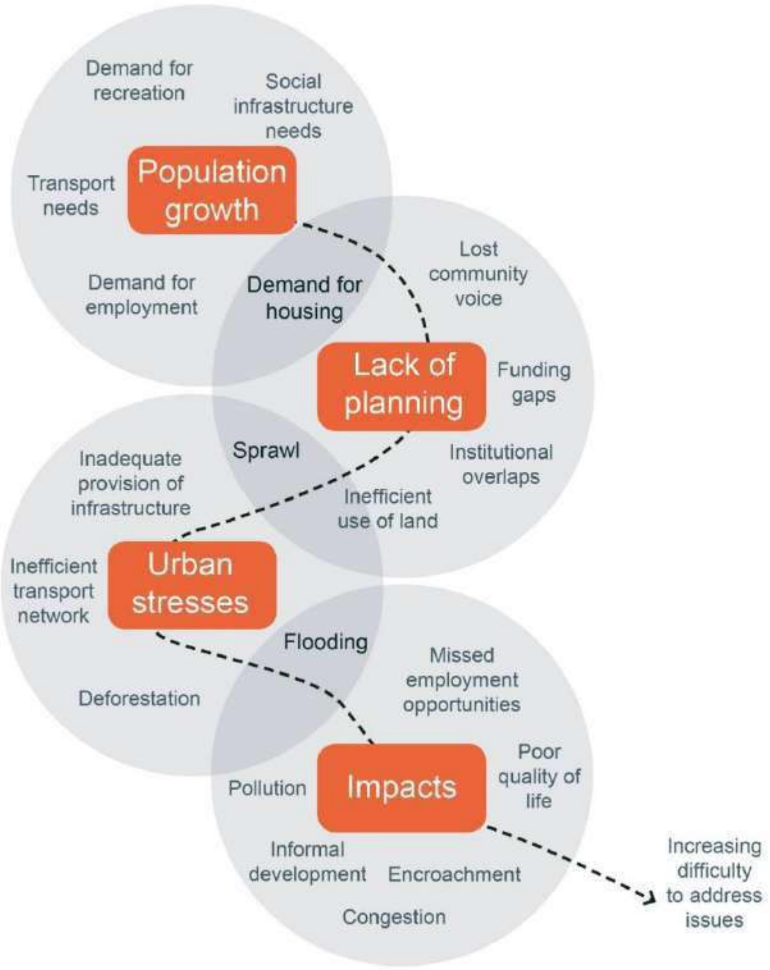

Figure 2.4 The causes of flooding in Ibadan

3 Addressing the Impacts

On the 26th August 2011 a rainfall downpour of 187.5 mm occurred in about 4-5 hours and resulted in the overflow of the Eleyele reservoir. The event resulted in the death of more than 120 people and inflicted serious damage to infrastructure (many bridges collapsed, roads were washed away, and substantial property was damaged).

This event was the trigger to the decision that something had to be done to address the issue. Assistance was sought from the World Bank to identify solutions to the problems. The first result was the establishment of the Ibadan Urban Flood Management Project (IUFMP), a task force on flood prevention and management "*to improve the capacity of Oyo State to effectively manage flood risk in the city of Ibadan*". The outcome was a report containing short, medium and long term recommendations to the state government, which identified the need to prepare three masterplans for the city:

- Ibadan City Masterplan (this project)
- Solid Waste Masterplan
- Drainage Masterplan

The Ibadan City Masterplan is the first strategic city-wide masterplan for Ibadan: it provides a policy-based framework that guides the future direction of growth of the city. These policies give the Government a set of actions that ensure they put forward a coordinated strategy for the implementation of the masterplan.

The Ibadan City Masterplan incorporates policy to address:

- Drainage
- Land use planning
- Tranportation, including walking, cycling mass transit, public transport, roads and rail
- Residential density distribution
- Distribution of social infrastructure
- Culture, heritage and tourism
- Economic development
- Utility infrastructure

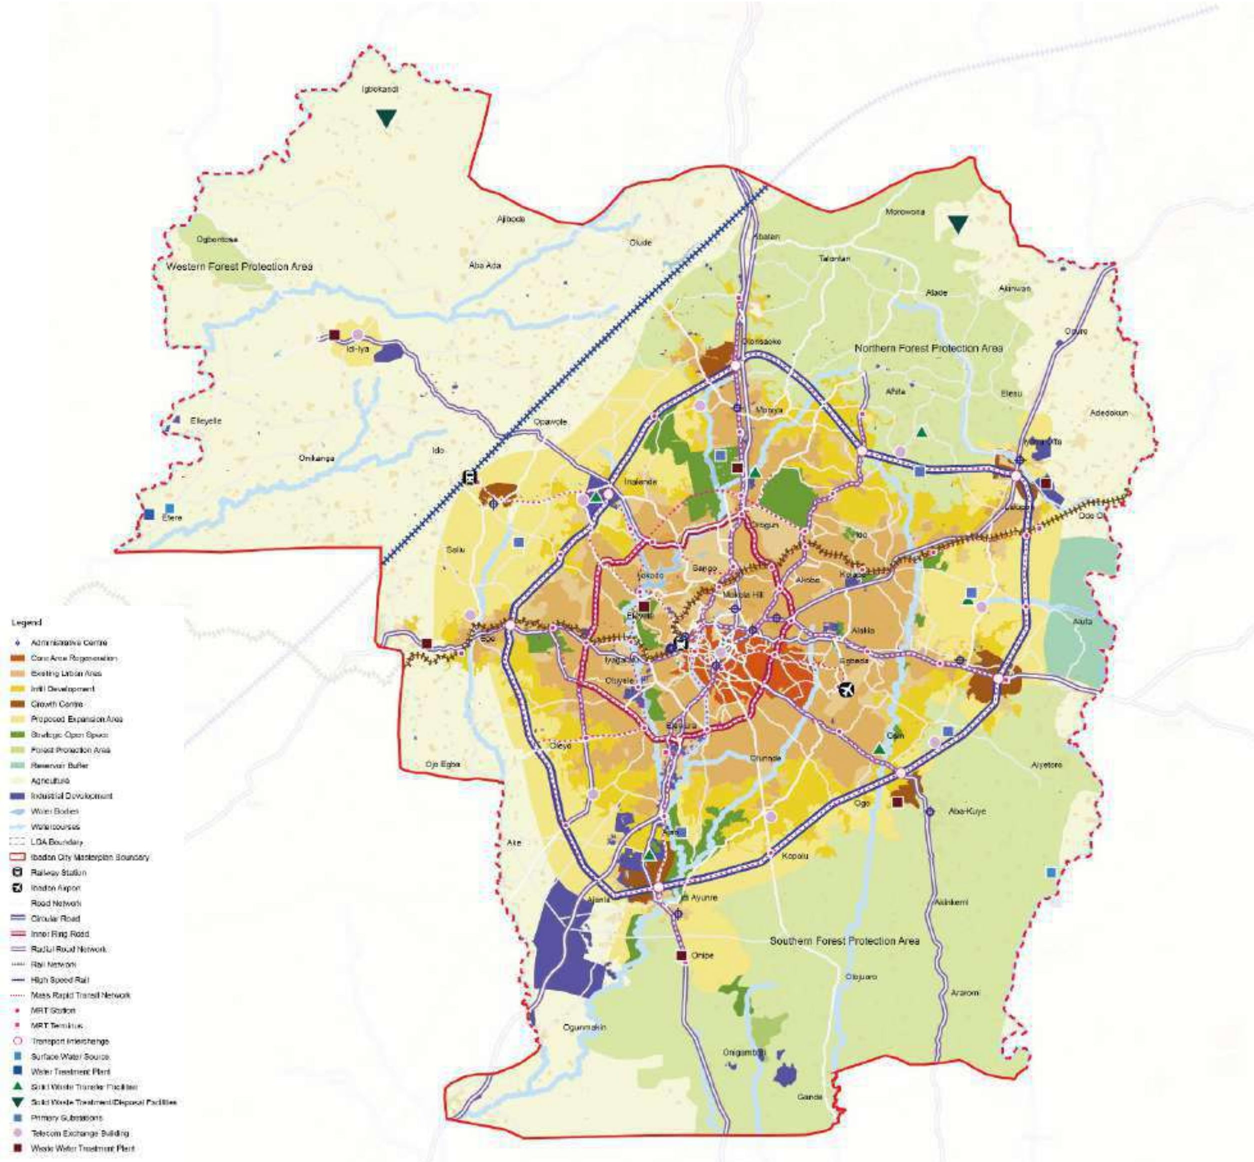

Figure 3.1 The Ibadan City Masterplan Key Diagram

The lack of a strategic plan for the city has been recognised as an impediment to the managed and safe growth of Ibadan. In effect, the masterplan provides a strategy to ensure Ibadan is resilient and prepared against future shocks.

Once completed, the three masterplans will provide a comprehensive set of plans to addressing the needs of the city over the next 20 years.

4 Finding Solutions

Typical of work undertaken in a context such as that of Nigeria, there was initially very little relevant or up to date data that could be relied upon. A mapping base therefore had to be initiated from basics, supported by gathering data, but also through field surveys. With the aid of GIS, a comprehensive mapping base covering the whole of the Ibadan area was created.

One of the first assessments was to identify across all of Ibadan's urban areas the extent of the areas prone to flooding. Every river and stream was surveyed and assessed. Each was classified over its potential flooding impact, to which standard set-backs were recommended, as shown in Table 4.1.

Table 4.1 Proposed Setbacks for Rivers and Streams

	DRAINAGE CATEGORY AND CATCHMENT AREA COVERAGE	PROPOSED RIVER CORRIDOR WIDTH	SETBACK FROM RIVER'S CENTERLINE	EXAMPLES OF RIVERS
1	Major River (50km^2)	120m to 200m according to analysis. Refer to flood corridor map shown in Appendix 3	60m to 100m	Ona, Omi, Iddo
2	Minor River (25km^2)	100m	50m	Alapata, Alaro, Ogunpa, Kudeti, Ogbere
3	Major Branch (5km^2)	80m	40m	
4	Minor Branch (2km^2)	60m	30m	
5	Major Stream (0.5km^2)	40m	20m	
6	Minor Stream (0.1km^2)	20m	10m	

This provided a picture of the annual, 10 year and 100 year potential for flooding. While this was only an initial assessment at first, it did highlight the established urban areas that were at greatest risk of experiencing flooding.

The results offered the opportunity to classify the river banks into several categories according to the degree with which they could be affected, and recommend solutions to how they could be used. The resulting varying widths identified were also an opportunity to mark out different levels of acceptable uses, as illustrated in Figure 4.1.

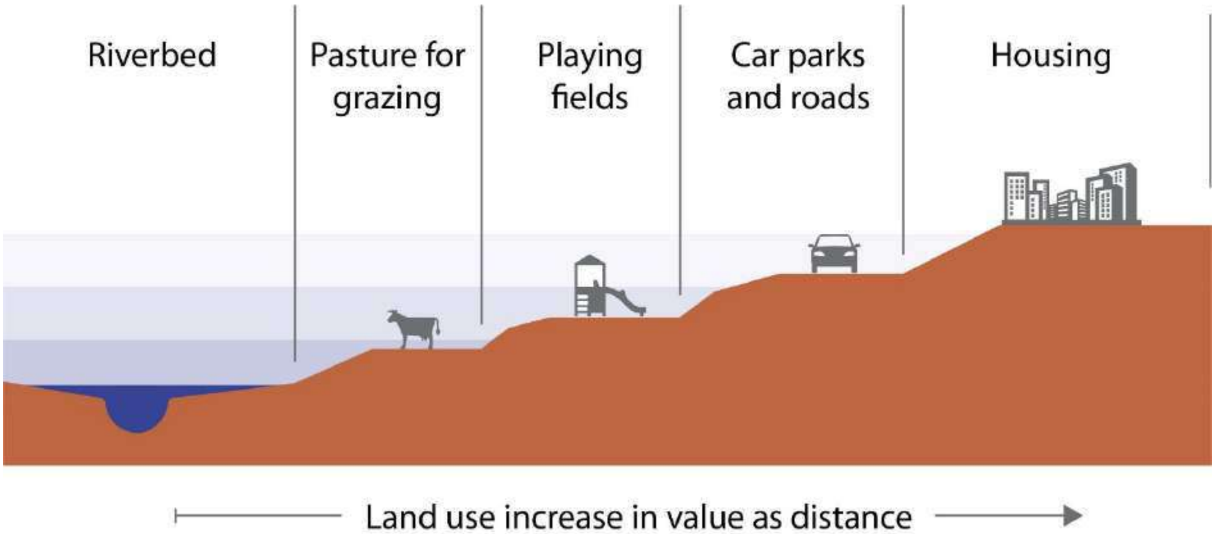

Figure 4.1 Floodplain Land Use Concept

A key aspect is about ensuring that encroachment into the flood prone areas does not reoccur. Finding solutions and getting communities to take ownership of the river corridors is critical to ensuring there is no urban development returning to these areas. This is about getting communities to recognise the areas as community assets.

Urban development is to be avoided within all areas identified as prone to flooding. In order to ensure this does not happen, alternative uses are therefore proposed. This includes the following:

- Urban agriculture, where local communities can use the river banks to grow crops, which is key to diversifying urban diets and providing local food security;
- Parks, providing accessible green space to local communities such as for sports facilities;
- Public open spaces, such as squares or markets;
- Channelisation – this enables the protection of established urban areas, minimising the needs for removal – only in exceptional circumstances is removal recommended.

One critical aspect to preventing future flood events is through the protection and preservation of the existing forest cover, in particular that in the north as it has the role of absorbing and retaining rainwater. Within Ibadan itself, a policy of greening the city through planting trees and shrubs will reduce runoff and therefore flooding, will preserve soil moisture and will reduce the rate of atmospheric warming.

Figure 4.2 One idea is to build public spaces that can flood and absorb overflow water

Figure 4.3 Sports fields are uses that can typically flood without affecting the urban environment

The Ibadan City Masterplan is supported by a Strategic Environmental and Social Assessment (SESA) which assesses the policy framework put forward. It ensures that sound decisions were taken in the establishment of the policies put forward and finally adopted.

5 The Institutional Framework

The masterplans developed for Ibadan are the first to address the city's many challenges in a holistic manner. This new set-up therefore requires a new approach to delivery: who will be responsible for implementing the plans, and how can we ensure that they are well and truly implemented. There are critical concerns that must be addressed so that this is not a plan that sits on the shelf.

The Ibadan City Masterplan therefore put forward an institutional framework strategy.

Three options were put forward for how the masterplan could be delivered – the preference being that the existing mechanisms are retained, but supported by capacity building to ensure that the existing state ministries and departments are well-versed on their own specific tasks in implementing the masterplan.

6 Conclusion

The city of Ibadan is projected to grow in population by 90% over the next 20 years. While it is affected by flooding events on a regular basis, the uncontrolled growth of the city, coupled with potential increases in extreme rainfall events brought about by climate change will mean that the city must address the challenges today.

The first strategic spatial planning framework for the city is a major achievement that provides implementable guidance to direct the future development of Ibadan. There are many issues that need addressing; it is now essential that the Ministries and Departments of Oyo State do not lose the momentum that has now been set and deliver on the proposals in the plan. This will lead to a more prosperous Ibadan in the future.

Evaluation of the impact of the urban morphology on building energy consumption in severe cold region cities-- Take the office building in Harbin, China as an example

Hong LENG, Xi CHEN, Zhe DIAO, Harbin Institute of Technology, School of Architecture; Hei Longjiang Cold Region Urban-Rural Human Settlements Science Key Laboratory, China

1. Introduction

China has been experiencing the world's greatest and most rapid process of urbanization, leading to both the urban population and the building area have been increasing greatly, and the proportion of urban building energy consumption to the gross has been growing consistently as well. As a consequence, this results in the ascending trend of CO_2 emission, and makes the construction of cooler city (i.e. low-carbon city) become more arduous. For people in cold region have to experience a long heating period during winter to overcome the cold weather which causes a heavy heating demand for buildings, with heating energy consumption in China northern cities accounted for 24.1% of the total energy consumption of buildings in 2010 (Zhang Y. 2012), while in Europe, the proportion of heating related energy utilized in residential buildings was approximately 70% of the whole (WBCSD, 2009). And it is natural to believe that the energy consumption must be greater for the severe cold regions with much higher latitudes. Therefore, more challenges of building energy-saving are faced by severe cold region cities.

Cities are the main positions to cope with global climate change (Lindseth, G. 2004). Its form or morphology plays an important role in reducing urban energy consumption (Chen et al.2011; Urquizo, J. et al. 2017), including transportation energy consumption, infrastructure energy consumption and so on (Grazi F et al. 2008), but also daily life living energy consumption, with building energy consumption as one big part (Ishii, S et al. 2010). In order to slow down the fast-growing consumption of energy from buildings, it is especially necessary to figure out the mechanism about how urban morphology impacts building energy consumption performance and then propose energy-saving oriented planning strategies in the process of urban planning. As the initial step to come up with related strategies, studying the relationship between urban morphology and building energy consumption should be carried out urgently in the discipline of urban planning.

Recent studies have shown that the variation of urban morphology (urban form; spatial configuration of cities) could affect building energy consumption directly or indirectly. Examples are: Ratti, et al. (Ratti, et al. 2005) demonstrated that the variance in building energy consumption on urban geometry was a considerable value; research of Wilson B. (Wilson B. 2013) revealed that density and adjacent structures mattered for residential electricity use at the subdivision level; Rode P. et al. (Rode P. et al. 2014) testified that denser and taller building type could contribute to a higher heat-energy efficiency at the neighborhood scale. In terms of indirect impact, Wong N. H. et al. (Wong N. H. et al. 2011) identified that air temperature varied because of different urban morphology which could lead to the building energy consumption variation in Singapore. Similarly, Zhou Y, et al. (Zhou Y, et al. 2017) also proved that the surrounding green space ratio, building density, floor area ratio affected the energy consumption of the building by impacting the intensity and frequency of heat island.

The approaches about the urban morphology factors affecting the building energy consumption has become relatively mature. According to the purpose of research and the situation of data collection, and the existing literature involves different (sometimes linked) approaches including the statistical analysis methods based on historical data (Wilson B. 2013; Tso, G. K. F. at el. 2014; Steadman, P. at el. 2014; Tian, W. at el. 2016) and the numerical simulation methods (Ratti, et al. 2005; Rode P. et al. 2014; Palme, M. et al. 2017; Zhou Y, et al. 2017). However, there are less research about the relationship between urban morphology and building heating energy consumption in winter, especially study referring to heating consumption in severe cold region. And the high resolution or district-based quantitative investigation has been less sufficient as well.

Therefore, the aim of this work is to quantitatively analyze the impact of urban morphology on building heating energy consumption in severe cold region cities, and help put forward corresponding suggestions in carrying out energy efficiently-consuming oriented urban planning.

This paper selects the winter heating energy consumption of sixty-nine sample office buildings in severe cold region City Harbin, China to carry out the research. It starts with proposing the significance of digging out the impact of the urban morphology on building heating energy consumption of winter cold cities in the first section. The second section explains the study area, spatial scale and the methodological approach. In the third section, we present the results in two subsections: results on data statistical analysis of the correlation between building heating energy consumption and six urban morphology indexes, and further analysis on how the urban morphology influences the energy consumption. The forth section is dedicated to the final conclusion and putting forward the possible urban morphological planning strategies for mitigating the heating energy consumption and even gross energy consumption of buildings for cities in severe cold region.

2. Data and Methodology

2.1 Study area and spatial scale

Figure 1: Two Categories of Urban Morphology in Harbin

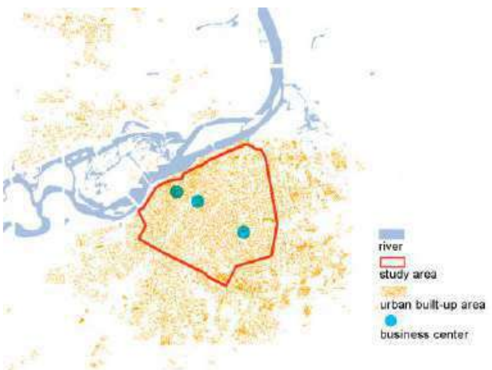

Figure 2: Study Area in Harbin

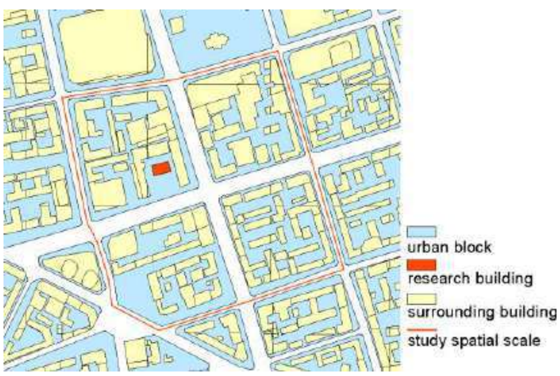

Figure 3: Spatial Scale of Study

2.1.1 Study area: climate and urban morphology characteristics of Harbin

In China, the severe cold region mainly refers to the area where the average temperature of the cold month is less than -10℃, and the average daily temperature is less than 5 ℃ for more than 145 days (GB 50178-93,1993). Harbin is one of the most representative cities in this region with a total 180-day heating period. In terms of morphology, Harbin can be divided into two categories: high construction intensity areas generally with medium and high rise buildings located in three business districts, and low construction intensity areas mainly with 3 to 6-storey buildings located around the three business districts (Figure 1 & 2). This indicates that the urban spatial construction intensity decreases from three commercial or business centers to the periphery of the city. Therefore, in order to ensure the diversity of urban spatial morphology, and according to the geographical location distribution of buildings as well as we can obtain energy consumption data, this study selects the built-up area within the Second Ring Road of Harbin as the study area (Figure 2).

2.1.2 Study spatial scale

For each individual building, this study defines the block where a building located in, and its surrounding blocks as the study spatial scale or scope of investigation (Figure 3) to calculate the urban morphology indexes. Usually, the scale of an urban block in Harbin is from 15000 square meters to 60000 square meters with the corresponding length from 80 meters to 300 meters. Choosing this spatial scale is mainly because urban morphology can indirectly affect building energy consumption by influencing daylighting, microclimate, users' behaviors and other ways, whereas only one block is not enough to influence microclimatic environment and users behaviors. Therefore, this study is supposed to be placed in a larger spatial context within city. Another reason is that urban block, as the basic unit of the city texture, forms a connecting link between the preceding planning conditions of urban planning or zoning to achieve the goals of planning and the following stage of urban design or architecture design to guide the construction, which lead to better implementability and practical significance for regulating the urban morphology.

2.2 Data set

2.2.1 Data of building energy consumption

The energy consumption of office buildings in severe cold regions mainly includes heating, air conditioning, lighting, office equipment and so on. According to the characteristics and statistical system of building energy in Harbin, the energy consumption of office buildings in Harbin is divided into two categories: building heating energy consumption (heating and hot water) and building electricity consumption (air conditioning system electricity, lighting power, office equipment, elevator electricity, other spare power). In this study, we only concentrate on the heating energy consumption which produces the greatest demand in buildings of severe cold region.

69 sample office buildings are selected in this paper as the study objects. In order to ensure that these energy data can reflect the spatial heterogeneity of urban morphology effectively, these buildings we choose are relatively evenly distributed in various positions of Harbin, from downtown to peripheral area, where the characteristics of urban morphology around them are different from each other. The winter heating energy consumption data used in this study comes from 2016-2017 Energy Saving Supervision Platform for Office Buildings and Large Public Buildings of Heilongjiang Province and 2016 Statistical Data of Building Energy Consumption from Harbin Statistical Bureau.

2.1.1 Data of urban morphology

"The urban morphology refers to the spatial configuration of urban land use within an urban area."(Urquizo, J. et al. 2018) And previous study (Ewing, R. et al. 2008) had shown three ways through which urban morphology have effects on buildings, with electric transmission and distribution losses as a direct way, and features of housing stocks, local temperature as two indirect ways. This study concentrates on the indirect ways which are more related to urban planning. Six indexes of urban morphology are calculated to evaluate the impacts on building energy consumption, which are surrounding Building Site Cover (BSC), Floor Area Ratio (FAR), Building Height (BH), Road Network Density (RND), Road Height-width Ratio (RHR) and Open Space Ratio (OSR) according previous studies (Wong N. H. et al. 2011; Rode P. et al. 2014; Zhou Y, et al. 2017).

In this paper, the building data including geographical location, bottom contour of building, building storey, building function, and green space data of Harbin city in GAD map are obtained by Parametric Language Python to establish the urban morphology model in ArcGIS software. based on this model, the urban morphology of each building is calculated quantitatively according to the definition and calculation formula of each index (Table 1).

Table 1: Definition and calculation formula of urban morphology indexes

	Definition	Calculation formula	Diagram of indexes
Building Site Cover (BSC)	The ratio of built ground to that of the sample district area.	BSC=footprint area/sample district area	Floor Area Ratio (FAR)	The ratio of the sum of the areas of all building floors to that of the sample district area	FAR=gross floor area/sample district area	Building Height (BH)	The average height of buildings within the sample district area	BH=[∑(footprint area× height)]/gross footprint area	Road Network Density (RND)	In a certain sample district, the ratio of the sum of the length of road network to the sample district area.	RND=gross length of road/sample district area	Road Height-width Ratio (RHR)	The average ratio of the height of the building on both sides of the road to the width of the road	RHR=[∑length of road (height of road/width of road)]/gross length of road	Open Space Ratio (OSR)	the ratio between the open space area and the gross floor area	OSR=gross green space area/sample district area	
Note: the first two diagrams of indexes referred from literature (Wei, R. at el. 2016)

2.3 Methods

First, the basic energy consumption of each building is calculated by OpenStutio software. On this basis, the measured building energy consumption is split into basic energy consumption (BEC) and external influence energy consumption (EIEC). Finally, the correlation analysis is carried out to analyze the correlation between building heating energy consumption and six urban morphological indexes, and multiple linear regression analysis is applied to identify the key factors of urban morphology affecting the performance of building energy consumption.

2.3.1 Step1: Calculating the basic building energy consumption

The measured energy consumption of a building in a city can be divided into two parts: basic energy consumption (BEC) which is dominated by the physical characteristics of a building and external influence energy consumption (EIEC) affected by the surrounding environment (Hong L. et al. 2015). In order to eliminate the influence from building physical features, such as shape factor, window to wall ratio and heat transfer coefficient of building envelope, on the total energy consumption, the EIEC should be used in the following statistical analysis of urban morphology and building energy consumption to increase the accuracy and rationality of the analysis results. For this reason, calculating the BEC of building shall be the initial step.

In this study, we choose the way of simulation to calculate the BEC of buildings. OpenStudio software, as a visual user interface of EnergyPlus which is an international commonly-used building energy simulation software (What is OpenStudio. 2015), is selected to conduct the BEC simulation.

2.3.2 Step2: Calculating the external influence building energy consumption

For measurement on building energy consumption level, most studies adopt the calculation method of energy use intensity (EUI) (Kavgic, M. et al. 2010; Howard, B. et al. 2012). EUI refers to the annual energy consumption per unit area of a building, usually expressed in units $kWh \cdot m^{-2} a^{-1}$, that is, EUI= Energy consumption per year / building area (Hong L. et al. 2015), hence this paper use EUI to represent the efficiency of building energy consumption. On the basis of the total annual energy consumption data and the basic building energy consumption calculated by step 1, the external influence EUI of each building can be obtained according to the formula $EUI_{EIEC}=EUI-EUI_{BEC}$. it is followed by locating the data of building energy consumption in the urban spatial model based on geographic information system and visualizing the distribution of building energy consumption with ArcGIS, and the spatial distribution of building energy consumption can be grasped in general, and the relationship between building energy consumption and urban morphology can be preliminarily understood.

2.3.3 Step3:Correlation analysis

In this study, statistical analysis is used as an analytical methods, including correlation analysis and multiple linear regression analysis. Before proceeding regression analysis, it is necessary to conduct correlation analysis between dependent variable and independent variables, so as to have a general understanding of their influence relationships.

Correlation analysis is a tool measuring the strength of statistical relationship between objects, which aims at measuring the degree of linear correlation between variables (Sun, Y. 2007). In other words, the task of correlation analysis is to give a quantitative description of the correlation. Correlation coefficient “r” is a value used to describe the degree and direction of linear relationship. If the variable y and x are functional relations, then r=1 or r=-1; if the variable y and x are statistical relations, then $-1 < r < 1$; if x, y has the same trend, then it is called the positive correlation; if the trend of x and y is opposite, then it is called negative correlation. In general, $|r|\geq 0.95$, $0.8\leq|r|<0.95$, $0.5\leq|r|<0.8$, $0.3\leq|r|<0.5$ $|r|<0.3$ mean significantly correlated, highly correlated, moderate correlation, low correlation, very weak correlation, respectively,. The correlation analysis results between urban morphology variables and building heating EUI are obtained by Pearson correlation coefficient in data analysis software SPSS Statistics 22.0 (hereinafter referred to as SPSS).

2.3.4 Step4: Multiple linear regression analysis

The relationship between building energy consumption and urban morphology indexes obtained by correlation analysis is only qualitative, so it is necessary to further analyze the quantitative relationship between the two with regression analysis.

Regression analysis is a commonly used analytical method in statistical analysis. The case of one independent variable is called simple linear regression. For more than one independent variable, the process is called multiple linear regression (David A. Freedman 2009). Multiple linear regression attempts to model the relationship between independent variables and a dependent variable by fitting a linear equation to observed data. Every value of the independent variable x is associated with a value of the dependent variable y. This means scholars can analyze the effect of an independent variable on building energy consumption when controlling other independent variables. Therefore, with SPSS, multiple linear regression analysis is used to explain the impact of urban morphology on Harbin office building energy consumption of heating.

3. Results and Analysis

3.1 Data Results

3.3.1 Simulation results of building basic energy consumption

According to the architectural form, the office buildings in Harbin can be divided into two categories--slab-type building and point-type building, and we abstract relevant parameters (Table 2) of these two kind of building type respectively on the basis of the sixty-nine sample buildings to set up models in the energy analysis software. Outdoor weather data are derived from the Chinese Standard Weather Data (CSWD). Winter heating period is set from October to April next year. Heating parameters are set as shown in Table 3, and other related parameters are designed based on appendix B data in the "Design Standard for Energy Efficiency of Public Buildings (GB50189)" (PGB50189. 2015).

Table 2: Relevant parameters of slab-type building and point-type building used in simulation

Item	Slab-type	Point-type	Item		Slab-type	Point-type
Model diagram in OpenStudio			Height of floor		3 m	3.5 m
			Glazing ratio		0.249	0.294
			Shape coefficient		0.1546	0.1558
Footprint area	2280 m^2	784 m^2	Heat transfer coefficient	Roofing	0.35 $W/(m^2 \cdot K)$	0.35 $W/(m^2 \cdot K)$
Gross floor area	20520 m^2	17248 m^2		Wall	0.45 $W/(m^2 \cdot K)$	0.45 $W/(m^2 \cdot K)$
Number of floor	9	22		Window	3.1$W/(m^2 \cdot K)$	2.5$W/(m^2 \cdot K)$

Table 3: Heating parameters set in OpenStutio

		Office	Lobby	Meeting Room	Corridor	Toilet	Lift
Heating set point(°C)		20	18	18	16	16	16
Density of occupation/(m^2/person)		12	3	3	50	50	50
Air change time(times/h)		0.5	0.5	0.5	0.5	0.5	0.5
Sensible heat gain(W/m^2)	Lighting	10	15	15	5	5	5
	Equipment	15	5	5	0	1	0

Table 4: Actual energy use intensity and simulation results

(Kwh/m2/a)	EUI	EUI-H	EUI-H_{BEC}	EUI-H_{EIEC}
Slab-type	217.52	165.03	146.09	18.94
Point-type	214.19	166.30	186.63	-20.33

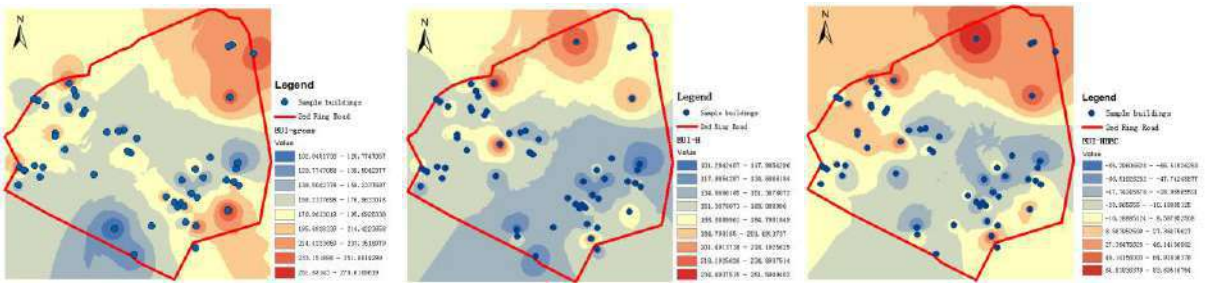
Based on the above parameters, this study run simulation in OpenStutio2.5.0 to get the basic average heating energy consumption intensity (EUI-H_{BEC}) of the two types of buildings respectively. As shown by the simulation results in Table 4, although the actual average heating energy consumption intensity (EUI-H) of the two is extremely close, the average EUI-H_{BEC} of slab-type building is much less than that of point-type building. Consequently, the calculated external influence heating energy use intensity (EUI-H_{EIEC}) of slab-type building shows a positive value of 18.94, while that of the point-type building is a negative value of -20.33. This indicates that the external space context, where the building located in, has reduced the heating energy consumption for most of the point-type buildings, whereas that of a majority of slab-type buildings has been raised by their surrounding environment.

3.3.2 Distribution results of external influence building energy consumption

Based on the simulation results of EUI-H_{BEC}, we calculate the EUI-H_{EIEC} of the sixty-nine sample buildings by deducting the EUI-H_{BEC} from EUI-H according to whether they are slab-type or point-type. Then, the actual gross energy consumption intensity (EUI), actual heating energy consumption intensity (EUI-H), and calculated EUI-H_{EIEC} data are placed in the corresponding sample office buildings of the urban model established in ArcGIS10.0. Further by using the Inverse distance weighted (IDW) tool in Spatial Analyst tool of ArcGIS, the three kinds of building energy consumption are interpolated to preliminarily estimate if there is any regularity for the spatial distribution of annual office building energy consumption in the study area. The results are shown in Figure 4.

As one would expect the three kinds of consumption located in the city did show different regularities. In terms of actual heating energy consumption, major parts with high EUI-H are located primarily in the north-eastern and south-eastern margin near the Second Ring Road of Harbin, and the areas consuming less heating energy are located in the central business districts which are made up with compact and tall buildings. Meanwhile, the external influence heating energy use intensity (EUI-H_{EIEC}) presents a more remarkable pattern compared with the distribution of EUI-H, with the largest concentration of building EUI-H_{EIEC} distributing mainly in the northern fringe and partly in the southern side of the city, while the lower EUI-H_{EIEC} locates around the midtown that consist primarily of tall buildings.

In order to conduct the comparation on the distribution of building gross energy consumption, we also visualizes the gross annual EUI distribution in ArcGIS. Interestingly, contrary to expectation that the highest EUI should be located in the business center of the city, it shows a similar pattern with heating energy consumption. This distribution regularity can be explained by the dominant position of heating energy consumption in the gross energy consumption, because the EUI-H (152.74 Kwh/m^2/a in average) is significantly larger than EUI-E (27.90 Kwh/m^2/a on average) for office buildings in Harbin. This distribution results imply that it do exist a certain rule of heating energy consumption distribution in different urban construction intensity of different geographical locations.



(a) EUI *(b) EUI-H* *(c) EUI-H_{EIEC}*

Figure 4: Spatial distribution of office building energy consumption

Table 5: Results of correlation analysis

Variables	EUI-H_{EIEC}		Sample size(N)	Mean	Standard deviation
	Cor.	Sig.			
EUI-H_{EIEC}	1	--	66	-9.87	36.96
BSC	-0.401	0.003	66	0.36	0.09
FAR	-0.518	0.000	66	2.30	0.82
BH	-0.613	0.003	66	23.10	5.30
RND	-0.521	0.202	66	0.022	0.0046
RHR	-0.552	0.000	66	0.85	0.17
OSR	0.456	0.000	66	0.64	0.09

Notes: Cor. refers to Pearson correlation; Sig. refers to significance.
When the significance is less than 0.05, the result of correlation analysis is significant.

3.3.3 Data results of correlation analysis

In order to have a general understanding between the urban morphology and the building energy consumption, this study takes the six calculated urban morphological indexes—Building Site Cover (BSC), Floor Area Ratio (FAR), Building Height (BH), Road Network Density (RND), Road Height-width Ratio (RHR) and Open Space Ratio (OSR),and external influence heating energy use intensity (EUI-H_{EIEC}) severally to produce the correlation analysis. After removing the three particular value points, the results of the correlation analysis are presented in Table 5.

According to the correlation analysis, it can be seen that the external influence Heating Energy Use Intensity (EUI-H_{EIEC}) has significant correlation with the respective independent variables except Road Network Density (RND). Among these significant independent variables, there is a significant negative correlation with Building Site Cover (BSC), Floor Area Ratio (FAR), Building Height (BH) and Road Height-width Ratio (RHR) indicating that these four variables have a inhibitory effect on EUI-H_{EIEC}, whereas a significant positive correlation with the Open Space Ratio (OSR) suggesting that GSR plays a positive role in promoting the value of EUI-H_{EIEC}. BH and RHR are demonstrated with the relative higher correlation with |r| being at 0.613 and 0.552 respectively, and Building Site Cover (BSC) shows a lowest correlation (|r|=0.401) with EUI-H_{EIEC}.

3.3.4 Data results of multiple linear regression analysis

The results obtained by regression analysis which constitute both significant and non-significant independent variables are unreliable. Therefore, according to the results of correlation analysis, this study removes non-significant correlation variables. Then the significant correlated urban morphological variables are retained as independent variables, and EUI-H_{EIEC} are regarded as dependent variables for proceeding multiple regression analysis in SPSS software. In order to eliminate the influence of collinearity variables, the regression method are selected as stepwise regression, and the final regression equation is as follows:

$$\text{EUI-}H_{EIEC} = -11.785FAR - 3.464BH + 122.678GSR + 81.203$$

The values of multiple correlation coefficient R is 0.780, indicating that the urban morphological variables are satisfactorily and linearly related to the dependent variable EUI-H_{EIEC}. For the determination coefficient R Square (R^2), it can be known from the statistics that the closer its value is to 1, the better the fitting degree of the model is to the data, so the relatively high fitting degree of the equation suggests that the interpretation of regression equation for EUI-H_{EIEC} is quite credible. The result can be used as a strong reference for studying the relationship between building heating energy consumption and urban morphology in severe cold regions. At the same time, the regression analysis result also outputs the Standardized Coefficients (Table 6) by which the effect of urban morphological variables, with different magnitude and units, on the dependent variables can be compared.

Table 6: Results of Standardized Coefficients

Dependent variables	R	R square(R^2)	Standardized Coefficients					
			BSC	FAR	BH	RND	RHR	OSR
EUI-H_{EIEC}	0.780	0.608	--	-0.263	-0.497	--	--	0.247

Based on the above multiple linear regression result, we can find:

(a) Because of the non-significant influence of Road Network Density (RND) on EUI-H_{EIEC} and the co-linear relationship with other variables of Building Site Cover (BSC) and Road Height-width Ratio (RHR), these three variables do not appear in the equation.

(b) It can be drawn from the R square that the surrounding urban morphology do produce impact on heating energy consumption of office building in the severe cold regions.

(c) Among the three urban morphological variables, floor area ratio (FAR) and building height (BH) present a negative influence on the annual external influence heating energy use intensity (EUI-H_{EIEC}) of the office buildings, which means the higher the average floor area ratio and building height of a district are, the lower the EUI-H_{EIEC} of the building will be, which will be more conducive to improving building energy efficiency. Specifically, if the floor area ratio (FAR) ascended by one, the total annual EUI-H_{EIEC} of the office building would be slumped by 11.785 Kwh/m^2/a; if the average building height of a district increased by one meter per year, the total annual EUI-H_{EIEC} of building would be reduced by 3.464 Kwh/m^2/a.

(d) The correlation between Open Space Ratio (OSR) and EUI-H_{EIEC} is positive. That is, the greater the OSR of the district is, the higher the heating energy consumption for office buildings would be, and less beneficial to improving heat-energy efficiencies. According to the regression equation, the EUI-H_{EIEC} will experience a 1.2267 Kwh/m^2/a increase for every one percentage point grow in OSR, which means the annual heating energy consumption intensity (EUI-H) will have a 1.2267 Kwh/m^2/a rise as well.

(e) Due to the absolute value of standardized coefficients, it can be known that the building height (BH) contributes the greatest impact to the heating energy consumption of office building (0.497) among the three urban morphological variables; next is floor area ratio (FAR) with 0.263; followed by open space ratio (OSR) at 0.247.

,

3.2 Analysis on the relationship between urban morphology and building energy consumption

Data results from statistical analysis displays that the different kinds of urban morphological indexes lead to distinctively different heat-energy demands of office buildings in severe cold region cities. However, the mechanism of urban spatial configuration affecting heating energy efficiency behind these data needs to be explored, so as to put forward effective planning suggestions at the fundamental level--urban design.

3.2.1 Building Site Cover, Floor Area Ratio and Building Height

Building site cover, floor area ratio and building height are three main indexes used to describe urban spatial intensity. Usually, a higher spatial intensity district combines a higher floor area ratio with a more compact building density and taller building height, and a lower spatial intensity area is characterized as lower floor area ratio with sparse building density and low-rise buildings. Our urban district morphology samples where the selected buildings seat in also confirms this factual regularity.

According to the data results, BSC, FAR and BH have negative correlation with building heating energy consumption. In other words, the higher the spatial intensity of construction, the more conducive to promoting the performance of building heat-energy efficiency. Moreover, the impacts from FAR and BH on building energy efficiency are proved more obvious.

From the perspective of urban climate, it can be argued that high intensity urban districts (usually city center) alter their thermal environment in the form of lifting temperatures relative to outskirts (usually the peripheral areas). Our previous study (Hong L. at el. 2018) on “the relationship between urban morphology and urban thermal environment in Harbin” also confirms this view. The study proves that the average district temperature grows up relatively significantly with the increase of floor area ratio and building height in winter, but the building site cover (building density) has little effect on the improvement of the surrounding thermal environment. At the same time, high intensity urban construction slows down the ventilation efficiency in district which contributes to less heat loss of building.

From the point of view of equipment use, high construction intensity areas in Harbin are the commercial and financial centers in where high intensity economic activities and work happen consistently. This causes more users, electrical equipment and lighting to release a more heat which leads to less heat-energy consumption. The above analysis also explains why the office buildings in the downtown of Harbin show better heat-energy efficiency in the results of EUI-H and EUI-H_{EIEC} distribution.

3.2.2. Road Network Density and Road Height-width Ratio

As urban ventilation corridors, roads play an important role in microclimate and thereby affect the energy consumption of buildings. Road network density (RND) and road height-width ratio (RHR) are important indicators for measuring road compactness and three-dimensional road morphology.

Looking at *Road Network Density ,* statistical analysis shows that road network density (RND) has little effect on building heating energy consumption. The possible reason, as the definition of road density shows, is that it is mainly used to reflect the number of roads, and only the length information of the road network is counted, but it does not reflect the road width that affects the urban ventilation. Hence, road network density is not an effective urban morphological index evaluating impacts on building energy consumption, and road area ratio might be a better indicator.

With regards to *Road Height-width Ratio,* it has a significant negative correlation with heating energy consumption, and can reduce the external impact energy consumption of buildings. One possible reason is the increase of surrounding RHR reduces the wind speed in ventilation corridors and facilitate the heat preservation in the city, which creates a warmer outdoor temperature to buildings and thereby promotes building energy conservation.

3.2.3 Open space ratio

A high Open space ratio (OSR) means there are more open space around the vicinity. The results of correlation analysis and regression analysis all show that the higher OSR is, the more unfavorable it is for building heat-energy saving in severe cold region cities. The microclimate influenced by OSR should be responsible for it indirectly. It can be known from the previous study that the place with lower open space ratio is found to be warmer as compared to the district with more OSR value in winter (Hong L. at el. 2018). It is because the lower ventilation rate and higher heat storage capacity reduce the heat loss efficiency of buildings. For this reason, OSR shall be regarded as an effective parameter to appraise the heating energy efficiency of urban morphology.

4. Conclusion and Discussion

4.1 Conclusion

In summary, this paper analyzes the influences that urban morphology factors exert on building energy consumption quantitatively in severe cold region, with Harbin as a case study. Sixty-nine office buildings' energy consumption data and six urban morphology indexes surrounding these buildings are studied in detail with a statistical approach.

From a theoretical perspective, the final results demonstrate that: (a) Urban morphology do has a remarkable effects on heating energy consumption of office buildings in severe cold region cities. (b) Higher construction intensity with taller buildings, denser building layout and higher floor area ratio feature greater heating energy efficiency of office buildings, while greater open space ratio leads to lower heating energy efficiency. (c) For estimating the heating energy efficiency of urban morphology, urban spatial intensity (BSC, FAR and BH), road height-width ratio and open space ratio are all effective urban morphological indexes.

With regard to methodology, our research increased the rigour of research through the combination of building energy consumption simulation and statistical analysis. Before the statistical analysis, the basic energy consumption(BEC) of buildings are simulated by OpenStutio software to obtain the external influence energy consumption(EIEC) of buildings which are used for statistical analysis to eliminate the influence of variables such as building construction, building equipment and other variables. This greatly increases the accuracy and scientificity of the analysis results.

It should be noted that other energy consumption of office buildings such as electricity which might have opposite correlation with some urban morphological indicators has not been included in this study. Therefore, it might be necessary to find the best urban morphology that can balance the energy consumption of electricity and heating energy in severe cold region cities in the future.

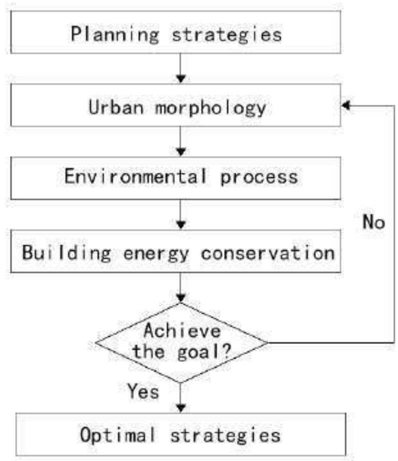


Figure 5: The relationship between planning strategy and building energy conservation

4.2 Discussion：Possible planning strategies

The same urban density, same volume rate or same population size can be realized by diverse urban morphologies, but there are different effects on the environment (Rogers R.G. 2007) or on the urban building energy consumption specifically. The close relationship between urban morphology and building heating energy consumption identified in this study also emphasis that urban morphology can be used as a valid way to save building energy and reduce carbon emissions in cold region cities. Consequently, the significance of energy-saving oriented urban planning strategies can be foreseen. To be precise, a preliminary planning framework (Figure 5) can be established theoretically: First, study the quantitative relationship between building energy efficiency and urban morphology of the city which is what we have done in this study; Afterwards, come up with energy-saving oriented urban planning strategies based on the above correlation; Finally, evaluate and compare the ability of different morphology scenarios until achieving building energy conservation goals.

For this study, after obtaining the above analysis results, the possible planning strategies in district scale can be put forward for severe cold region cities: compact building layout; appropriate high development intensity, building height and road aspect ratio; moderately reducing open space ratio. However, we must take the impacts of these strategies on other factors such as urban society, transportation efficiency into consideration comprehensively and deliberately.

Overall, introducing the concept of building energy conservation in urban planning and proposing energy-saving oriented urban planning strategies in cities are significant for the mitigation of climate change and the development of cooler cities.

Construction of Resilience in Urban Fringe Based on Sponge City: an Example of Green Space Planning of Shahe in Beijing, China

（Construction of Resilience in Urban Fringe Based on Sponge City：an Example of Green Space Planning of Shahe in Beijing, China）

Li Xin, Beijing Forestry University, China

Abstract：Urban fringe area is important to maintain the sustainable development of ecological safety and security. Under the background of rapid urbanization, the ecological environment in the urban fringe is facing great threat to urban and rural construction. The acceleration of urbanization has brought a series of problems, such as the deterioration of the ecological environment and so on.

This article summarizes the inadequacies of the urban fringe area and the future direction of development from the perspective of landscape architecture through literature surveys, conceptual analysis and related historical research. Clearing research direction is construction of resilient landscape in urban fringe. The study object is the Shahe area in Beijing, China. I analyze the status of the macro and meso level of the site using the 2017 Remote Sensing Images and Field Survey Data. In response to the current status issues, the potential characteristics of water elasticity in this area are proposed. The current status is severe soil desertification, non-point source pollution, pollution of water bodies, imperfect drainage systems, serious water pollution, lacking of systematic green areas, etc. Different resilient solutions are proposed for within the embankment and outside the embankment.

1) Within the embankment: giving space for the river
   Opening the local embankment and adding the ecological embankment; setting the pond to resist the impact of heavy rain; adding wet meadows, increasing ecological habitat.
2) outside the embankment: providing site for the storm-water
   Adding permeable paving and roof greening; organizing storm-water discharge; Designing storm-water pond.

According to Sponge City's control standards formulate storm-water runoff control objectives and conduct catchment zoning planning and calculation. According to the results of the calculation adjust the green area within the studying area. The benefit evaluation of ordinary rainfall mode and rainstorm mode is carried out.

Keywords：Urban fringe area，Low impact development of rainwater system，Elasticity landscape

1. Introduction

1.1 Urban fringe area

Urban fringe is the transition zone of urban and rural areas with the nature of urban and rural land use property. It is an important area to maintain urban and rural ecological security and ensure sustainable development. There are obvious differences in the landscape between the early cities and the countryside. With the rapid urbanization process, the city continues to expand to the periphery. The land use adjacent to the rural areas has changed from agriculture to industry, commerce, residential area and other functions. Compared with the suburban or urban central areas, the urban fringe area has a low population density, lack of planning guidance and infrastructure.

1.2 The urban fringe of Beijing

Beijing is located in the north of the North China Plain. It is the capital of China, a super large city and an international city. Since the founding of new China, the social and economic development in Beijing has been sustained, rapid and healthy. At the same time, the problem of urban space has also been exposed. The single center focus of Beijing leads to the unordered development of urban construction in the urban fringe area. With the continuous development of urban space, the urban fringe area is gradually reduced to the obstacle of urban development. Through literature review and field investigation, from the perspective of landscape architecture, it is found that there are the following problems in the urban fringe of Beijing:

1)Due to the rapid development of the city, agricultural land has been greatly reduced. The urban fringe area of Beijing covers most of the plain areas, which is the main distribution area of cultivated land, and the fringe area is also the pioneer zone in the process of urban expansion and urbanization. Since 1980s, land use in the urban fringe of Beijing has shown obvious transformation characteristics. In the case of a large number of agricultural cultivated land, a series of problems such as soil fertility decline, soil desertification, soil pollution and so on are caused by the high exploitation and utilization depth of cultivated land and the intensity of exploitation and utilization.

2)The large influx of the floating population and the migration of urban population caused the growth and the irrational spatial distribution of the population size of the urban fringe. The distribution of Beijing population is the trend of urban expansion, mainly concentrated in the inner border area of the urban fringe.

3) The climate in Beijing is a typical semi humid continental monsoon climate in the north temperate zone. The average annual rainfall is 500 mm, which is one of the most rainfall regions in North China. The seasonal distribution of precipitation is uneven. 80% of the annual precipitation is concentrated in June July August for three months, and heavy rain often occur in July and August. Due to the weather characteristics, the urban fringe area often occurs waterlogging, some small and medium rivers and reservoirs will have flood situation, causing serious economic loss and inconvenience of people travel.

2. The elastic landscape in the urban fringe area

Through the summary of the above problems, we found that the urban fringe area has developed rapidly and has many problems, the land and population in the urban fringe are not stable, and the elasticity of resisting the influence of natural weather is small. Based on this feature, it is very important to design flexible landscape in the urban fringe.

Resilience is "the ability of ecosystems to tolerate disruption without breaking down". Elastic landscape is an artificial and natural landscape with flexibility in response to weather conditions and external disturbances. It can maintain or try to maintain the traditional values and natural harmony. The elastic landscape includes the capacity to accommodate and adapt to rainwater. Sponge city (low impact development rainwater system) is one of the elastic landscape. Sponge city is a "flexible city" for cities to adapt to environmental changes and cope with natural disasters caused by rainwater. When it rains, absorb water, store water, seep water and clean water. When it needed, the stored rainwater will be released and utilized.

3. Taking the Shahe reservoir area in Beijing as an example

3.1 Background introduction

The area is located in Shahe to the Wenyu River Basin, Changping District, Beijing（Figure 1）. There are two subway lines across the channel. This area is an important node in the development belt of Western Beijing. It is the key area for the industry and population of the evacuation center city. It is an important industrial base in the northwest of Beijing, mainly with high and new technology and R & D production; it is one of the important higher education bases in Beijing, and one of the important tourist areas

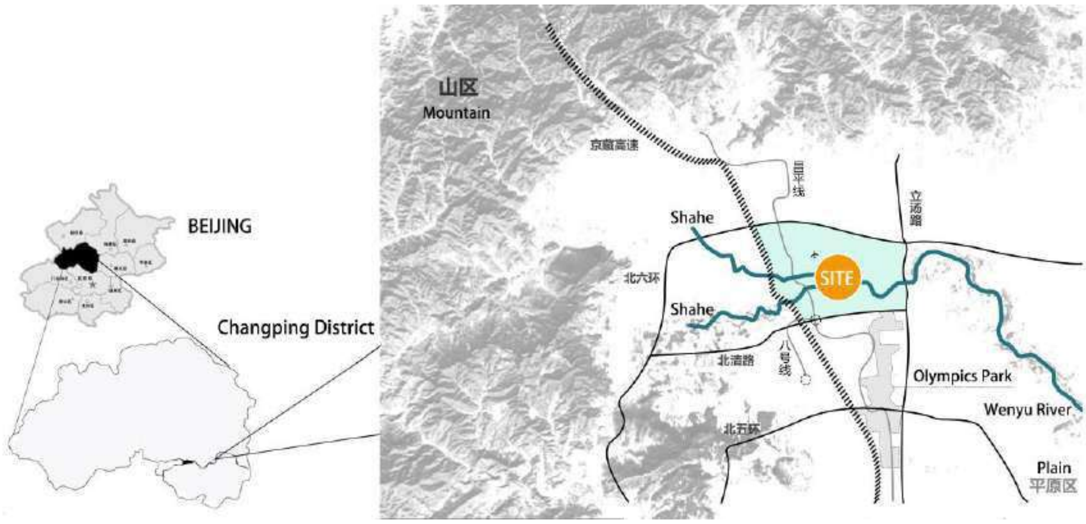

Figure 1: Location diagram

The location of the site in the space layout of the green space system is a green isolation, a green isolation belt between the central Jingmi diversion canal and the six ring, which is the main part of the second road greening and isolation belt in Beijing. Two sides barrier, North upper body green belt, southeastern part of the Wenyu River as the main wedge-shaped green space. In the five ecological corridors, there are 2 green corridors along the highway and three blue ecological corridors along the water. There are nine important urban parks.

3.2 Present situation analysis

3.2.1 Site analysis

On the basis of site investigation and data sampling, the arcGIS software is used to analyze the status of the site.

1）Altitude: the height of the northwest and south of the site is relatively high, showing a trend of gradual decline to both sides of the river, and the overall topography of the site is relatively flat. 2）Slope: the status quo of the site is relatively flat, with easy water accumulation. 3）Rainwater confluence: according to the elevation, the flow direction and the confluence accumulation can be calculated. It can be seen that the drainage of the land on the dyke is disorder, and there are several obvious drainage lines. 4) Soil: the soil in the field is mainly loam and sandy loam, and the permeability of sandy loam, loam and sandy loam is good, which provides nutrition and fertility for plant growth. 5) Water conservancy facilities: there are dams on both sides of Shahe to Wenyu River Basin. There are Shahe gates at the junction of Shahe and Wenyu River, and there are many drain outlets along the river. 6) Vegetation: using NDVI software to analyze the current vegetation status, identify the appearance of dense forest area, and try to preserve it in the future. There are large areas of farmland in the current situation, and the plant species are relatively simple. （Figure 2）

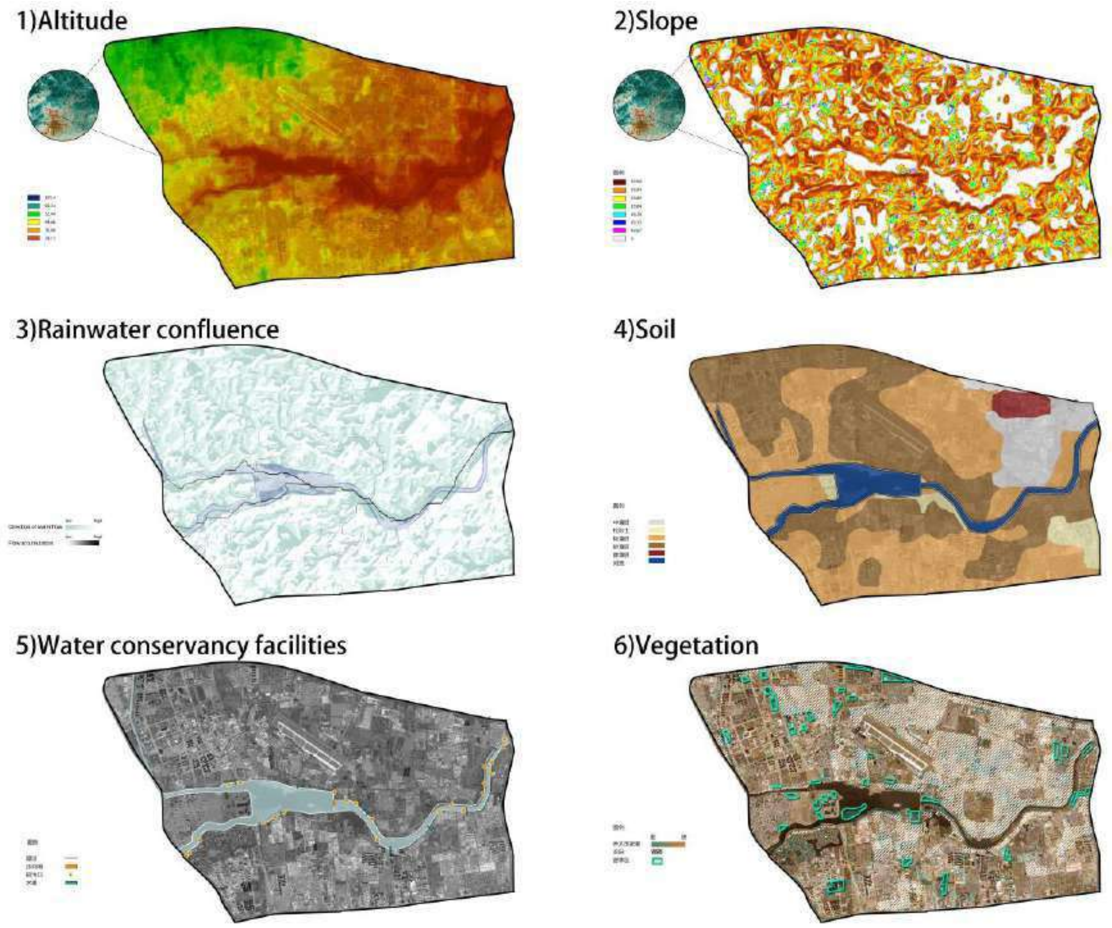

Figure 2: Site analysis diagram

3.2.2 Land-use analysis

According to the site investigation and land use planning, the nature of the current land use is analyzed.

1) Green space: the overall distribution of green space is scattered and poor coherence. The green space for public activities is small. There is a lack of active sites in the current park. It has a single function and poor openness. It can't meet the needs of use and ornamental. In some areas, the green plants are in good shape and can be retained. 2) Farmland: the proportion of farmland in the field is significant. 3) Residential land: in the scope of the study, the current situation of residential land is very polarized, and most of them are rural construction land with poor features. At the same time, there are several high end residential areas being built, and the roof afforestation can be built in the future. Measures are taken on the pervious pavement. 4) Village land: village land scattered scattered in the site, compact space, more crowded, poor accessibility, lack of space, can't meet the needs of the use of the status quo. 5) Industrial land: the parts of industrial land are distributed in pieces, partly scattered in the field, with general accessibility and poor environment, and industrial land is easily affected by other surrounding land. 6) Education and scientific research land: mainly concentrated in Shahe High Education Park, partly

scattered in the field, with general connectivity, poor surrounding environment, and good interior landscape conditions. 7) Road: the traffic of the site to the traffic is unimpeded, the North-South part of the road is not connected because of the obstructed part of the reservoir and the river; the internal roads are separated by the wall to form the broken road, and the connectivity is poor. （Figure 3）

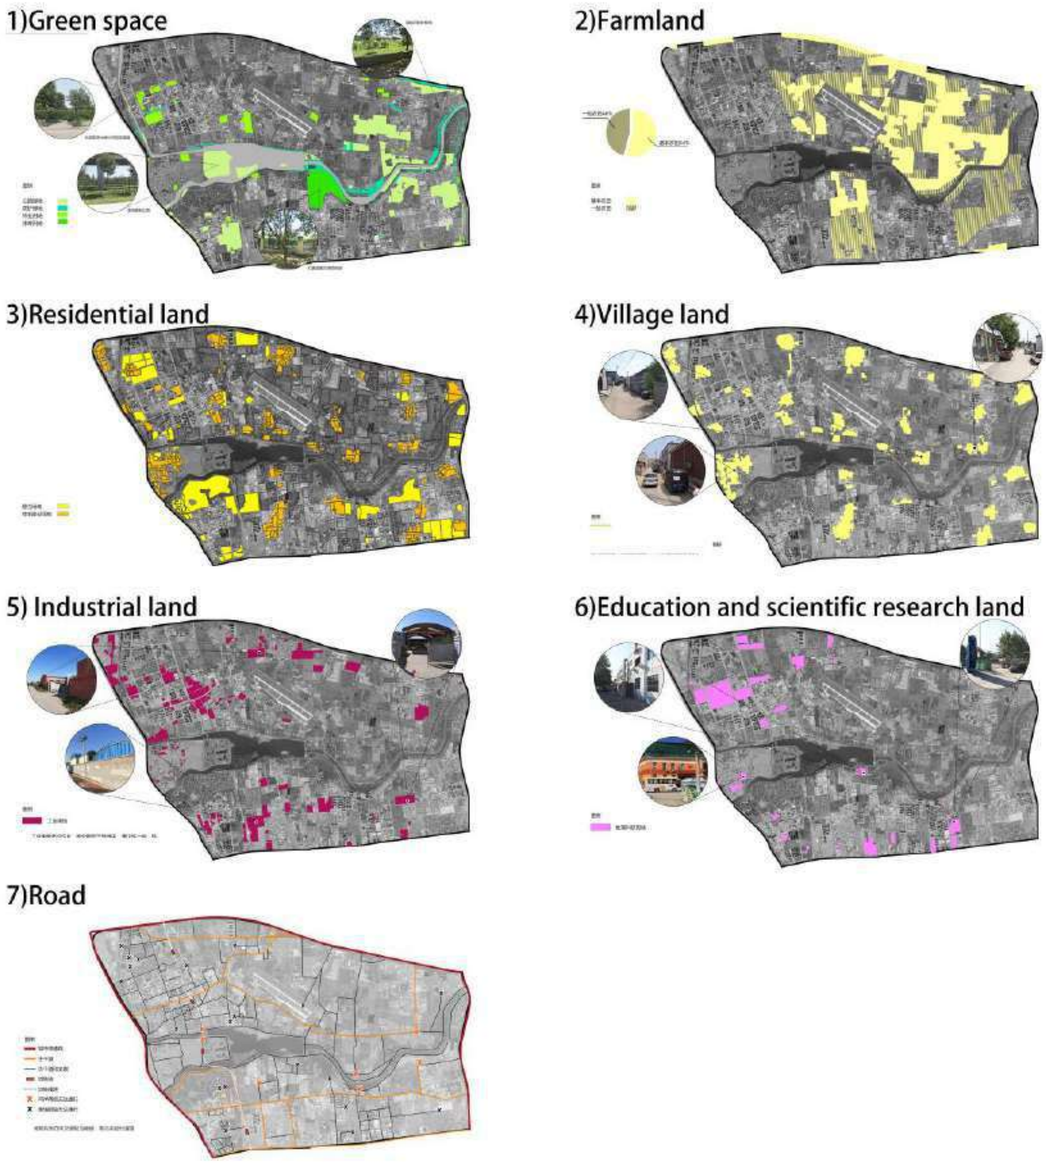

Figure3: Land-use analysis diagram

3.2.3 Summary of current problems

1) Excessive use of groundwater led to the desertification of soil: according to the literature, it can be seen that the water demand of living and agricultural land is large, while the site life and agricultural land occupy a large amount, while the surface water quality is not good, so a lot of groundwater is exploited in the field. Due to long-term over exploitation, the groundwater level decreases at the rate of 1.3m per year, which indirectly leads to soil desertification. 2) Non-point source pollution in water system is serious: non-point source pollution is caused by dissolving and solid pollutants from non-specific sites, under the action of precipitation or snow melting, through the flow of runoff into the water body. Frequent rainfall in summer produces more runoff, resulting in an increase in the proportion of non-

point source pollution. Due to the rain runoff produced by precipitation in the process of different underlying surface, pollutants are carried, and the water pollution problem will be caused by the entry of the urban drainage pipe network into the Shahe reservoir under untreated conditions.

3.3 Planning concept

After combing the research area, we hope to manage rainwater through the intervention of the elastic landscape, give priority to the natural drainage system, build the ecological drainage facilities, make full use of the effect of the urban green space, road and water system on the absorption, infiltration and slow release of the rainwater, and effectively slow the solution of urban waterlogging and reduce urban runoff pollution. Load, saving water resources, replenish the water level of the city, thus improve the urban ecological environment, and provide important guarantee for the construction of the sponge city with natural accumulation, natural infiltration and natural purification. In addition, integrate the current green space, add green space to the demand, and put in the function. Through the planning and design of the park under the management target of rain and flood, "the cold gray zone" is transformed into the "active green open space" in the city, the urban ecological environment is improved, the traffic system of the district is perfected, the slow running system of the riverside is built, and the living quality of the surrounding residents is improved.

In the construction of the "Hydroelasticity" system, the embankment space and the outer space of the embankment from the Shahe to Wenyu Reservoir River Basin are respectively taken into consideration. Inside the levee, second ecological embankments are added to the local dam(Figure 4), and the pit is set up as a rainstorm reservoir, dredging the silt at the bottom of the river, expanding the flood area, adding the submerged meadow, and increasing the ecological habitat. Provide greater space for the river to accommodate rainwater.

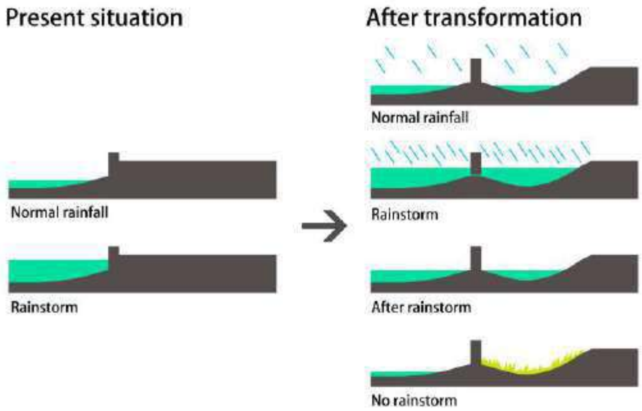

Figure4: ecological embankments diagram

Outside the levee, the source of rainwater is reduced, the middle section is transported and the terminal is absorbed, and the grass planting ditch, the concave green land, the reservoir and other passageways and sites are set up. Guide rain, give space to rain. At the same time, landscape design methods such as plant landscaping make the site more eco efficiency and landscape effect.

3.4 Hydroelasticity strategy

3.4.1 Rainwater runoff control

In the field investigation and analysis, there are many low runoff coefficient agricultural land underlying surfaces. We expect that under the condition of one year's 24h rainfall, the site controlled rainfall event is 85% and the designed rainfall is h=33.6mm. The area of the study area is F=9555ha, and the total runoff control rate is 85%. The design rainfall is h=33.6mm, and the overall runoff coefficient of the field is Ψ=0.49 (ideal water surface Ψ=1, green space Ψ=0.15, hard roof and asphalt roof Ψ=0.3, concrete and asphalt pavement Ψ=0.85), and the total volume is $W=157*10^3m^3$ in the study range.

$$W=10\Psi hF$$

3.4.2 Water collecting zoning planning

The rainwater collection area layout should first be based on the total amount control index of the rainwater runoff in the region, to convert the required volume of the sponge facilities, and to carry out the construction of the sponge facilities in the present situation and the future new park green land. In the layout, using the current high - range low-lying land, ditch and so on, the terrain design is carried out and the direction of rainwater runoff is arranged reasonably so that the sponge facilities can collect the rainwater effectively, avoid the intensive planting area of the present trees, transplant the trees, and empty the space for the construction of the sponge facilities.

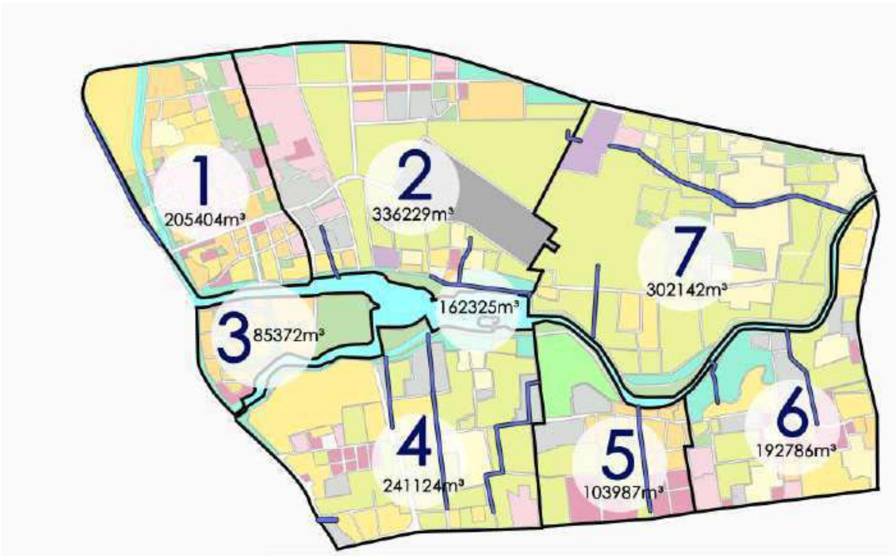

Figure5: Water collecting zoning planning diagram

There is a difference in the spatial distribution of land use in the scope of study, which leads to a large difference in the underlying surface of the different plots. In order to achieve the total runoff control rate of 85%, the study area is divided into the area of water collection, according to the hardening degree of different land use, the position of the water channel and so on, according to the principle of near emission. The scope of the study is divided into 7 water collecting zones(Figure 5). The discharge volume required for each partition to be controlled (Figure 6) is calculated. The discharge volume of each zone is $163*10^3m^3$, which is close to the $157*10^3m^3$ of the total runoff volume.

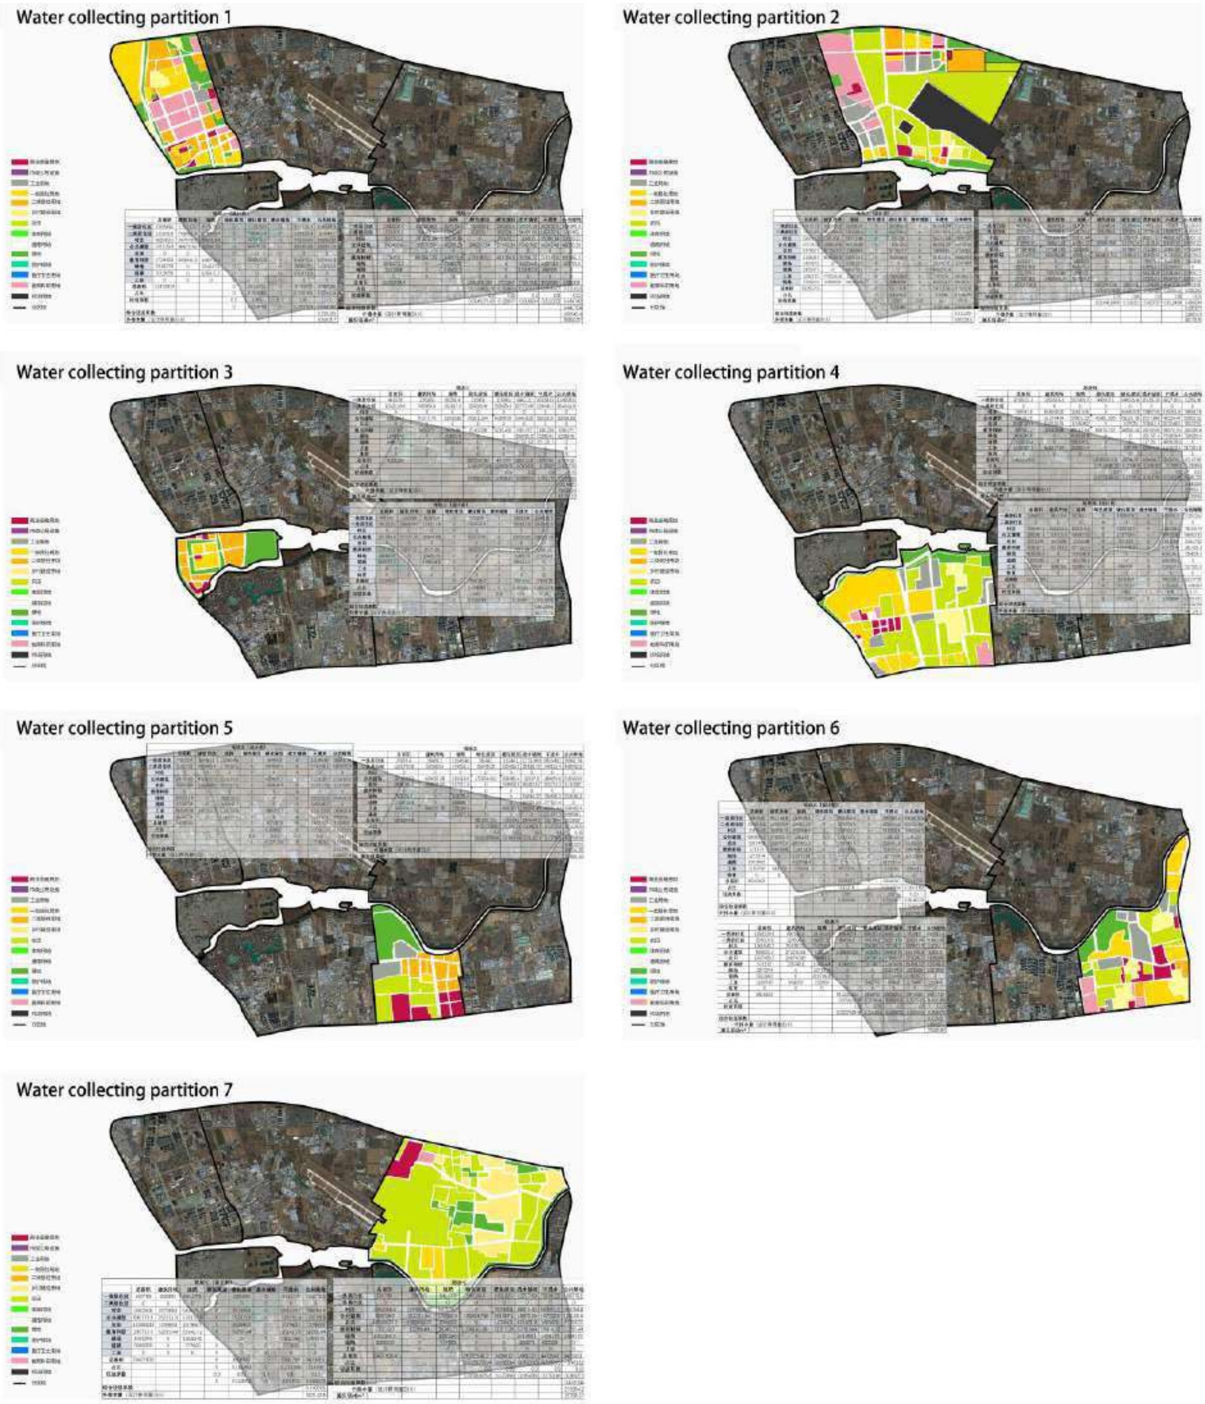

Figure6: Water collecting partition calculation diagram

1）Source reduction

The building area, road area, road area, road area, green roof area, hardened roof area, permeable paving area, water permeable paving area and public green space area are calculated and the runoff coefficient is calculated and the amount of external drainage is V1. In the design, the green roof, hardened roof, and water permeable of all kinds of land are designed. The area of loading, permeable pavement and public green space was redistributed, and the external drainage volume after design was V2. The rainwater volume at the source was V3. (Figure7)

<u>V3=V1-V2</u>

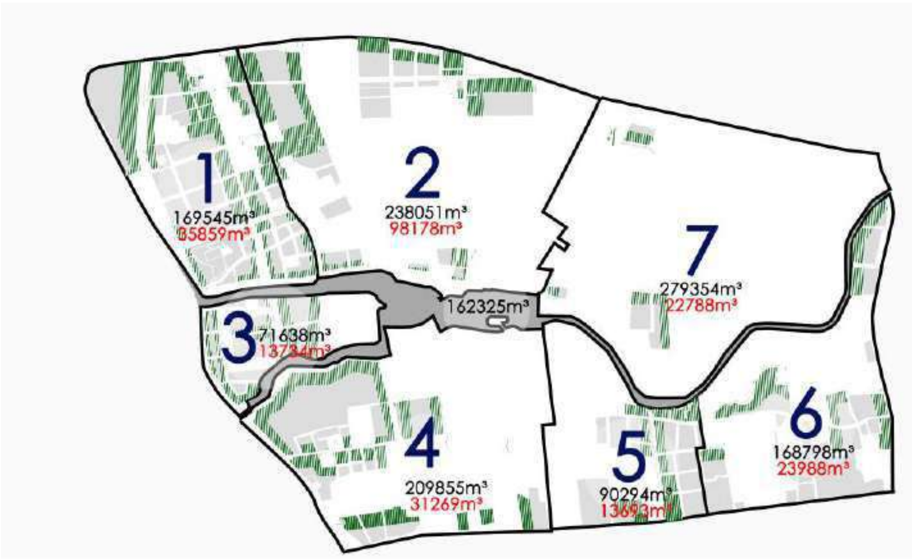

Figure7: Source reduction calculation diagram

2）Middle end transmission

During the middle end transmission, the water conveyance corridor is used to transmit rainwater. The water corridor is divided into two grades. The first grade corridor is the surface runoff from hard pavement to the lower concave green space in the vicinity of rain. The second corridor is after the rainwater passes through the first grade water transport corridor to the concave green space, which is stagnant in the green space, and finally into the green wet pond in the dike dam through the grass planting gully side of the road. Selecting the road side ditch in the research area as the water conveyance corridor and connecting the water conveyance corridor into a system. (Figure8)

Figure8: Middle end transmission diagram

3) Terminal elimination

New green spaces are placed in each catchment area to store rainwater transported by water conveyance corridors. The newly increased green space should be chosen from the general farmland close to the canal or the current green space, and the principle of distribution should be distributed as evenly as possible. After the increase of green space, the depth of the sunken green space is 0.3m, and the V4 of the newly increased green space should be greater than or equal to V2 of the external drainage after design. (Figure9)

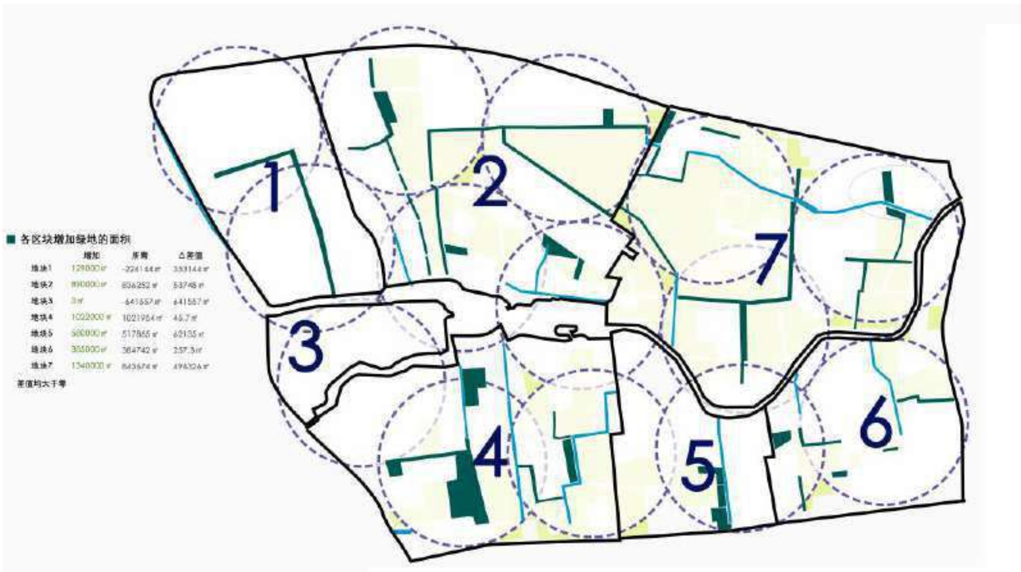

Figure9: Terminal elimination diagram

3.5 rainfall model simulation

In ordinary rainfall, the hard surface runoff is brought into the nearby green space, the green space is permeated with the rainwater, the orderly transport in the first grade corridor, the green and wet pond in the embankment and the dam, and eventually into the river. The total runoff of the area is $157*10^3m^3$, the total runoff is $157*10^3m^3$, the total runoff is $134*10^3m^3$, the source reduction rainfall is $24*10^3m^3$, the terminal elimination rainfall is

124*$10^3 m^3$, and the total amount of control runoff is 130*$10^3 m^3$. The target of total annual runoff control rate of 85% can be achieved in the region. （Figure10）

Figure10: Model simulation of ordinary rainwater diagram

In the rainstorm model, the runoff of hard surface flows into the nearby green space, the green space permeates the rainwater, and the remaining rainwater is discharged into the city pipe network through the spilled water pipe, and the rainwater collected in the city pipe network is arranged into the river. （Figure11）

Figure11: Model rainstorm diagram

4. Summary

The green space planning of the Shahe reservoir in Beijing is a controlled detailed planning case. The plan reflects that the theory and planning method of "sponge city" is suitable for multi-layer and multi scale. The trend of landscape construction in the urban fringe is an elastic landscape. The construction of "sponge city" has opened a hopeful journey to solve the problems of water and related ecological and environmental problems in the border area of China, including the management of rain and flood, ecological flood control, water purification, groundwater replenishment, palm restoration and habitat construction. Park green space construction, as well as urban micro climate regulation.

Towards a sustainable and eco-civilized era: a national-wide project of pairing Ecological Restoration with Urban Repair (ERUR) in China

Lian, Xin, BEIJING, China

ABSTRACT:

40-year rapid and massive urbanization and industrialization has caused serious problems of environmental pollution, ecological degradation, and function deterioration of urban habitat in China. Meanwhile, climate change put forward a new challenge of sustainable and resilient development on cities globally. Aware of those challenges, the government and the public in China has raised their interest and made efforts on restoring urban ecological system. As a pilot step, a national-wide project called “Ecological Restoration and Urban Repair (ERUR)” has launched in 2015 by the Ministry of Housing and Urban-Rural Development. Ecological restoration is quite a well-known, universal approach to restore the natural settings. Different from traditional ecological restoration projects, ERUR attempted to pair the ecological restoration with efforts to tackle with issues concerning human habitats, such as quality enhancement of urban built environment, urban disaster prevention, storm water management, brownfield restoration, historical and cultural heritage preservation etc. The urban repair component has therefore been well-integrated into the whole picture of ecological restoration. In this paper, the overall initiatives and objectives of the ERUR project will firstly be addressed. Following that, several cases will be discussed to identify the key features and main approaches on addressing both ecological restoration and urban repair within one project.

Study on microclimate Environment of Jiaodong Seaweed house -- Taking Dongpudao Village as an Example

(Study on microclimate Environment of Jiaodong seaweed house)

Liu Xiang, TianJin University, China.Zeng Jian , TianJin University, China.

Fang Yanan, TianJin University, China.

【Abstract】 Taking the seaweed house settlement in Jiaodong as the research object, this paper study the microclimate of seaweed house through experimental data, wind environment and thermal environment simulation. The analysis of seaweed house under the coastal climate conditions have three aspects: macroscopic settlement form, middle view block form and microscopic courtyard.

【Keywords】 seaweed house, settlement, ecology, microclimate

In the long history of farming in China, the unique geographical, climatic characteristics, historical , cultural of various places have created many traditional settlements, such as the settlement of cave dwellings in Shanxi, the settlement of Tulou in Fujian, and the settlement of bamboo buildings in Yunnan. Although these traditional settlements have different forms, they all contain ecological wisdom that is ingeniously adapted to the regional climate. The settlement of Jiaodong seaweed houses(Figure 1) is one of them. The existing traditional seaweed house settlements are mainly distributed in the coastal areas of Weihai, Yantai and Qingdao. The complex and diverse climatic conditions of the region (wet and rainy, high salinity, windy, strong radiation) and the geographical features of the integration of mountains and seas have an impact on the settlement pattern of seaweed houses. At the same time, the settlements of seaweed houses also form from macroscopic settlements. The settlement form, block form and micro-court form respond to the local geographical climate. After long-term development, the seaweed house settlement not only forms a simple and beautiful settlement environment, but also has ecological characteristics, realizing the unification of ecology and modality, and is a precious ecologically sustainable architectural cultural heritage in the northern coastal of China.

Figure 1 :seaweed houses

1. Macro ecological strategy

At the settlement level, temperature, ventilation and drainage are the main factors affecting the settlement pattern of seaweed houses. The seaweed house settlement creates comfortable temperature and ventilation conditions through the location of facing the sea with the hills for a background, the compact layout, reasonable orientation and the sand surface with big specific heat capacity increase the thermal stability of the settlement, at the same time, The good permeability of sand land and open ditch can effectively reduce the impact of the torrential rain disaster that is prone to occur in the coastal area. The macro-settlement ecological strategy of seaweed houses includes,

1.1 Settlement site of facing the sea with the hills for a background

The seaweed house settlement is generally located on the adret in the coastal zone. This traditional location of facing the sea with the hills for a background can make full use of the climatic characteristics of the land and sea junctions in the coastal area of Jiaodong to create a comfortable and livable settlement.

Utilization of coastal climate: Seaweed house settlements are generally distributed within a certain distance from the coastline but not more than 10km. This kind of sites can take full use of the climatic characteristics of the summer and winter temperatures in the coastal zone, and avoid the humid climate in the coastal area. Living close to the sea is also facilitates fishermen to go out to sea and effectively improve the comfort of living (Figure 2). Relevant meteorological data show that the distribution area of seaweed houses is obviously affected by ocean climate. The temperature in summer is 4℃~6℃ lower than that in inland areas in the same latitude, and the temperature in winter is 3℃~5℃ higher than that in inland areas in the same latitude.

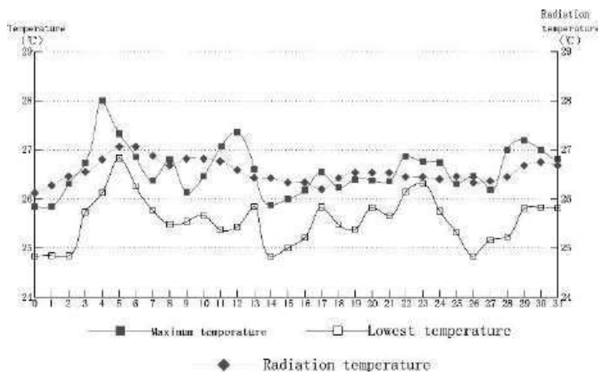

Figure 2 : Indoor daily highest (lowest) temperature measured in August

Use of altitude difference: Most of the mountains in Jiaodong are wide and gentle. The settlement of seaweed houses is generally located in the area with suitable slope and open terrain on the south side of the mountain. The flat land below the mountain is reserved for cultivated land. The building gradually rises with the hillside in order to obtain good sunshine, while the good ventilation of the sunny slope helps to accelerate the diffusion of humid air. In the winter, the mountain can also block the cold wind for the settlement.

1.2 The settlement form on the mountain

Affected by mountains and coastlines, the construction base of seaweed houses is relatively small, so the settlement is compact (Figure 3). Take Dongchuudao Village for example, the settlement covers an area of 2,160 ㎡, its total construction area is 90,65 ㎡ and building density is 42%. This compact space shape can maximizes the impact of the external environment and creates a comfortable thermal environment inside the settlement. In summer, the high-density settlement form allows buildings to block each other, greatly reduce the area and time of exposure the sun and increase indoor thermal comfort (Figure 3). In winter, the cold wind passes over the roof of the seaweed house and the Internal space forms a continuous wind shadow, which can effectively reduce the wind speed inside the settlement (Figure 4) and reduce heat loss.

Figure 3 ： Seaweed house courtyard form

1.3 Sandy and soil mixed ground

The ground of the of seaweed house settlement is the sand formed by the weathered mountain stone, which has good thermal stability and drainage performance. First of all, the specific heat capacity of the sand is large and a large amount of solar radiation is absorbed during the daytime, so that the temperature inside the settlement is lower near the ground. At night, the sand has good air permeability, fully releasing the heat accumulated during the day and maintaining the temperature stability at night. Secondly, the porosity of sand is high, a large amount of rainwater can quickly infiltrate into the sand during the rainy season. The remaining rainwater flows into the open channel and is discharged into the sea, so that the settlement avoids the impact of rain and flood disasters (Figure 4). In addition, the sand is not easy to produce muddy water after the rain, so it has little impact on the outdoor activities of the fishermen after the rain.

Figure 4 ： *After the rainstorm*

2. Block Ecological Strategy

The streets are not only the transportation spaces of the seaweed house settlement, but also important places for outdoor activities of local fishermen. Therefore, the microclimate environment of street space directly affects the quality of outdoor activities of fishermen. The microclimate environment in the street space is mainly affected by two ecological factors, wind and solar radiation. The seaweed house settlement can provide fishermen with a cool space through the appropriate street height-width ratio .The streets can also guides the summer ventilation and blocks the winter cold wind with reasonable street orientation; The ‘long street short lane mode’can effectively stabilize the wind and thermal environment of the street space. The ecological strategy of the seaweed house street space includes,

2.1 Shade-cooled street aspect ratio

The air permeability in the coastal areas is high. The ultraviolet rays can effectively pass through the atmosphere to reach the ground. In addition, the reflection of ultraviolet rays by seawater and the stimulation of human skin by saline-alkali air can easily cause ultraviolet burns on the skin. In the summer, reasonable street height ratio of seaweed houses helps to create more shaded areas street space, effectively alleviating the effects of ultraviolet rays, and avoiding the radiation warming effect caused by direct sunlight. It is important for seaweed house settlements to improve the comfort of summer street space.

In the seaweed house settlement area (latitude 37°north), the influence of solar radiation on the thermal environment of the north-south roadway is greater than that of the east-west street. Therefore, the seaweed house settlement is usually have east-west street and north-south narrow alley. Take the street space of Dongchudao Village as an example, the height-width ratio of the street of east-west streets effectively reduce the solar radiation entering the street. At night, the sky space

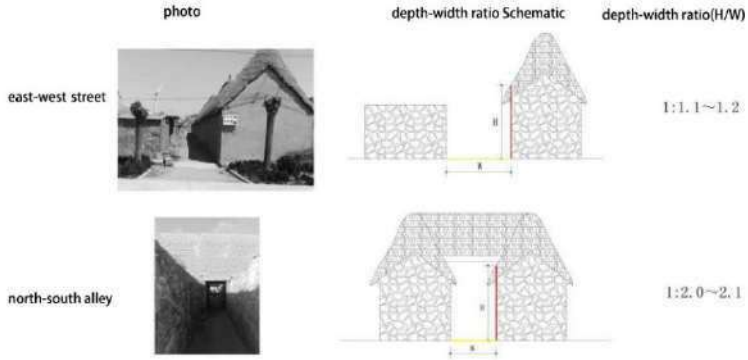

Figure 4 ： *street (alley)shade*

factor of the seaweed house street space is large, and the heat dissipation through long-wave radiation with less hindered. The heat accumulated during the day can spread rapidly so that the street space in summer is very cool. For the north-south narrow alley, although it is exposed to direct sunlight at noon, its small width prevent solar radiation from entering the alley so the solar radiation has little impact on the outdoor activities of fishermen. Local fishermen often use the method of riding the roof to enhance the shading effect (Figure 6). In addition, because the sunshade effect of the seaweed house settlement space is good, the air temperature in the street space is lower during the daytime, and the high temperature air above the roof cannot enter the street space, so the street space can be keep cool.At night, the solar radiation

disappears, the temperature of the air above the roof drops sharply, the temperature is lower than the temperature of the street space, and the cold air enters the street space and forms a convective wind, which makes the micro-climate in the street space cool and pleasant.

2.2 The influence of street orientation on the wind

The seaweed house settlement street is about 15°eastward from the south of the settlement, which can effectively guide the summer ventilation and block the winter cold wind. In summer, the local wind direction (southeast wind) and the street direction (east-west street) are at an angle of 60°. The wind environment simulation software PHOENICS was used to simulate the wind environment of the seaweed house street space. It can be seen from the simulation result 1 (Figure 5) that when the street interface and the airflow direction are at an angle of 60°, the effective span becomes smaller, which can effectively guide the airflow . so that the wind speed in most areas of the street space is between 1.2 and 1.8 m / s, which is very comfortable in summer. In addition, when the basic airflow in the summer is weak, the unique' sea breeze and land breeze' is blown into the settlement with the wind direction is parallel with the street direction. So that the wind has less resistance during the flow, and the street space can still obtain a comfortable wind speed. In winter, the local wind direction (northwest or northwest) is between 95°and 110°from the main street, and the wind direction is basically

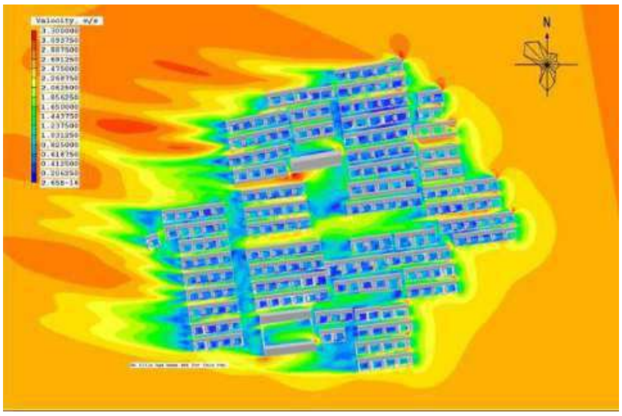

Figure 5 : Summer wind simulation

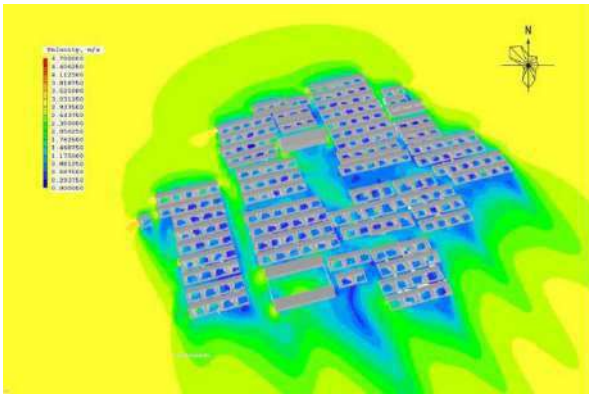

Figure 6 : Winter wind simulation

perpendicular to the street. From the wind simulation result 2 (Figure 6), the wind speed in the street space is significantly smaller than the wind speed outside the settlement. In most areas, the wind speed is between 0.3 and 0.9 m / s, and the human body barely feels the wind speed. It can be seen that the street space can effectively block the cold wind, greatly reduce the wind speed in the street space, and minimize the heat loss caused by the cold air movement.

2.3 Climate stable street pattern

The reasonable orientation and aspect ratio of the seaweed house settlement street effectively improves the thermal comfort of the street space, while the' long -street-short-alley' mode can further stabilize the thermal environment in the street space. Limited by topographical factors such as mountains and coastlines, seaweed house settlements are generally arranged in rows (Figure 3), forming a street pattern of' east-west long streets and north-south short alley' (Figure 7). This kind of street mode can bring more shadows in the summer while storing more heat in the winter. In addition, the number of north-south alley in the seaweed house settlement is small, which can reduce the channels for the northerly winds entering the settlement in winter. The existing north-south alley are also tortuous. After the cold wind enters the alley, the flow is blocked and the wind speed is greatly reduced.

3. Courtyard ecological strategy

Courtyard is the most commonly used place for fishermen. Its temperature, humidity and wind speed directly affect the comfort of living. Seaweed houses are highly ecological and coastal in terms of courtyard layout, building scale, building materials and their construction practices. The ecological strategy of the courtyard of seaweed houses includes:

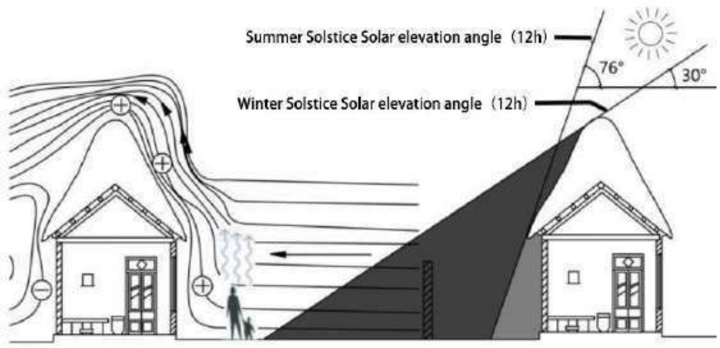

Figure 7： Seaweed house profile

3.1 Reasonable courtyard space

(1) The combination of courtyards: affected by the coastal climate and the defense military, 3 to 5 seaweed houses are general in a row, and the two share the middle wall (locally known as “JieShan”). This type of courtyard link can save land and save building materials and reduce heating energy consumption. It also reflects the good neighbourhood between fishermen.

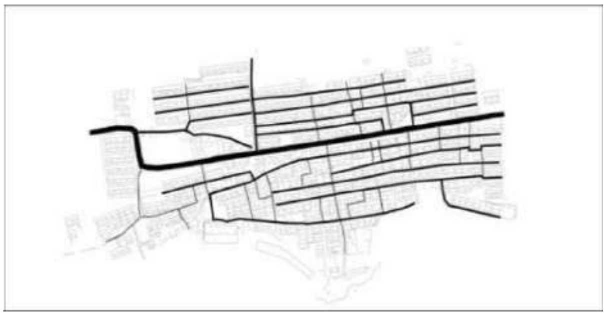

Figure 8 ： street and alley

(2) Reasonable courtyard size: The courtyard of the seaweed house is 5~7m long from and 4~5m wide. In summer, the deciduous trees planted in the courtyard are lush and cover almost the entire courtyard and making the temperature in the courtyard lower than the temperature outside the courtyard. The difference between the internal and external air pressure promotes the air flow, which brings the cool air and promotes the evaporation of water, which can effectively dehumidify and dissipate heat. In the winter, the small courtyard space and the heavy structure make the inner space of the courtyard less affected by the external cold wind, forming a stable and comfortable microclimate.

(3) Reasonable main room scale: The plane of the main room of the seaweed house is rectangular, and the width of main room (9~12m) is beneficial to increase the radiation heat in winter, and the depth of main room (3.6~4.0m). At the same time, the square shape has the smallest coefficient (about 0.6), which can effectively improve the indoor thermal environment.

3.2 Towering roof

The roof of the seaweed house has a large slope, usually between 50°and 60°, which adaptability to local climate well. In view of the climatic characteristics of high winds, high precipitation and sufficient sunshine, the slope roof can make full use of wind resources and solar energy.

3.2.1 Leading the winter cold wind to high altitude

In winter, the wind speed and humidity in the coastal zone are large, and the humid cold wind makes people feel abnormally cold. The roofs of seaweed houses are connected to each other to form a continuous wind-shielding interface, which can effectively lead the winter cold wind to the high altitude, greatly reduce the wind speed inside the settlement, and slow down the heat exchange process through the vertical circulation flow. In the simulation of the winter wind environment in the seaweed house settlement (Figure 9), the wind speed at the courtyard space of the seaweed house settlement and the pedestrian height (1.5m) of the street space is 0.5~0.9m/s, which wind speed in winter. In addition, the saddle-shaped curve

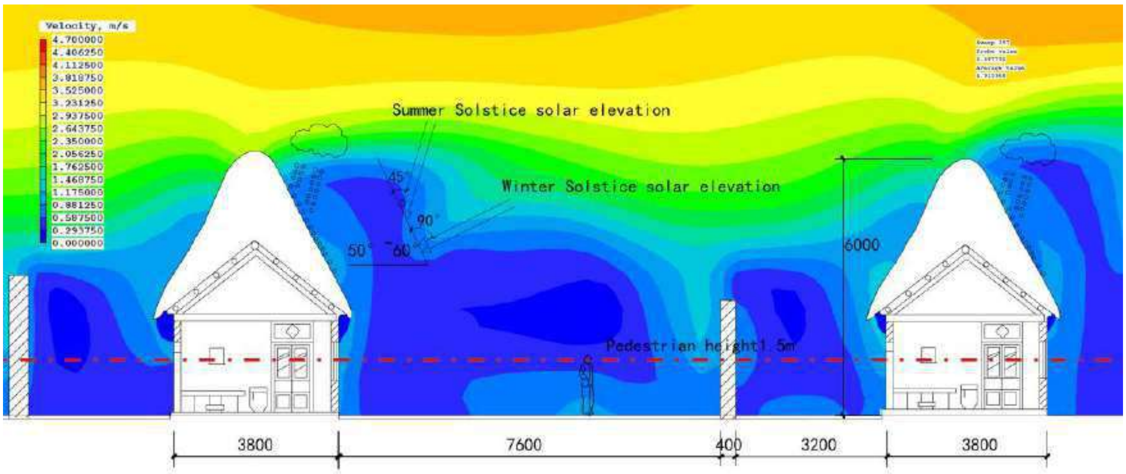

Figure 9：Profile wind simulation

of the ridge of the seaweed house can smoothly guide the airflow, avoiding the “corner wind” effect, causing the wind speed at the ridge to be too large, and blowing the seaweed on the ridge.

3.2.2 Make full use of sun radiation in winter

The roof of the seaweed house helps to absorb winter solar energy and prevent summer exposure, improving the thermal comfort of the indoor environment. As shown in Figure 10, the roof of seaweed house is basically perpendicular to the sun's rays on the winter solstice. The effective area on the sunny side of the roof is the largest. The thick material absorbs the solar radiant heat during the day and effectively blocks heat loss the indoors On the summer solstice, the roof and the the sun's rays at a angle 45°, which reduces the roof's radiation area by 30%, helping to create a cool interior environment .

3.2.3 Accelerate drainage and reduce accumulated snow

In order to minimize the impact of heavy rain and snow in the coastal zone, the slope of the seaweed house has a slope of 50°~60° (Figure10), which can quickly eliminate summer rain and reduce accumulated snow. According to the mechanical calculation, under the same friction coefficient (with a friction coefficient of 0.1), the 60°slope roof is 1.7 times better than the 30°slope roof, and can reduce the snow by 50%. The good drainage performance of the seaweed house roof prevents the seaweed from being damp and greatly prolongs the service.

depth-width ratio	Slope	Windward wind pressure	Leeward wind pressure	Description
≤1:7.5	≤15.0	-0.6	-0.5	The slope is very small, the windward surface reaches the maximum, and the roof is very threatening.
1:6.3	17.5	-0.5		The windward and leeward negative pressure values are the same, and the roof is subjected to a thrust of 0.
1:5.5	20	-0.4		The negative pressure on the leeward side of various slope roofs is -0.5
1:5.0	21.8	-0.3		Fujian coastal residential roof slope
1:4.0	26.6	-0.1		The windward negative pressure is very small
1:3.5	30	0		Windward without wind load
1:3.0	33.7	0.1		The wind pressure on the windward side is small and positive
1:1.0	45	0.4		Positive pressure on the windward side increases with increasing slope
≥1:1.2	≥60	0.8		Slope ≥ 60°, positive pressure on the windward side is equivalent to vertical wall positive pressure

Figure 10： *Roof wind pressure*

3.2.4 Wind disaster reduction

Because the seaweed is light and easily blown by strong winds, the windproof performance of the seaweed roof is very important. The towering roof of the seaweed house can effectively alleviate the impact of strong winds. Table 1 shows the wind load coefficient of the roof under various slopes calculated according to the current 'Load code for the design of building structures'. It can be seen that the flatter the roof, the greater the negative pressure on the windward side, and the greater the negative pressure coefficient of the windward side of the roof. The slope of the seaweed house roof is generally between 50°and 60°, and the windward side of the roof is in the positive pressure zone (Figure 10). Therefore, the seaweed is not easy to be blown by strong winds, and the positive wind pressure on the windward side of the roof can press the seaweed more compact. In addition, the seaweed slowly absorbs the moisture in the air, and the roof becomes compact from fluffy, and the whole body is strengthened, and it is not easy to fall off. Even if the part is blown off, the seaweed is light, and it will not hurt local fishermen.

3.3 Ecological materials and construction

The fluffy seaweed roof and the thick rock wall are typical features of the seaweed house, which is due to the particularity of the building materials and the complexity of the construction process. The main materials of the roof are seaweed and wheat straw, and both materials are taken locally. The straw is smooth and breathable, and the seaweed is firm and resistant to corrosion. The thickness of the seaweed is gradually thickened from the eaves to the ridge, and the thickest part is 1~2m (Figure 11). This special structure maximizes the ecology of the material. The characteristics make the roof have good thermal insulation effect. The gap between the seaweeds also gives the roof a 'breathing function', which provides a cool and breathable condition for the interior space. In addition, the seaweed used for roof contain halogen and glue, so its service life can be as long as 100 years.The seaweed also has the characteristics of insect proof, antisepsis and non-burning. The granite blocks of the wall are all from the mountain around the settlement, the stone masonry is round and be builded in a random way. In order to achieve thermal insulation, the thickness of wall of the building is more than 400mm, and some of the walls are covered with a layer of plaster to prevent moisture. At the same time, the tiny permeability of granite (0.2%~4%) can effectively prevent outdoor moisture and rain from entering the room.

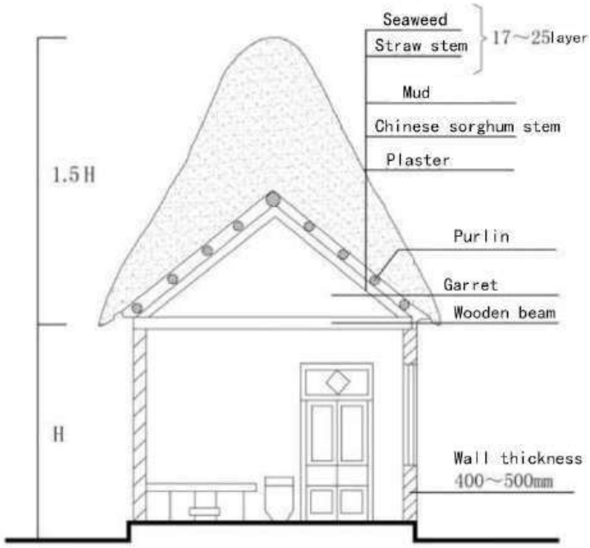

Figure 11： Construction practice

Conclusion:

The seaweed house is an important part of traditional Chinese dwellings which was been created in a specific environment for generations. As a symbolic residential symbol in the Jiaodong area, seaweed houses are gradually disappearing as the fishermen's lifestyle changes. We have the responsibility to protect the remains of the seaweed house and the ancient technology. At the same time, it is necessary to understand the aesthetic value from the construction process of seaweed house, explore the value of traditional ecological residential building technology and materials. We should study the application of traditional building materials in modern architecture, then promote development of traditional architecture.

Planning for Change: The Forms and Flows of Lisbon Metropolitan Area Food System

Teresa MARAT-MENDES
Instituto Universitário de Lisboa ISCTE-IUL, DINÂMIA'CET-IUL, Lisboa, Portugal.

1. Introduction

The aim of this paper is to introduce the goals and some preliminary results of a research Project 'SPLACH – Spatial Planning for Change', financed by European Funds through Portugal 2020 Program, which aims to contribute with new knowledge for a desirable shift of existing urban planning policies, in order to promote a low carbon and social inclusive urban system. SPLACH is about the role of cities, city networks, urban regions, metropolitan regions, and of spatial planning, in addressing structural changes (from crisis and post-crisis issues to climate change issues) and the societal challenges associated to those changes.
In order to contribute to the debate placed by SPLACH, this paper focusses its analysis on the contributions of two specific working packages prepared for SPLACH Project, which deals specifically with the thematic of Urban Planning and Food, namely: i) Transition paths to urban sustainability; and ii) Food Security and Sustainability.

2. Climate Change and the society request for Sustainability

Cooling the planet and improving the environment of our cities emerges as a collective social duty to which urban planners, urban dwellers, but also urban policymakers, should respond equally to counteract the effects of the occurring climate change, as argued within major international policies, ratified by most members of the United Nations, inclunding the Paris Agreement (United Nations, 2015a) and the Sustainable Development Goals (United Nations, 2015b).
Guiding the work of urban planners and policymakers, as well as the choices and daily practices of urban dwellers, in order to practice such Sustainability goals and agreement, emerges therefore as a crucial task. One, that should contribute to understand and intervene over the deep structure of cities, while acknowledging how the urban realm works and functions in terms of its various networks and respective flows (Batty, 2013).
A number of efforts, applied at the municipal level, are deemed to be identified as important contributions to respond to such request, at the same time that do emphasize the social and ecological dimensions of Sustainability, to which 'The New Urban Agenda' (United Nations, 2017) should also respond. For example, the recent Milan Urban Food Policy Pact (MUFPP, 2015) acknowledges the strategic role of cities and municipalities in promoting sustainable food systems, whereas enhancing food security and nutrition for healthy and equitable territories. Moreover, this Food Policy Pact reinforces the idea that is precisely at the municipal level, where urban agriculture and food provision can contribute to centre such debate on the urban planning sphere. Nevertheless, neither the urban forms that have been explored to respond to such problematic appear to have been sufficiently investigated (Lo, 2016; Parham, 2015), nor the processes of living, consuming and producing in cites, in which are included the social and economic flows that sustain the urban food system, appear to have also sufficiently investigated (Neuman, 2005). Therefore, a comprehensive approach to the metabolic function of cities, which could contribute to inform on how to optimize the efficiency of an existing urban fabric (Thomson and Newman, 2018), for example in terms of its food system functioning has not been sufficiently investigated.

In order to contribute to this debate, this paper argues for an integration of food within urban planning to support future planning policies and urban form guidance, that while emphasizing the metabolic functioning of the urban realm, could catalyse a desirable urban sustainability transition of the current urban system. Therefore, this paper aims to discuss the theoretical and methodological framework that has guided SPLACH project to approach the food system problematic, while dissecting the urban forms and the social-economic flows that affect the urban metabolic function of the urban realm. The research that is conducted at this project shall be applied in Lisbon Metropolitan Area (LMA), where most of Portuguese citizens live and work. In order to do so this paper aims to focus on the forms and flows, which seem to have been determinant within LMA food system, while scrutinizing possible typologies and relations, among them, which are deemed to be evaluated from a metabolic perspective. This theoretical and methodological framework aims to guide a possible analysis of the food system of LMA, whereas informing future analysis applicable to other areas.

3. Food and Urban Planning: towards a systemic approach of the socio-ecological urban system

"*Planning can and should constitute a sustainable transformative device for our cities in Europe and elsewhere, and particularly in times when environmental and societal pressures are being assigned. Indeed, current practices and behavioural changes seem far deeper within existing urban fabrics where a profound reorganization of functions and activities are occurring, when compared to urban areas, where past investments in infrastructures and in the built environment seemed to have exceeded the real demand and generated a surplus of the building stock, which in some cases remain partially empty or underused*" (SPLACH Project brief, 2017: 16).

In order to identify possible areas where urban planning could contribute to a sustainable transformation of the current urban system, the SPLACH Project was prepared for financial evaluation of the Program Portugal 2020, co-financed with European and Portuguese funds. This Project, coordinated by the University of Porto, was prepared with the contribution of the main areas of knowledge of three Portuguese research centres respectively, namely: i) CITTA, from the University of Porto; ii) DINÂMIA'CET-IUL, from Lisbon University Institute ISCTE-IUL; and iii) GOVCOPP, from the University of Aveiro. While the first centre is specialized in the areas of urban metabolism and urban planning and transport, the second research centre focus on the socio-economic perspective of the metabolic functioning of cities, Urban Morphology and Sustainability Transitions; and the third centre on issues related to Tourism and Urban Modelling. Furthermore, "*two to three main areas of knowledge were identified for each of these centres, respectively: post carbon cities, transformative policies, spatial planning, socio-technical system, food security, services of general interest, tourism and modelling. Based on these areas of knowledge and on the research strategy of each centre, seven Work Packages (WP) were identified for the SPLACH Project: 1) contemporary spatial dynamics, 2) transition paths, 3) food security and sustainability, 4) urban metabolism, 5) sustainable tourism, 6) planning services of general interest in times of austerity, 7) the potential of transformation of public policies. Finally, a further WP on urban modelling will congregate the contributions from the previous WP"* (SPLACH Project brief, 2017: 16).

The main objective of the SPLACH Project is to produce a comprehensive and coherent body of development control and transformative planning policies, implementation mechanisms, planning models and decision support systems, able to guide Portuguese planning practice, including both the public and the private sectors, at the plan making and the licensing stages - towards a rapid and effective transition to a low carbon and social inclusive urban system. The overall team of SPLACH Project includes Architects, Civil Engineers, Economists, Environmental Engineers, Geographers, Landscape Architects, Sociologists and Urbanists.

The work that is being introduced in this paper, regards in particular the line of thought which has been followed at DINÂMIA'CET-IUL, in order to contribute to the SPLACH Project, throughout the development of two specific but interlinked working packages, namely: 'Transitions Paths to Urban Sustainability' and 'Food security and Sustainability'. Furthermore, the research team that embraces the development of these two specific WP includes a multidisciplinary background, which includes Architects, Economists, Geographers, Sociologists and Urbanists.

3.1 Transitions paths to urban sustainability

"*Transitions paths to urban sustainability is a Work Package that is built upon a theoretical framework where the concept of Socio-Technical Systems (SST) is central. SST are sets of linkages between elements that are necessary to perform the big societal functions such as communication, energy, housing, transport and nutrition. The main goal of this WP is to produce new knowledge that supports the reading of a possible transition of the current function of SST towards sustainability, informing future territorial oriented policies on how to allow such transition process. Research developed at DINÂMIA-CET, over the last years, includes a number of financed projects which have covered this issue, wherein applied at Lisbon Metropolitan Area (for example the MEMO and the PERIURBAN Research Projects*[i]*) - its main case study, while covering different but specific problematics, such as land use, housing distribution, access to water facilities and agriculture uses*" (SPLACH Project brief, 2017: 46).

"The main strategy of the WP 'Transitions Paths to Urban Sustainability' is to draw on the available body of knowledge of the various disciplinary areas present at DINÂMIA'CET SPLACH Project research team, in order to support the reading of future areas of interest for the sustainability transition of the current functioning of the food system, in order to inform future urban policies" (SPLACH Project brief, 2017: 46).

Territory oriented policies, in general, and urban policies, in particular, constitute one of the main dimensions within such reflection for the achievement of urban sustainability. The implementation of a strategy towards a more sustainable city and of urban form (Marat-Mendes, 2002, 2013) and the shift to a new societal paradigm involves policy-driven actions aiming at land uses, territory planning and environmental issues (Marat-Mendes, 2014). *"Therefore, the analysis of SST and of Urban Metabolism includes the identification and the critical assessment of policies concerning Urban Planning, Agriculture, Rural Development and Environment"* (SPLACH Project brief, 2017: 46).

"*Land use and the development of economic activities in metropolitan areas are influenced by the classification of land through urban planning policies, which may present multi-level and multi-scale nature. Agriculture and rural development activities have an important role in the reflection of sustainability, including in the design of metropolitan areas. Therefore, agriculture and rural development policies are at the core of the debate on paradigmatic changes involving those areas. The financial support and the regulation of farm and rural activities supported by these policies have direct and multidimensional impacts on the territory and should be assessed in the debate on sustainability and urban metabolism. In addition, environment and ecological values do determine policies on land use restrictions and territory planning. This is the case of the Habitats Directive, the European Natura Network 2000 and legislation on Agricultural and Ecological Protected Areas integrated in territorial urban planning tools. Environmental policy includes other regulations and mandatory actions like EIA of projects with territorial relevant impacts in multiple dimensions. To sum up, the policy-driven strategy towards sustainability and the design of urban metabolism should also address the identification of policies which present important impacts on land use and territorial development, as here proposed*" (SPLACH Project Program, 2017: 46).

3.2 Food security and Sustainability

The main goal of the Work Package entitled 'Food Security and Sustainability' is to *"design a strategy that integrates concerns of food security with spatial issues towards a*

Post-Carbon City (PCC). This Work Package aims to provide an evaluation of the specific nutrition SST of Lisbon Metropolitan Area, while establishing a possible methodology which can be applied on other urban areas. This Work Package is established on the assumption that the nutrition SST is very relevant to sustainability and as such can contribute to a future agenda for a PCC, as already advocated by a number of political and scientific agendas (e.g., Europe 2020; EU Common Agricultural Policy; and Milan Urban Food Policy Pact). The acknowledgement of this issue is in line with the multidimensional approach to sustainability and the resilience of cities, which should consider the current main societal challenges such as food security, at different scales of approach in simultaneously. A number of complementary approaches to access the nutrition SST, including urban metabolism, food security, and technological and social innovation, accessed in the above identified working package 'Transitions paths to urban sustainability' are therefore determinant to inform the methodological approach that will be here followed. In addition, distinctive methods, tools and sources with interest to the investigation, which contribute to build the main analytical framework of the investigation, will also be identified during the development of this Work Package. Likewise, a number of relevant case studies carried out in other contexts will be used" (SPLACH Project Program, 2017: 48).

This framework should provide views on the impact of production, distribution and access to food at different territorial scales. "*The proposed framework acknowledges the analysis of the food SST of LMA, in a sustainability perspective, while prompting for an identification of the: (i) main obstacles that operate in the dominant system, in practice; (ii) the new and emerging experiences which are taking place in LMA, at present; and (iii) the characterization of the SST landscape of LMA*" (SPLACH Project brief, 2017: 48).

This Work Package draws upon previous research developed at DINÂMIA'CET, which included PERIURBAN, MEMO and TESS[ii] Projects. In particular, the first two have investigated the changes occurred in the territory of LMA in terms of land use, water infrastructures, agriculture, food and other resources, both in a historical and contemporary perspective, while making use of multidisciplinary methodological approaches, which have allowed the direct interaction with the main actors involved in the study area, and of varied methodological contributions from various disciplinary areas, from the social sciences mostly. *"The final output of this Work Package shall be the characterization of the nutrition SST of LMA; the identification of the key factors and agents able to promote change towards sustainability; and the construction of an analytical framework applicable to other contexts*" (SPLACH Project brief, 2017: 48).

4. The Food System. Concepts and main approaches

Following the introduction to the SPLACH project and to the two specific Work Packages, within which the relationship between the Food System and Urban Planning will be examined at SPLACH Project, the present section aims to introduce the preliminary results of the Food System literature review analysis, conducted at DINÂMIA'CET-IUL Research team, in order to identify how is the Food System defined and approached within current scientific literature, in particular dedicated to urban planning issues.

From the identified literature, it is possible to verify that there has been an increasing interest to the thematic of the Food System, from the scientific community, as testified by the available number of publications (articles and books) but also institutional and governmental reports. From this growing body of literature, it is also possible to identify a common ground of covenant in what regards the definition of food system itself. Unanimously described as a system of activities across which food is produced, processed, distributed, cooked, eaten and disposed. Within this description, other elements are also included, such as: i) the activities which are performed within the several steps of the food system; ii) the institutions and the actors which are related to those activities (Pothukuchi and Kaufman, 2000, p.113); iii) as well as the power relations established throughout such activities processes (Wekerle and Classens, 2015, p. 1178).

Consequently, this identified agreed basic definition of the food system seems to have contributed to the construction of an analytical methodological approach of the food system, which has mostly guided a process of desegregation of the food system itself. Thus, allowing the reading of the food system throughout its several elements and layers of contact, among its different scales of resolution (inclunding the individual and the collective, the public and the private, the local and the global, among others). Interestingly, Reisch et al (2013) have employed the term 'integrative paradigm' to define an adequate methodology towards the reading of the food system.

The definition itself and the above identified methodological approach has been able to place a number of problematics among the scientific community, namely: i) the impacts of the agri-businesses and the economies of scale, which have affected the western world and in greater level the emerging countries, throughout their processes of modernization of agriculture industry (Battersby, 2017; Steel, 2013); ii) the problematic of the high fragmentation character of the food industry (Reisch et all, 2013) which have urged a number of calls towards the need for interdisciplinary links between this field of study and urban planning (Brinkley, 2013; Cabannes and Raposo, 2013); iii) the fact that the food system has been left predominantly to the private sector in most western cities (Pothukuchi and Kaufman, 2000); and iv) the transformation that is occurring within the food system due to the absence of a food system planning (Battersby, 2017); among others.

Interestingly, it is precisely at the domains of the several points of contact of the food system (which integrates the social, the economic and political spheres) and on the best way to approach them towards a sustainability transition of the food system, where one finds however less consensus among the scientific community. This situation reflects a contemporary opposite positions towards the specific problematics, which affect society and the environment. For example, in what regards the level of acceptance of the neoliberalism position or the domain of the private market over the cities and its public space, but also the existing social inequalities (Cabannes and Raposo, 2013; Drago, 2018) and the sustainability threats (Cohen and Ilieva, 2015; Fischer-Kowalski and Weisz, 2016). These in turn, contribute to question which institutional structures or solutions of power distribution, do respond better to such urban systems and problematics.

In what regards the food system, its link to society, either in terms of subsistence, access to food, health issues, or its organization within space is paramount to the sustainability of the urban environment (WCDE, 1987; United Nations, 2015b; Mazzocchi and Marrino, 2017). Accordingly, Gandy (2006, 2004) identifies the functioning of any urban system, as determinant to the metabolic function of the urban environments, in all its various dimensions (social, environmental and physical for example). Therefore, understanding the functioning of the food system do contributes to rethink a new conceptual framework, which promotes a new imagine of how different institutions (which results from a social organization) could eventually respond in a closely manner to the society demands, across a variety of scales of space but also governance (Webb et al, 2018).

The relationship of the food system with the spatial dimension of the urban system (urban form) emerges therefore as a critical point. However, this has been mostly disregarded among the available literature, as already argued by a number of researchers (see for example: Cabannes and Raposo, 2013; Pothukuchi and Kaufman, 2000; and Brinkley, 2013).

From the available literature dedicated to the study of the food system and with interest to urban planning one should recall Carolyne Steel's book 'Hungry City – How food shapes our lives' (Steel, 2013) and Susan Paraham's book 'Food and Urbanism' (Parham, 2015), for expanding the discussions on food system within the domains of urban planning, wherein focusing on issues such as urban agriculture and urbanism, which were initiated in the beginning of 2000's with Kameshwari Pothukuchi and Jerome Kaufmam.

The research initiated by Pothukuchi and Kaufman (2000), based on an inquiry to planning agencies and institutions, concluded that most problems associated with the food system were expected to be resolved by the private sector, exposing however that the public planning authorities would be unable to ascertain its role.

It would be later in 2013 that two published works would underline the interest that the food system was gaining from the scientific community. One by Catherine Brinkley (2013) 'Avenues into food planning: a review of scholarly food system research', which would provide a comprehensive literature review, focusing on several aspects which has been approached by studies about the food system. Furthermore, Brinkley attention was mostly placed on recaps previous holistic definitions of the food system. Yet, it identified two specific areas, which were being missed in the food system literature: cultural capital and waste-disposal.
The second work regards the publication of the journal 'International Planning Studies', which in 2013 would dedicate an entire issue to the thematic the food system planning. Edited by Kevin Morgan (2013), issue 1 of volume 18 of this journal comprised an editorial text and eight papers dedicated to the rise of the food system in urban planning, while integrating both theoretical discussions but also the analysis of specific case studies from varied geographical contexts and problematics.
Interestingly, it was at the economics domain that the urban form, understood as the configuration of fixed metropolitan elements, which comprises several important features of cities, including density, compactness and land-use (Lo, 2016), emerges as an important issue to be considered within the analysis of the food system. Specifically, in what regards the increasing importance to the food system with a required analysis of sustainability transitions, which is in turn highly dependent on individual and community patterns of behaviour, mostly of households and communities (Lo, 2016). Understanding the behavioural dimensions of both sustainability (Lo, 2016) and the food system (Timmer, 2012), emerges also as an unexplored area particularly with respect to the food system. This includes dietary problems which despite their recurrent problematization in health scientific community but also urban planning (see for example Drewnowski et all, 2016 and Jiao et all, 2016), are not widely discussed in food system papers. Steel (2013) is again a very important exception, as her book explores consumption patterns and dietary behaviours in her discussion of the food system.
Furthermore, not only urban planning appears to have disregarded the analysis of the food system, despite the growing literature on this thematic, as the several layers of the food system seem also to have received different levels of attention from the scientific community. For example, preference seems to have been placed on the food production level, when compared for example with consumption, distribution or even preparation phases. In turn, the urban planning responses to these specific problematics do find also different echo's, whereas the predominant one seems to be on the urban agriculture, at the production stage, linked to a particular fascination for the creation of a 'productive multifunctional landscape' (Viljoen & Bohn, 2012). However, this is a situation that places into question the social role of a future urban agenda, and of the planner's professions, as the agricultural labour that could shape such landscape has largely decreased since the 1970's, to the point of almost despairing within the western world (Fisher-Kowalski, Hass, 2014).
Although urban agriculture is also being studied by itself as a social and even political movement, there are many reasons why it is being so stressed within the food system literature. One important aspect is that the production phase of the food system is where most environmental implications are located, including land-use, soil degradation, water consumption and pollution, eutrophication, biodiversity loss, and introduction of hazardous chemicals (Reisch et all, 2013). On the other hand, industrial agriculture itself is a problem in terms of metabolism, as it is mostly dependent on non-renewable energy sources, with deep implication in Net Primary Production – energy fixed by autotrophic organisms – which is at the basis of heterotrophic food chains and accumulation of carbon stocks in soil (Erb et all, 2016).
As most planning activities are related to urban soil, and specifically into the organizing and development of built areas, the reconceptualizing of urban land and urban landscape to include productive areas (Viljoen and Bohn, 2012) merges as a critical debate. An understanding of the socio-metabolic implications of this problem is important, as different types of land-use will translate into different advantages and potential sustainability pitfalls.

Land-use intensity, rather than land-cover seems to be a more productive option, although it entails problems on its own, including soil degradation, groundwater and air pollution and biodiversity loss (Fischer-Kowalski and Weisz, 2016; Erb et al, 2016).
People living in cities must recognize themselves as selective agents in the determination of what species can and cannot live in cities, including the possibility of reducing the number and variety of native species of a given territory (Alberti: 2015,115). Thus, this place into question the participative level that urban citizens should take in future urban agendas and the social role of planners themselves in such a process of sustainability transition.

5. Searching for Forms and Flows of the Food System. Towards a social-ecological reading of its metabolic behavior: LMA case study

As in many other European cities, LMA has witnesses in particular after the financial crisis of 2008 a number of new situations, either in planning practices and policies (Mourão and Marat-Mendes, 2016), but also in its food system, in terms of urban fabric but also of new social and economic practices. However, what are the impacts of these changes on the metabolic function of the city? What lessons can we retrieve from these to regenerate the urban realm in a Sustainable manner? Finally, further work of Project SPLACH aims to contribute to clarify to some of these questions, and therefore offer a more territorialized and spatialized clues about the metabolic function of cities.

Cascading Threats of Climate Change on the Food System in Nigeria: An Overview

Olusola OLUFEMI PhD, Independent Urban Planner/Researcher, Oakville, Ontario, Canada,

> "When risk cascades through a complex system, the danger is not of incremental damage but of runaway collapse or an abrupt transition to a new, suboptimal status quo" (WEF, 2018:6).

Abstract

The cascading threats of climate change on food production, procurement and distribution and the resulting vulnerability and reduction of people's access to food (physical accessibility, quality of food available and purchasing power) have become issues of compelling attention in contemporary times. Increasing temperatures, declining and more unpredictable rainfall, more frequent extreme weather and higher severity of pest and disease are among the more drastic changes that would impact food production (Parry et al, 2007; Kotschi, 2007; Morton, 2007; Brown and Funk, 2008; Lobell et al, 2008). The paper utilizes a qualitative, informal approach and participant observation in examining the cascading threats of climate change on the food system in Nigeria. Content analysis was used in analysing secondary data captured through various books, academic journals, Internet reports and newspaper clippings. The paper adopts the vulnerability-hazard-risk framework as a conceptual approach. Integration of the food system and food planning within the Green and Brown agenda through participatory governance, collaboration and authentic dialogue provides an eco-efficient approach to minimising the ecological footprint and foodprint. A secure ecological foundation guarantees food planning within a cascading complex and interconnected threats of climate change.

Introduction

Climate change is defined as "a sustained shift in the average value of climatic elements (temperature, sunshine, precipitation, wind etc.) either singly or in combination, the shift must be maintained for sufficient time to be measurable by Climate Normals, which are calculated over 30 year periods by the World Meteorological Organization and other bodies" (Smith, 2013:408). It is an outcome of human-induced driving forces such as the combustion of fossil fuels and land use changes, but with wide-ranging consequences for the planet and for human settlements all over the world (UN-Habitat, 2011). Climate change is caused by natural processes (biogeographical) and human activities (anthropogenic) (IPCC, 2007). Climate change impact on land uses is one of many complex and interconnected challenges that Planners deal with in the built environment. Paradoxically, failure of urban planning, failure of regional or global governance and increasing urbanization are among the interconnected risks of climate change (WEF, 2018).

World Economic Forum 2018 report indicates the most pressing threats that are perceived as having the biggest impact in the next ten years are extreme weather events and natural disasters, failure of climate change mitigation and adaptation, water crises, biodiversity loss, and air and soil pollution (WEF, 2018). For example, the Intergovernmental Panel on Climate Change (IPCC) report predicts the probability of more heat waves, heavy rainfall, droughts and other extreme weather throughout the 21st century (Parry et al, 2007).

The food system constitutes a critical and sensitive part of climate change. The connection between climate change and the food on your plate, our diet and global warming (Lappe, 2009) is, therefore, very profound. Climate change threatens biodiversity and ecosystem services across the planet (Millennium Ecosystem Assessment, 2005) and is a threat to the ecological foundation of agriculture and the food system. Climate change threatens the livelihoods, food availability and health of the population (Bassey, 2013:101). Destruction of forests for farming, mining, and oil and gas production, not to mention infrastructure development, remains the main driver of biodiversity loss" (Lancet, 2018:e51).

Climate change presents the food system in Nigeria with challenges for physical planners especially, land use and infrastructure planning. Planners are faced with the task of planning, shaping and designing liveable, equitable and sustainable communities as well as ecologically secure food system for future generations. As the population of Nigeria grows (about 195 million) and agriculture declines in importance, national attention to food production and food prices become compelling issues of attention.

The paper is structured in four parts. It gives a background to climate change as a threat to the food system, discusses briefly the food system in Nigeria, conceptualizes climate change and food security and suggests food planning as an eco-efficient approach to securing the ecological foundation in Nigeria's food system.

Cascading Threats

Mark et al. (2008) highlighted some of the direct impacts of climate change on agricultural system as: (a) seasonal changes in rainfall and temperature, which could impact agro-climatic conditions, altering growing seasons, planting and harvesting calendars, water availability, pest, weed and disease populations; (b) alteration in evapo-transpiration, photosynthesis and biomass production; and (c) alteration in land suitability for agricultural production. Some of the induced changes are expected to be abrupt, while others involve gradual shifts in temperature, vegetation cover and species distributions.

Climate change is the second type of systemic shock threatening cities with prospective unparalleled short to long-term impacts. Climate change comprises two complementary elements namely (a) the increasing frequency and severity of extreme weather events with short durations (e.g., hurricanes, storm surges or heat waves); and (b) slow-onset changes that are semi-permanent or permanent (e.g., sea level rise, falling groundwater tables or desertification) (UN-Habitat, 2010**)**. These two complementary elements of climate change bring about unprecedented levels of food insecurity especially among the poor and vulnerable groups who are always at the receiving end of extreme weather events because of their exposure. Climate change due to anthropogenic global warming (AGW) is commonly perceived as the greatest contemporary environmental threat facing the world. Urbanization and climate change are co-evolving in such a way that populations often in densely packed urban areas will be placed at much higher risk from climate change as well from other profound societal and environmental changes (UN-Habitat, 2011:2).

When the food infrastructure (land, soil, vegetation, water) is threatened by climate change, food security (availability, access, utilization and stability) is also threatened. Climate change according to WFP (2018:2) affects:

- “Food availability: Changes in climatic conditions have already affected the production of some staple crops, and future climate change threatens to exacerbate this. Higher temperatures will have an impact on yields while changes in rainfall could affect both crop quality and quantity.
- Food access: Climate change could increase the prices of major crops in some regions. For the most vulnerable people, lower agricultural output means lower incomes. Under these conditions, the poorest people — who already use most of their income on food — sacrifice additional income and other assets to meet their nutritional requirements, or resort to poor coping strategies.

- Food utilization: Climate-related risks affect calorie intake, particularly in areas where chronic food insecurity is already a significant problem. Changing climatic conditions could also create a vicious cycle of disease and hunger. Nutrition is likely to be affected by climate change through related impacts on food security, dietary diversity, care practices and health.
- Food stability: The climatic variability produced by more frequent and intense weather events can upset the stability of individuals' and government food security strategies, creating fluctuations in food availability, access and utilization".

Cascading Effects

Climate change exacerbates the risks of hunger and undernutrition through:

- Extreme weather events
  Climate change increases the frequency and intensity of some disasters such as droughts, floods and storms. This has an adverse impact on livelihoods and food security. Climate-related disasters have the potential to destroy crops, critical infrastructure, and key community assets, therefore deteriorating livelihoods and exacerbating poverty.
- Long-term and gradual climate risks
  Sea-level will rise as a result of climate change, affecting livelihoods in coastal areas and river deltas. Accelerated glacial melt will also affect the quantity and reliability of water available and change patterns of flooding and drought (WFP, 2018:2).

Vulnerability, Hazard and Risk Framework

"Food systems encompass all the people, institutions and processes by which agricultural products are produced, processed and brought to consumers. They also include the public officials, civil society organizations, researchers and development practitioners who design the policies, regulations, programmes and projects that shape food and agriculture" (FAO, 2013:x). The food system comprises the 5A's of food security namely; accessibility (effective distribution), availability (sufficient supply), acceptability (culturally acceptable/nutritionally adequate), appropriateness (ecologically sustainable) and agency (enables action).

Vulnerability to climate change manifests in three ways: people/population vulnerability, resource/infrastructure vulnerability and spatial/locational vulnerability. The co-evolving partners (urbanization and climate change) place a large proportion of the population, especially the poor, destitute and inadequately housed people, to much higher exposure and risk in urban areas. As Rosenzweig et al (2011: xvi) observes:

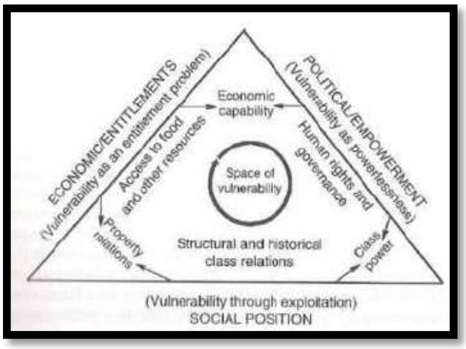
> "climate change exerts added stress on urban areas through increased numbers of heat waves threatening the health of the elderly, the infirm, and the very young; more frequent and intense droughts and inland floods compromising water supplies; and for coastal cities, enhanced sea level rise and storm surges affecting inhabitants and essential infrastructure, property, and ecosystems. At the same time, cities are responsible for no less than 40% of global greenhouse gas emissions, and given current demographic trends, this level will likely only increase over time".

The vulnerability, hazard and risk framework provides a conceptual basis to situate the vulnerability of the food system to climate change and its subsequent impact on agriculture and food production. This framework seemingly could be applied to agriculture and food production both in urban and rural areas.

Vulnerability is defined as the characteristics and circumstances of a community system or asset that make it susceptible to the damaging effect of a hazard (UN/ISDR 2009). Vulnerability is a dynamic concept rather than a constant state; it is constantly in flux due to changing interactions between geophysical and social processes through time and space (Smith, 2013).

Watts and Bohle (1993), described vulnerability as an aggregate measure of human welfare that integrates environmental, social, economic and political exposure to a range of potential harmful perturbations Vulnerability is a multilayered and multidimensional social space defined by the determinate, political, economic and institutional capabilities of people in specific places at specific times. Vulnerability arises from a complex web of economic (vulnerability as an entitlement problem), political (vulnerability as powerlessness) and social conditions (vulnerability through exploitation) (Figure 1) which vary over time and space.

Figure 1: Dimensions of Vulnerability



Source: Adapted from Watts and Bohle, 1993.

Vulnerability can be seen in terms of exposure, capacity and potentiality (Watts and Bohle,1993). Or in terms of exposure and defencelessness (Chambers 1995:175,189) comprising of two sides: “the external side of exposure to shocks, stress and risk; and the internal side of defencelessness, meaning a lack of means to cope without damaging loss. Loss can take many forms from becoming or being physically weaker, economically impoverished, socially dependent, humiliated or psychologically harmed”. Or in terms of exposure to risk and ability to cope (World Food Program 2002). Vulnerability context refers to the seasonality, trends, and shocks that affect people’s livelihoods and it is the result of many factors some of which relate to policies and institutions and a lack of assets, rather than particular trends, shocks or aspects of seasonality per se (Guidance Sheets, 1999, 2000).

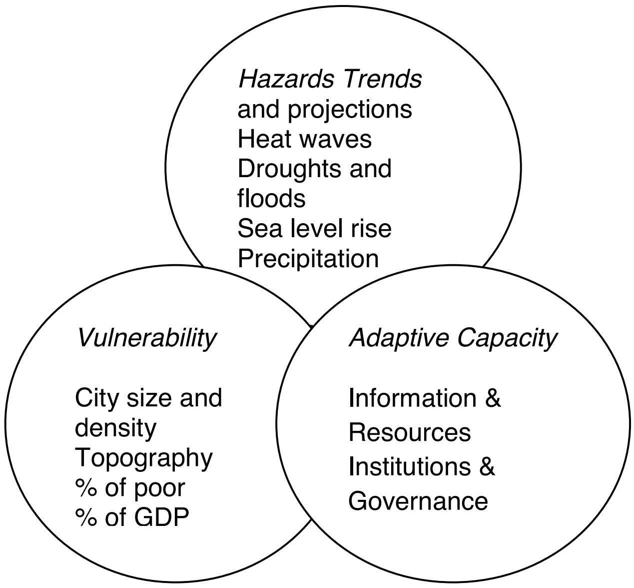
Thus, vulnerability can be summed up as the predisposition or susceptibility to any hazard that could cause harm or loss to human and/or physical and natural resources. In regard to the food system in Nigeria the complex interrelated and cascading threats and effects of Lake Chad Basin shrinking, Tomato Ebola, Boko Haram insurgency (conflict) and climate refugees among others, continue to impact on people’s livelihoods and their vulnerability.

In any climate change event (land degradation, pollution, flood, drought or desertification) people become vulnerable and food insecure. As a result there is the need to access food and this need hinges on entitlement. The various institutions machinery set up to ease the impact by providing resources sometimes exert their power over the powerlessness of the situation and thereby exploiting the weak and poor who lack economic capability during this period. Ultimately, this increases the space of vulnerability in terms of people, property, resources and infrastructures. Vulnerability seeks to capture the underlying causal processes that led to the actual status and which will probably influence future conditions (Lautze et al, 2003). Vulnerability is dynamic and describes how people move in and out of poverty and food insecurity (Frankenberger 2003; Brown and Gentilini, 2007).

The UCCRN climate change vulnerability and risk assessment framework (Figure 2) is composed of three sets of indicators:

- Climate hazards facing the city, such as more frequent and longer duration heat waves, greater incidence of heavy downpours, and increased and expanded coastal or riverine flooding;
- Vulnerabilities due to a city's social, economic, or physical attributes such as its population size and density, topography, the percentage of its population in poverty, and the percentage of national GDP that it generates;
- Adaptive capacity aspects, factors that relate to the ability of a city to act, such as availability of climate change information, resources to apply to mitigation and adaptation efforts, and the presence of effective institutions, governance, and change agents

Figure 2: Urban Climate Change Vulnerability and Risk Assessment Framework.

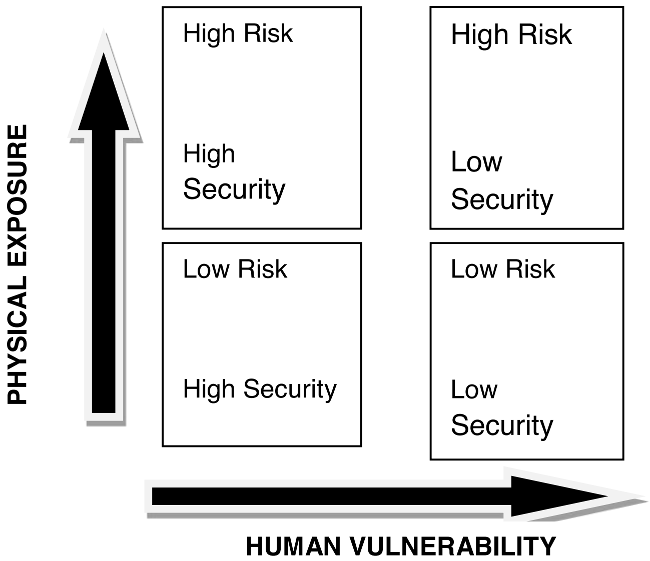


Source: Mehrotra et al. (2009).

Smith (2013) explains risk as: RISK= Hazard Probability x Elements at Risk x Vulnerability. "Hazard is a potential threat to humans and their welfare arising from a dangerous phenomenon or substance that may cause loss of life, injury, property damage and other community losses or damage while Risk becomes the combination of the probability of a hazardous event and its negative consequences" (Smith, 2013:11).

Smith (2013:9) affirms that "human sensitivity to environmental hazards (natural or technological) is determined by the physical exposure of people and their assets to potentially damaging events and by the degree of human vulnerability (or resilience) to such damaging events. Exposure and vulnerability are hazard specific in any one location, such as a river floodplain, but broader relationships can be displayed in a simple matrix (Figure 3). As physical exposure increases, human vulnerability also increases. Nigeria, with high exposures to risk especially in the coastal communities, find it difficult to fund hazard protection and to reduce exposure.

Figure 3: A Matrix Showing Possible Combinations of Physical Exposure to Hazard and Human Vulnerability in Relation to Risk and Security



Source: Smith (2013:9)

The food system in Nigeria is vulnerable to internal and external shocks presented by climate change. Natural and human vulnerability to the impacts of climate change are very high. Adaptive measures through food planning could be put in place to secure both the natural systems and human environment. Reducing the exposure to risk enhances the ability of the population, particularly, the vulnerable groups to cope. Vulnerability and exposure to risk could be mitigated through effective land use planning and food planning that facilitates accessibility (effective distribution, availability (sufficient supply), and appropriateness (ecological sustainability).

People/Population Vulnerability

The population groups most vulnerable to climate change and food insecurity include the low-income, poor, marginalised or indigent people in both developed and developing countries. Within this group are men, women, children (households, individuals), the elderly, homeless or inadequately housed, lone parents, disabled (physically challenged, mentally retarded), the poor living in food desert areas or do not have access (physical or economic) to food. These vulnerable groups do not have access to basic infrastructures and lack assets and do not have shocks to climate change impact. Lack exposes people's vulnerability. Lack, whether physical, financial, health, or otherwise, is profound among low-income, poor and no-income groups. The poor's resources and livelihoods become vulnerable to climate change impact particularly when there is flood, drought or other disaster occurrences. They do not have the shocks or safety nets to absorb the impact of climate change. These vulnerable groups skip meals, go on compulsory fasting due to erratic nature of access to food, unemployment and are always at the receiving end of climate change impact which subsequently makes them food insecure.

Correspondingly, the vulnerable groups' spatial location predisposes them to direct impact of climate change devastation. Evidently in most cities in Asia, Latin America and Africa most of the vulnerable groups are located in slums, squatter and informal/illegal settlements, marginal lands, hillsides/slopes, swampland with no infrastructures and facilities. The living conditions expose them to the vagaries of climate change and food insecurity. With poor assets, unstable livelihoods, and no entitlements, the vulnerable groups experience the complete onslaught of climate change and food insecurity. Low-income households often lack the resources to mitigate damages after they occur-for instance, through healthcare, structural repair, communication, food and water (Adger, 1999, 2000). In the absence of adequate recovery assistance, the poor often sacrifice nutrition, children's education or any remaining assets to meet their basic needs thereby further limiting their chance of recovery and escape from poverty (UNDP, 2007). When the poor's vulnerability increases, livelihoods become less securely sustainable; safety nets are weakened, and there is little or no family support.

UN-Habitat (2011) notes that poorer groups are disproportionately at risk for a variety of reasons such as:

- Greater exposure to hazards (Ruth and Ibarraran, 2009);
- Lack of risk reducing housing and infrastructure (poor quality housing, lack of drainage systems);
- Less adaptive capacity (lack of income or assets that allow to move to less dangerous sites or more quality housing);
- Less state provision for assistance in the event of a disaster (e.g. needed emergency responses and support for rebuilding or repairing homes and livelihoods; indeed, state action may increase exposure to hazards by limiting access to safe sites for housing) (Syukrizal et al, 2009);
- Less legal and financial protection (lack of legal tenure for housing sites; lac of insurance and disaster-proof assets) (Bartlett et al, 2009; Hardoy and Pandiella, 2009).

However, the vulnerability, risk and exposure of rural areas and its inhabitants to climate change and food security is different. Rural areas constitute the food production engine because of the vast land available for agriculture and food production. The components of a food system, i.e. production, processing, distribution, consumption and waste management are severely disrupted when there is drought, flooding, heat wave or rise in sea levels.

Climate change effects place additional stress on the already stressed agricultural land and the vulnerable groups, particularly poor farmers, become worse off. The most profound and direct impacts of climate change over the next few decades will be on agriculture and food systems (Brown and Funk, 2008). Climate change will adversely affect food security as shown by all quantitative assessments (Schmidhuber and Tubiello, 2007). Climate change threatens this engine base and the livelihoods of many who are dependent on land for survival and sustenance are compromised when there is soil erosion, landslide, and/or environmental degradation.

Resource/Infrastructure Vulnerability and Food Production

Olaniyi et al. (2014) opined that the dearth of statistical data and non-collection environmental data in a systematic manner make it difficult to estimate in concrete terms the overall effect of climate change on agriculture and food supply, flooding and erosion, health risks diseases spread, water resources, wildlife, level of CO2 emission and trends in temperature increase, and their effects on the social and economic systems of the country. In Nigeria, Odjugo (2008) shows that climate change has led to a shift in crops cultivated in the northern region as well as reduction of arable lands.

In Nigeria with regards to food availability, utilization, access and utilization, climate change affects food production, procurement, processing, distribution, consumption and waste management/disposal. A disruption of any of this leads to a cascading disruption of the entire food system. The cascading effects of climate change on food security include: Disruption in food production: irregular cycles of production; disrupted from the regular pattern of planting, harvesting; threat to national food security (local production is impacted, reliance on imports); global food security; Erratic food supply; Epileptic food access and availability; Increase in food prices; Artificial food scarcity/shortage; Market failure; Food-borne diseases from bacterial growth; Poor food quality; Declining incomes; Nutritional inadequacy and deficiency; Declining health/wellbeing and Increase in hunger and malnutrition.

The negative impact of climate change erodes the assets base of many countries and dislocates the food system as well as the human, natural, physical, financial and political capital of many. The components of a food system, i.e. production, processing, distribution, consumption and waste management are severely disrupted when there is drought, flooding, heat wave or rise in sea levels. The connection between soil erosion and food production, or flooding and food availability and access, or extreme heat, inadequate soil moisture and crop yield, or the destruction of micro-organisms which helps improve soil fertility and burning are part of the intricate web of food production.

Agriculture also provided gainful employment and a satisfactory livelihood to over 90 percent of the Nigerian population (NDHS, 2009). Agriculture remains a major driver of economic growth in Nigeria. It is composed of four subsectors: arable crops (including food crops), forestry (including tree crops), livestock (including poultry) and fishery. Agriculture contributed 41.5 per cent to GDP in 2008. The sector has continued its dominance in the economy, in terms of its

size and contribution to the GDP. The policy thrust during the first National Implementation Plan (NIP) (2010-2013) was to enhance total factor productivity in the agricultural sector through the application and diffusion of knowledge and improvement in the technology base.
However, the agricultural sector remains weak despite its contribution to the GDP. The inefficient production system is characterized by poor input; weak inter-sectoral linkages; ageing operators and an informal production and marketing structure and the agricultural sector remains strategic for national food security, employment generation, wealth creation and poverty reduction as over 65 per cent of the labour force is engaged in the sector (FRN, 2010).

Spatial/Locational Vulnerability

- *Desertification*

Climate change has started impacting on desertification (Odjugo and Ikhuoria, 2003) and it is impacting negatively on plant species composition in Northeastern Nigeria (Ayuba et al., 2007). Desert encroachment with its associated sand dunes is depriving farmers of their agricultural farmlands and grazing rangelands. It has also led to uncertainties in yield predictions, implying that crop productivity could either increase or decrease in a changing climate. Other potential impacts linked to agriculture include erosion that could be exacerbated by expected increased intensity of rainfall and the crop growth period that is expected to be reduced in some areas (Campbell et al., 2014). Odjugo and Ikhuoria (2003) observe that Nigeria north of 12°N is under severe threat of desert encroachment and sand dunes are now common features of desertification in states like Yobe, Borno, Sokoto, Jigawa and Katsina. The migrating sand dunes have buried large expanse of arable lands, thus reducing viable agricultural lands and crops' production. This has prompted massive emigration and resettlement of people to areas less threatened by desertification. Such emigration gives rise to social effects like loss of dignity and social values.

- *Rising Sea level*

Coastal settlements like Bonny, Forcados, Lagos, Port Harcourt, Warri and Calabar among others that are less than 10 m above the sea-level are now seriously threatened by a metre rise of sea-level. The sea incursion due to sea-level rise means salt-water intrusion into the fresh water, invasion and destruction of mangrove ecosystems, coastal wetlands and coastal beaches (Odjigo, 2010). Sea incursion is reducing the arable land of the coastal plains. The coastal inundation and erosion with their associated population displacement are currently major environmental problems in Nembe, Eket and other coastal settlements in Bayelsa, Delta, Cross River, Rivers, and Lagos States of Nigeria. It is estimated that a metre rise in sea level will displace about 14 million people from the coastal areas of Nigeria (Abu, 2007).

- *Shrinking Lake Chad*

The regional impact of Lake Chad shrinking, flooding and drought have significant impact on the food system and food security in Nigeria and increasing numbers of climate refugees.

Lake Chad provides water and sustenance to around 30 million people in four neighbouring countries. The crisis afflicting the strife-torn Lake Chad Basin is rooted in decades of neglect, lack of rural development and the impact of climate change. Some 7 million people risk suffering from severe hunger in the Lake Chad Basin, which incorporates parts of Cameroon, Chad, Niger and northeastern Nigeria.

In the latter, some 50,000 people are facing famine. Conflicts, environmental degradation and climate change including repeated droughts, are exacerbating the situation. Lake Chad has lost some 90 percent of its water mass with devastating consequences on the food security and livelihoods of people depending on fishing and irrigation-based agricultural activities. (FAO UN, 2017). The Chad Basin is one of the irrigation food baskets in northern Nigeria and it serves the whole country. The federal Government's efforts at augmenting food production at the Chad Basin have also come under serious threat causing food instability from the activities of Boko Haram insurgents.

Food Stability

Food stability in Nigeria is also threatened by Boko Haram insurgency, herdsman influx, the shrinking of the Lake Chad Basin, Tomato Ebola and the destructive impact of the extractive industry sometimes causing climate induced flooding, desertification and erosion.

Boko Haram Insurgency

The Boko Haram insurgence, the Fulani herdsmen intrusion have contributed to the fragility of the food system and increased the number of food poor and food insecure people. Boko Haram insurgency is a threat to food security in Nigeria. Citizens cannot go to the market or access food whenever and wherever they want, and farming activities are disrupted. The North Eastern part of Nigeria has been ravaged by Boko Haram insurgency displacing over 2 million people, causing hunger and poor food diets for several millions including children, women and nursing mothers; and killing over 17000 people since 2009. Several hectares of land prepared for rice cultivation and other grains have been abandoned in Borno because of insurgency and the multibillion Naira irrigation project is under threat (Soriwei and Okechukwu, 2013). Vast expanse of arable land has been destroyed and for two season farmers have been unable to go the fields to plant for fear of being attacked (Soriwei and Okechukwu, 2013).

Conflict between Boko Haram and the Nigerian Armed Forces has escalated since 2012 and is concentrated in the northeast and around Lake Chad in Borno State (Figure 6). The impacts of conflict on livelihoods, market functioning, and humanitarian response have severely limited access to food for both resident populations and displaced households. Acute food insecurity is widespread in northeast Nigeria, with the March 2016 Cadre Harmonisé estimating that more than 3 million people are in crisis (CH/IPC Phase 3) or worse and in need of humanitarian assistance. There is also visible malnutrition among adults and children, an extreme scarcity of food and water, very limited health facilities and a lack of functioning markets.

The impact is also felt in the south west. The south western region relies on the north for food grains. Olufemi and Ojo (2015) notes in the South west of Nigeria the impact of the insurgency is being felt in Lagos and Oyo States. Prices of foodstuffs like yam, beans and onions have skyrocketed. The open market became a space of insurgent citizenship where pandemonium breaks out between ethnic traders. In May and June 2013 about 14 Yoruba traders from Bodija market in Ibadan (Oyo State) were killed in Borno State by Boko Haram and this led to clashes between Hausa and Yoruba traders at the market. Food produce worth millions of Naira were destroyed.

- *Herdsman Influx*

Aside from the seemingly political undertone, the influx of herdsmen (Figure 4) into urban communities is partly a result of decreased fodder, famine, drought and desertification caused by both climate change and anthropogenic factors. Many farms and farmers have been driven out, displaced or killed by the herdsmen who take over these farms to graze their cattle.

Figure 4: Herdsmen in the City

Source: This Day Live 2018

In 2016 a Grazing Commission Bill was set up to propose a National Grazing Bill in the light of the Herdsmen incursion. The Bill aims at creating specific grazing areas as well as reducing attacks on states and communities by suspected herdsmen. Specifically, the National Grazing Reserve Bill seeks to institutionalize pastoral farming seeks to establish a commission which will take land in any part of Nigeria for use as grazing reserve. 75% of the farming population in Nigeria are women and there are about 50000 ha grazing reserve. There has been opposition to this proposed Bill due to its impact on the Land Use Act, grazing and ranching activities. Nigeria has about 84 million hectares of fertile land and agriculture accounts for two thirds of Nigeria's employment.

- *Tomato Ebola*

Tomato Ebola outbreak in 2016 led to scarcity of tomatoes. Tomatoes is used in almost every local dish/delicacy particularly stew and jollof rice. Its scarcity meant a lot deprivation for households. The moth 'Tuta absoluta' destroyed 80% of tomato farms in Kaduna State (Kaduna is the Tomato capital), and more than 90% of 17,000 hectares (42,000 acres) of tomato fields outside the northern city of Kano have been destroyed by the insect . More than 200 tomato farmers in the region have already suffered losses of more than 1bn naira ($5.02m) from the disease in Northern Nigeria (Agence France-Presse, 2016). This led the State to declare emergency, tomato processing factories shutting down and astronomical increase of tomatoes and scarcity of it as well. *Tuta absoluta*, which originated in South America and spread to Europe and Africa, quickly develops resistance to pesticides, making it difficult to contain. The brown moth lays eggs on tomato plants and develops into a hungry caterpillar that feeds on the leaves, stems and fruit.

- *Extractive industry*

Extractive activities make leads to the fragility of the ecosystems. Local droughts, relentless pollution, rise in temperatures, it is very clear that the continent is being cooked on carbon fires (Bassey, 2013:101). The exploration of oil in the Niger-Delta area has caused irreversible degeneration of the biodiversity and ecosystems, soil depletion and contamination as well as soil erosion. This is devastating for food production activities in the region and it has a cascading effect on the rest of the country. For example, the National Oil Spill Detection and Response Agency (NOSDRA) announced 2122 oil spill incidents were recorded between 2006 and 2009 (Bassey, 2013). The Niger-Delta region of Nigeria is one of the most polluted places on earth due to physical evidence of degradation, at least 10 communities in Ogoniland have contaminated drinking water with high levels of hydrocarbons, with 8cm layer of refined oil floating on the groundwater which serves wells and a depth of 5m hydrocarbon pollution in the soils (UNEP, 2011).

Food Planning: Preventing Runaway Collapse

The Federal Government of Nigeria established the National Fadama Development Project which is in its third phase and the presidential initiatives on rice, cassava, maize, vegetable oil, tree crops, tropical fruits, livestock and fisheries; and continues to maintain the National Strategic Food Reserve to meet food emergencies and for the stabilisation of income to enhance access of Nigerians to adequate food. There should be an emphasis on sustained policy and strategic food planning to ensure the achievement of the Sustainable Development Goal two to “End hunger, achieve food security and improved nutrition and promote sustainable agriculture” and the section 2.4 indicator to ensure sustainable food production systems and implement resilient agricultural practices that increase productivity and production, that help maintain ecosystems, that strengthen capacity for adaptation to climate change, extreme weather, drought, flooding and other disasters and that progressively improve land and soil quality” by 2030. “Security of our food supply will diminish unless we realize the central importance of the ecological foundation of the food system” (Achim Steiner, United Nations Under-Secretary-General, and Executive Director United Nations Environment Programme, UNEP, undated, p.vi). Securing the food infrastructure through food planning embedded in an eco-efficient approach will avert or prevent the runaway collapse or an abrupt transition to a new suboptimal status quo that will drive several millions to food poverty and hunger.

Food Planning

Food planning, the planning and spatial distribution of edible spaces to enhance accessibility, availability, ecological sustainability and reduction of foodprint in a way that fosters health and well-being, is the overarching strategy that could be adopted to secure the ecological foundation of the food system. Food planning would promote efficient and effective use of land, land use regulation and control; promote good environmental management practices to reduce land degradation, and enforcing land use laws among various land users. Physical planning could be effective in guiding food infrastructure, that is, what, where, when and how land is used for food production, procurement, processing, distribution and waste. This could be achieved by land use and environmental regulations to determine the spatial location of farms and edible food spaces without compromising future needs.

Food Planning could be achieved in Nigeria and other regions within the global context by:

- Recognising and linking the food system to other systems and subsystems like health, education, culture, transportation, housing, environment, economy and the spirit (faith).food planning with effectively foster this linkage(s) by providing adequate plans, spatial mapping of the food system and suitability or not of land use for agriculture and food production.
- Reducing Ecological footprint: Integration of the Green and Brown agendas. The Green and Brown Agenda emphasises reducing the ecological footprint and ensuring that the ecosystems are not degraded by climate change or human endeavours. The eight trends of the Green and Brown agendas (UN-Habitat, 2009) which focuses on: developing renewable energy, striving for carbon-neutral cities, developing distributed power and water systems, increasing photosynthetic spaces as part of green infrastructure, improving eco-efficiency, increasing a sense of place, developing sustainable transport and developing slum free communities have significant relationship with food security and planning values. Both Agendas emphasise maintaining ecological health and sustaining the bioregional ecosystems on the long-term for future generations. Physical planning promotes the same core values of environmental management and sustainability in an equitable and efficient way. Embedding physical planning within the green and brown agendas helps to secure an ecological foundation for Nigeria's food system.

- Promoting eco-efficient communities: an integration of the natural, human and planning values would provide a secure foundation for an eco-efficient food system in Nigeria. Also by reducing, recycling and reusing food waste, communities can begin to be more eco-efficient. Adapting the cradle to cradle concept (developed by McDonaugh and Braungart, 2002) in Nigeria where resources and wastes can be shared like an ecosystem is a germane to an eco-efficient food system. This can be achieved through:
    - Food Infrastructure: Promotion of Green food infrastructure and Green Planning (eco-friendly planning), renewable energy, local food and fibre, and biofuels. There has been a positive trend in planning in the direction of an expanded notion of urban infrastructure that includes the idea of 'green infrastructure' based on photosynthetic processes. Green infrastructure refers to the many green and ecological features and systems, from wetlands, to urban forests, which provide a host of benefits to cities and urban residents-clean water, storm water collection and management, climate moderation and cleansing of urban air among others. Growing energy and providing food and materials locally is becoming part of urban infrastructure development. The use of photosynthetic processes in cities reduces their ecological impact by replacing fossil fuels and can bring substantial ecological benefits through emphasis on natural systems (UN-Habitat, 2009:119).

    - Food Governance: Encouraging Participatory food governance and collaboration. Planners should take the leadership role in fostering authentic dialogue, collaboration and interdependence within and among various role-players (Agriculturists, Local Governments, Research Institutes, Universities and other relevant institutions and professionals), stakeholders (private sector, small scale business owners, informal sector), and the civic society, Community Based and Faith-based organizations. Public-Private governance which encourages voluntary, private and mobilization could be a step in the right direction to securing the ecological base of the food system in Nigeria.
    - Food sovereignty is the principle that people have the right to define their own food and agriculture system (Food and Water Watch, 2009:42). Food sovereignty is the people's right to define their own policies and strategies for sustainable production, distribution and consumption of food that guarantee the right to food for the entire population (World Forum on Food Sovereignty, 2001). Food

Sovereignty is the people's right to voice their opinion on food issues and decisions, from farm to table (production to consumption) (Olufemi, 2013).

Conclusion

The importance of the ecological foundation of the food system for the local, national and global economy requires adequate and sustainable protection, otherwise, it will continue to diminish right in front of our eyes and the food security of generations to come will be threatened. Building a sustainable food system in Nigeria and elsewhere is a means to secure the ecological foundation of food security (UNEP, undated). Sustainable food systems, as part of a new Green Economy, provides an alternative to current food systems and can help secure the ecological foundation of agriculture and fisheries. Sustainable food systems enable the production of sufficient, nutritious food, while conserving the resources that the food system depends on and lowering its environmental impacts (UN-Habitat, 2009). Food planning secures current and future land use, food supply capacity and production,

Planning to secure the ecological foundation of the food system must focus on land use, land use regulation, reduce sprawl and encroachment of the agricultural lands, environmental management, governance, promoting green infrastructure and green planning (more trees, vegetation and greenery), and campaign to reduce ecological footprint and foodprint. These can be achieved by good and participatory governance (not representative governance) and effective leadership, appropriate financing to minimise waste and corruption, discipline on the part of all citizens (green mindset and integral ecology), political will, education and awareness, sustainable participation, collaboration and authentic dialogue at every level from household to highest level of government and effectively engaging cooperatives and associational life groups such as youth, town unions etc., through mutual cooperation and authentic dialogue.

Shymkent City

Pomazan, Roman; Khvan, Alexander; Ostapenko, Pavlo, KYIV, Ukrain

ABSTRACT:

Shymkent is the fastest growing city of Kazakhstan, that has large amount of urban issues to be solved.
Shymkent City was envisioned as the key urban driver of the most young-populated megalopolis of Shymkent. This new neighborhood is going to represent new comfortable urban environment, that should became the specimen for urban transformations of Shymkent in the future.
The whole concept of Shymkent City built on eleven qualitative criteria of urban environment: human scale, regulation of building height, differentiated transportation, comfort public spaces, mix use, open city structure, compact city, diverse architecture, city anchors, BIM standards and green building. Key developed strategies of Shymkent city envelop quarters, landscape, transport, public spaces, creative indutries, education and business, smart city and stakeholders.
Key urban issues of Shymkent are transportation, education and arid climate. All these issues worked out in Shymkent City. Bioclimatic architecture encircled basic solutions for arid South Kazakhstan climate. Education facilities and business incubators resolved the challenge of large generation of schoolchildren and self-employed young entrepreneurs. Tram and Bus Rapid Transit made circlulation through the city fast and comfortable.
Urbanization traditions of Middle Asia has not been left aside. Urban structure of Shymkent City based on the grid of quarters, those resemble traditional "makhallya" - perimeter-build-up courtyards, that compose the whole pattern of the city.
Design of Shumkent was performed by mixed team of Ukrainian and Kazakh professionals in the beginning of 2018. Later it was adopted by local authorities and started implemented. Albeit some challenges, we consider Shymkent as a key finance and cultural city of Middle Asia in closest future. And Shymkent City is going to became the kick off for this urban transition.

Past knowledge and new strategies: Are Iranian cities ready for climate change?

Renault, Pierre, PARIS, France

ABSTRACT:

Iran is known to have sheltered the first cities of the world, using several technics of construction to adapt as well as possible to the hot and semi-arid climate which is covering the vast majority of its territory. The *Qanats*, a three thousand-year-old irrigation system were used for drinking water supply as well as irrigation of agricultural lands or lush and shady gardens. The underground drainage system takes source on the foothills aquifer of the numerous mountain of Iran. The *Bad-gir*, (wind tower), is a system creating cycles of fresh air inside the houses, playing with the pressure balance and the humidity rate. In Yazd, some of wind towers were even connected to the Qanats to increase the freshness effect when the air is in contact with the water.

The management of air, water and sun/shadow and technics such as *Qanats* or *Bad-gir* have however gradually disappeared, replaced by more modern technics but certainly less ecological or economic.

It seems interesting to confront the neglect of those localized technical tools to a more global reflection on the urban issues of climate change, particularly through the question of urban heat islands.

In Tehran, the urban dynamic is currently more spreading than the rehabilitation of old neighborhoods. The north of the city is denser and new cities appear while the old buildings fall into ruin. Human activities (the presence of the Grand Bazaar) and the hyper-motorization of society (private cars, cheap oil ...) contribute to change the form of the city. In addition to these issues, many *Qanats* have been closed (construction of the Metro, foundation of high-rise buildings) and, in the 1970s, most of the mountain streams that used to pass through the heart of the city were deviated from the city, for security reasons related to flash-floods. All those phenomena giving rise to a real “drying out” of the old city center

As part of the city's river renovation program, the municipality's services are currently conducting a series of technical studies on all the city's rivers with 5 main goals: Security, Ecological environment, Relation with citizen, Water quality and quantity, Urban renovation.

There is no doubt about the relevance of the water return in the city through the questions of urban renovations, notably to remedy the question of the islands of heat: refreshment, creation of landscape and shaded environment, and for inhabitants, back to the pleasure of contact with water.

The return of water to the city is proposed through the river renovation program, which certainly deserves to be conducted as part of a broader reflection, a vision that takes into account the urban dynamics at the metropolitan scale. How to integrate the city within its geographical Hinterland and how to take into account the large landscapes as green or Blue corridors?

Otherwise, it appears that a number of technical solutions are known: Retention of rainwater, Water Sensitive urban design... If so, how to promote and implement them? How to consider the urgency of the climate issue on urban planning documents?

It appears that the climate subject is beyond us, by its temporality and by its universality. But it also appears that many solutions exist before our eyes. Could Iran, through its ancient technics of air, water and sun/shadow management, become a hotbed of knowledge and practice for cities and constructions adapted to the arid climate?

Substitute industries and economic change as a chance for cities to become more sustainable

A Case Study examination of the City of Völklingen, Germany

Jakob SCHACKMAR, Technische Universität Kaiserslautern, Germany

Introduction

Globalization causes an ongoing process of structural economic transformations on local and regional level and the relocation of industry changes the economic basis of a lot of cities worldwide. Many of these cities also have to face long-term economic and demographic challenges. The impact on cities and citizens pose big challenges on today's urban planning (Pallagst 2008). Cities struggle to reinvent themselves based on new economic principles (e.g. sustainability) and new substitute industries. Substitute industries are defined as a primary replacement of jobs as well as a strategy for the general revitalization or restructuring of the local economy. The term "substitute industries" does not give any concrete pointers to a specific industry or sector (Pallagst 2017).

However, in many cities around the world, the share of the three economic sectors changed in the last decades, from the secondary to the tertiary sector leaving many old industrial and commercial brownfield sites in urban cores. Furthermore, many citizens have lost their jobs and could not easily be re-employed in the tertiary sector due to different qualifications needed In the meantime, globalization causes not only economic but also environmental problems by rising cargo trade and relocation of economic branches overseas due to lower production costs (Ellrich, Neuhaus 2012). This creates increased CO_2 emissions, particularly because of longer transport distances. In times of climate change and an alteration to a more sustainable-based economy, this matter is in need to be rethought and analysed. Long-term demographic changes (e.g. aging society & migration) in combination with economic changes result in a social aspect that also needs to be included when aiming at sustainable future development (Pufé 2014). Urban planning can play its chare to contribute to a more sustainable urban environment and develop approaches and tools towards more sustainable solutions. Urban planning can provide necessary frameworks and test fields by cooperating with the city in promotion of economic development. New substitute industries, such as commercial urban farming, can be attracted to provide sustainable new future-oriented jobs.

The case study of the City of Völklingen was selected to be on display in this paper based on its path of economic transition: From a mining and manufacturing town to other somewhat more innovative economic branches of the green economy and specifically urban farming. The research presented here is amalgamating select results of the authors master thesis as well as the Technische Universität Kaiserslautern's GIAGEM (Green Innovation Areas in Revitalizing German and Mexican Cities) project, funded by the German Federal Ministry for Education and Science (BMBF). The project as well as the thesis-applied case study research as a methodological approach, involving literature analysis, data analysis, and semi-structured interviews with stakeholders from the case study city. Preliminary research results were then validated in the frame of two workshops in the year 2017 and 2018 with experts from the respective cities.

1. The cause and effects of economic change and shrinkage in cities

The causes that can lead to an economic change and shrinkage of a city include various aspects. Characteristics are the following indicators as causes of urban shrinkage and economic change:

- Downwards spiral through global economic and social shifts
- Deindustrialisation of traditional locations in western economies
- The decline of a city-defining economic sector or several areas
- Outflow of the population of inner cities (suburbanization and long-distance migration)
- A special concern in monostructured spaces (Henckel 2003, Liebmann and Kühn 2010).

There are also other reasons for the already described, mostly economic phenomena (that are derived from different political and economic systems in west and east Germany), as well as the spatial relocation of entire industries and the associated job losses: The general difference is on display within Germany between the old mining and industrial regions in West Germany and the deindustrialized regions in the eastern part of the country. In the East, structural change was prevented due to the political system until reunification. As a result, the process of structural change and the associated urban shrinkage came suddenly and to unpredictable severity. In the West, however, it was and is a slow process (Ellrich and Neuhaus 2012, Glock 2007, p.1).

The natural population development in Germany is negative in terms of the natural birth rate since 1972. In addition, there is a shift in the average age and rising life expectancy. This so-called aging of the population is the result of the outmigration of mostly young, qualified and employment-oriented citizens from eastern Germany to western Germany as well as from old industrial centres (effected by economic structural changes) to cities with more modern oriented economies and employment opportunities. Furthermore, the migration from rural to urban areas for the same reason can influence population developments.
Thus, it can be concluded that the demography changes by its negative birth rates and due to population migration in the absence of prospects on the labour market and lack of education opportunities (Spiegel Online 2007, Deutsche Akademie für Städtebau und Landesplanung 2002, p.7ff).
At the moment, Germany is experiencing positive population growth on average. This is mainly based on immigration from economically weak European countries and on refugee movements from the crisis areas of the Middle East and Africa since the summer of 2015 (Breuer 2017).

A result of economic decline in the old mining and steel industries is a weakened local and regional economic base. The declining economic situation is characterized by a lower supply of jobs for the citizens, which in turn can lead to an increased outmigration of young and well-educated people as well as to a drastic labor shortage in the long term (Institute for Regional and Urban Development Research and Construction of the State of North Rhine-Westphalia (ILS NRW) 2003, S.A4).

The spatial consequences of structural change include among other things are inner-city vacancies and the urban sprawl or suburbanization of the urban peripheries (so called doughnut effect). Higher-income families looking for a single-family home in the countryside mainly practice this. Other effects can be the “perforated city”. It indicates visible unstructured shrinking within the city, resulting in urban brownfields or abandoned buildings everywhere in the city (Glock 2007).
With the loss of jobs, a spiral of self-accelerating decline can begin, resulting in sometimes existential-threatening consequences (for the municipalities). The question arises: Can the

shrinkage of a city be absorbed, mitigated or prevented if enough alternative, new jobs are being created?

The answer could be the formation and location of new clusters. Many municipalities or regions have their own cluster concepts for this purpose and try to locate and promote them in a targeted manner. In doing so, the focus is primarily on the new economy, e.g. information and communication technology companies or the green economy. But developments in the logistics industry also play a major role. An area dominating here is, for example, the increase of logistics centers, both in their number and in the claimed area (Henckel 2003, Haas 2017a). The most well-known types of **substitute industries** in Germany are industries or services that are credited with a certain innovative or economic power. The following typologies are the most common examples: **Culture and cultural industries** are becoming increasingly important for German urban development policy. It plays a special role in the "renaissance of the cities", since people live, produce and consume culture throughout every day. Thus, culture is constantly changing, it cannot be assumed that the same kind of project or initiative will work everywhere (Dengler 2010, Florida 2003). The substitute industy of **education and medicine** have always been important aspects for citizens. In the future, with increasing global competition for education and research resources, with the aging of society, and with medical advances, this importance will increase even further (Schober 2014, p.9; Peuling 2017). The production of goods and services around **High-tech and IT** will continue to be unabated in the coming decades. The developments are happening across all sectors of the economy and are characterized by a great dynamism of innovation. Therefore, the promotion and settlement of companies and institutes of this economic branch is considered to be particularly future-proof and is very popular with municipalities (Bundesministerium für Bildung und Forschung 2017). **Festivalization** is a new informal urban development instrument that emerged in the 1990s. The term refers to public events that have an influence on the city (planning). These include, for example, major sporting events such as Olympic Games or football championships, as well as other cultural events such as city festivals or performance shows like world exhibitions or fairs (Häußermann and Siebel 1993, p.7 ff.).

This development also includes the development of tertiary institutions (including service, research and education centers) within the city centers. These are called new forms of urbanization. Other aspects include the rediscovery of old means of transport such as the rail-bound infrastructure. But airports are also increasingly seen as an important means of more urban and regional development. Here, the influence of the logistics industry and the increased mobility behavior become visible. They count as a positive location factor and are regarded as the key to economic (re-) ascension (Henckel 2003).

Creating and locating new and alternative jobs for workers who have lost their jobs as a result of structural change is a tedious and complex task (Peuling 2017). The key to success seems to be the creation of a replacement or substitute industry for the municipality and its employees. The effects and consequences of city shrinkage particularly effect urban planning and municipal areas. At the same time, the question always arises as to whether it is possible to counteract these developments by means of a city-planning instrument, for example with the establishment of new companies and the associated new jobs. Urban planning needs to provide a new framework for the affected cities to make this reinvention possible.

2. Substitute industries and the tool's revitalizing role

Substitute industries can be economically, ecologically and socially profitable for a city if the choice on „the right“ industry and solution for the city is made. Also, the question arises “Can substitute industries generate or at least stabilize growth in a shrinking city, stop the population shrinkage and restore jobs?". The following chapter further defines and explains the instrument of the substitute industry, as well as needed vocabulary to understand the nature of the tool.

Revitalisation

Prior to the establishment or implementation of a replacement/ substitute industry strategy is the principle of revitalization. Revitalization (in the spatial sense) means that a city has basically set itself the goal of reviving a neighborhood, a district or the whole city. This includes both the repair of public infrastructure, the adaptation of public services to the population and a willingness to intervene in local economic development. The public sector can partially control this or set impulses in a direction of development. For example, it is possible to ban certain industries or trades (Peuling 2017).

However, it is more important to incentivize and promote specific industries where the city already has a certain base. Incentives can i.a. in the offered location, in the networking with science and research, in the connection to universities, colleges, in the technical infrastructure, in the possibility for clustering or even in financial nature. The financial incentives are divided into the activities of the municipality, in a deduction of trade tax or in the assumption of development costs and in an external share of public funds, such as corresponding subsidy programs of state, federal or European Union (Peuling 2017). Depending on the starting position of the city concerned, an individual case-by-case solution is necessary. There is not one strategy for a revitalizing measure (Pallagst 2017).

Substitute industries

In order to understand the concept of the substitute industry in the context of this work, it is necessary to explain and classify this tool.
Many shrinking cities have lost a major employer, or a whole branch of industry. They try to (re-)create jobs by means of targeted settlement of new companies in various branches of industries. In this case, the correct name in the sense of meaning would be the term "new settlement of alternative economic branches" (Pallagst 2017, Kunzmann 2009).

The term "substitute industries" is used to describe the primary replacement of jobs as well as the strategies for the general revitalization of the local economy. The term "substitute industries" does not give any concrete pointers to a particular industry or sector. There is no "right strategy" in dealing with shrinking cities and the location of one or more replacement industries from one industry or sector. Each city and region has other unique focuses in their (economic) history and therefore needs individual consideration. Nevertheless, some economic sectors are ahead of others when it comes to settling a particular replacement industry: Preferred industries include the tourism, logistics, cultural & creative, education & medical, high tech & IT and green technologies and infrastructures industries (Pallagst 2017, Pallagst et al 2017b, Pallagst et al 2018).

Green infrastructure

The green infrastructure (also called blue-green infrastructure) represents a strategically planned, urban network, which is composed of natural and semi-natural areas. These form a networked ecosystem that performs various functions for the community. For example Air pollution control, natural water management and the habitat for humans and animals. These areas are characterized on different levels of scale of different natural spatial configuration and equipment (European Commission 2013, American Planning Association 2007).

Often, revitalization projects focus on the use of inner-city fallow land, especially on the use of vacant, individual plots of land. These formerly commercial real estate or land areas provide a place where commercial and social projects such as urban or community gardening and urban farming can be implemented (Pallagst et al 2017b, United States Environmental Protection Agency (EPA) 2014).

The use of fallow or abandoned urban spaces offers the potential for a sustainable transformation of formerly polluted sites, as well as job creation in new emerging or revitalized areas, thereby sustainably changing and shaping the identity of places (Pallagst et al 2017b, United States Environmental Protection Agency (EPA) 2014).

The connection to high-tech or traffic projects is close. Green infrastructure can also be linked to new regenerative energy and new mobility concepts (Pallagst et al 2017b).

Urban Farming

One of these links of green infrastructure and the bioeconomy, as the more environmentally friendly oriented branch of industries, is urban farming. Urban farming combines the aspects of green infrastructure with a social context in terms of the creation of jobs as well as new farming produce as new resources. It has many positive effects, such as the reduction of the ecological footprint or the food security of urban residents. In recent years it became more popular and can be seen as an opportunity to revitalize densely populated cities, also due to the growing need of city residents to engage themselves in horticulture and to participate in civic projects (Pallagst et al 2017b, Peuling 2017).

By definition urban farming or urban agriculture is the use of land by individuals or groups in urban and urban like areas or their peripheries for the cultivation of food, for whose agricultural land consciously urban spaces are sought and used. The cultivation usually is closely connected with ecological and economic cycles as well as with the social life of the city (Stierand 2016). Urban farming is possible on small and large scales. Smaller scales are often referred to urban gardening. In this case, all forms of food production in settlement areas are included, such as inner-city farms or peri-urban gardens and solidarity-based as well as social agricultural projects (Haide 2014, p. 5).

Furthermore, there is a broad variety of urban farms, not solely the production of agricultural produce. There are many different forms of urban farming: **Leisure Farms** aim to combine the range of recreational activities associated with agricultural activities within or near the city. The farms offer ranges from practical experience with animals and crops, dining and agritourism or the equestrian sports. At **Therapeutic Farms**, the garden, forest, landscape, animals and plants are used for recreational or work-related activities. Target groups are in particular psychiatric patients, mentally stressed persons or people with learning disabilities. In the Netherlands, therapeutic farms, with a strong national organization are a successful concept in peri-urban areas. **Social farms** are designed to promote the integration of disadvantaged and marginalized people, for example by offering them jobs. Networks of social farms have already been developed at national or regional level in Germany, Italy, France, the Netherlands, Belgium and Norway. **Educational Farms** are often affiliated with Leisure Farms and may have a recreational component, but the educational function is dominant. These Farms usually offer recreational or educational activities to learners of all ages in urban areas of Central Europe (for example in Geneva, Toulouse or Stuttgart) (Lohrberg et al 2016).

From a historical view urban farms are not an invention of the 20th century. A very early form of urban farming is being practiced since the 14th century in the Mexican capital, Mexico City created by the Aztecs: The Chinampas Gardens, with sustainable and organic food production 20km outside central downtown (Sieg 2018). In the US there are efforts to establish the term Agrarian Urbanism or Agricultural Urbanism in urban planning to highlight the growing importance of food security. The Prinzessinnengaerten project in Berlin describes itself as an Urban Agricultural Project with the goal (Haide 2014).

However, since large-scale **urban farming**, run by company's rather than individuals or small groups, is more relevant to this case study than it is on a small scale because of its job creating nature. A good example of large scale urban farming is the town of Völklingen in the land locked German State of Saarland: Here, a **sea fish farm** was built within the city on an area formerly used as a coking plant. New future-oriented jobs were created in an old industrial location in a new branch of economy for the city (FRESH Corporation AG 2018).

Critics try to put the importance of urban agriculture into perspective, because they do not allow self-sufficiency of the cities yet. As the technology of urban farming, on large-scale food production is still being developed, it is expected to become more efficient and productive in the future. Today it is important to recognize benefits in the overall urban perspective. Urban agriculture produces many other goods in addition to agricultural produce: education, social cohesion, effective use of space and design, as well as the quality of life of its citizens. Urban Farming thus has a diverse potential for the city and its society (Stierand 2016).

3. The case of the City of Völklingen

The city of Völklingen, located in the German State of Saarland, showcases how green infrastructure is leveraged as a substitute industry in a former mining town. As Völklingen - in the early 2000s - came to a point when there was no significant job-creating industry left, the city decided to actively try to attract new industries and initiate revitalising projects. This practical example is characterized by its innovative approach of creating new, future-oriented jobs at the old industrial and mining areas. Therefore, the City of Völklingen has promoted a new industry for fish farming in the town (results of the GIAGEM Workshop in 2017).

Historical Background

However, the years of decline because of the monostructured economy has become a major problem for the city since the 1980s, as more and more factories (huts, mines, etc.) have had to close down due to increasing globalization. In 1973, 20,260 workers worked in the mining industry, representing 64% of jobs in Völklingen (with a population of 48.000 citizens). In 2016 the city's economy offered around 12.500 jobs in total with a unemployment rate of 11,1% (German median 6,1% for 2016) (Stadt Völklingen 2016, FIRU 2007, p. 42).

The geographical situation of the steep Saar Valley (at the German border) and the lack of awareness of alternative economic activities have resulted in this overall disastrous economic situation of the city. The municipal administration in Völklingen began to take care of the restructuring of the economy only around the turn of the millennium, beginning with the recognition of the Völklinger Hütte as a UNESCO world industrial heritage in 1994 (Stadt Völklingen 2017a).

As the city's financial dept restricts significant investment the city's public services company 'Stadtwerke', which is in charge of supplying the inhabitants of the city with the usual basic services such as water and sewage, electricity, gas, refuse collection, took on the role of looking for alternative, innovative and sustainable business plans. New forms of income should be generated with the aim of safeguarding the future viability of municipal utilities and at the same time improving the city's economic situation as well as create new jobs (results of the GIAGEM Workshop in 2017).

The Sea Fish Farm

As the new and innovative branch to be implemented in the city of Völklingen, Stadtwerke identified marine aquaculture, which is part of the emerging branch of bio-economy as well as urban farming. Aquaculture offers an alternative to both overfishing and the negative impacts of coastal marine fish farming. All in all, it helps reducing the ecological footprint of the production of fish. The site of the former coking plant Fürstenhausen was chosen to host Stadtwerke's aquaculture project. After the decontamination on site was completed, Stadtwerke built a pilot plant for marine fish farming. Part of the joint vision by Stadtwerke and the city of Völklingen was to generate future-oriented jobs in a new branch of economy with the first commercial land locked sea fish farming facility of its kind. The project is part of the global trend towards urban farming, as the fish farm can be built virtually independently of the sea or other bodies of water in almost all (urban)locations (Saarländischer Rundfunk Online (SR) 2018; GIAGEM Workshop 2017; Höll 2017).

With its innovative use, the sea fish farm can be seen as a best practice for a commercial urban farming project. Its nature is a new kind of land use type with the purpose of revitalizing vacant or abandoned spaces. It is of experimental and innovative character. The fish farm addresses a number of public, private and civil society actors as well as bringing a change to the city in social and economic terms as well as offering a new vision for the city's future (development). They nature of urban farming projects in general is an aim in particular at connecting the communities' and the entrepreneurs' interests by means of long range land use planning and sustainable land use allocations. In doing so they support two aspects: sustainable and land conscious urban planning and implementing bioeconomic (or other entrepreneurial) uses in urban revitalization processes (Pallagst et al 2017b).

Today, the area around the project has undergone a tremendous redevelopment process initiated by the city government. However, plant construction and the cultivation of saltwater fish far from the sea proved to be complex (Saarländischer Rundfunk Online (SR) 2018; results of the GIAGEM Workshop in 2017; Höll 2017).

The beginning as a public project (2007-2015) was characterized by problems and the project could not be implemented as originally planned. This is partly due to the nature of the project since this was a pilot project without existing blueprints. Thus, there was no empirical data for orientation help in planning, implementation as well as the strategy. On the other hand, it must be stated that employ important job-positions with public utility employees or politicians did not provide the necessary expertise to successfully implement this type of project (Fresh Völklingen GmbH 2018, Zeller 2017).
Since the Sea Fish Farming project was a pilot project with no precedents, the costs could not be accurately calculated as there were unpredictable funding gaps and additional costs. The plant did cost around € 25 million (including commissioning costs of around € 3 million), from an estimated construction costs of € 12 million (Fresh Völklingen GmbH 2018, Zeller 2017).

This initial process was characterized by a highly contested mix of over-ambitious goals and mismanagement. Despite its innovative approach, the project is still stigmatised by the bad image of its first years of implementation.

Due to this process, the fish farm was sold to a private investor in 2015 and is called Fresh Völklingen GmbH now. Nevertheless, as the project stands now, the sea fish farm was able to reach its primary goal of the development phase- namely create future oriented jobs for high and low skilled workers, generate revenue for the city and introduce a new industry to the City of Völklingen as well as providing a vision of the future development of the City in commercial urban farming.

Basic data of the project

To better understand the marine fish farming facility, the most important characteristics and data are listed below:

- Project, the first of its kind, no comparable facility or standards worldwide.
- The area size of the Fresh Völklingen GmbH is 10,000 m², the production area is 6,400 m².
- The large saltwater pools have a capacity of 1,800m³ of water. There is a fresh water requirement of about 1% per day. This compensates for water loss through evaporation and fumigation.
- The breeding facility consists of four large pools and a 100% mechanical-biological water treatment plant that adds no chemical additives. Therefore, the saltwater pools

create a closed circuit, in which the water is purified in a biological way, free of artificial additives.
- Runs on 100% renewable energy and heat generation.
- In its current structure, the plant can produce between 500-700 tons of fish annually (depending on the species)
- Achievement of EBIT at the beginning of 2018
(neomar 2017, Fresh Völklingen GmbH 2018, GIAGEM Workshop 2017).

A **theoretical second plant** with a production volume of 1000 ton of fish per year (i.e. about 1/3 larger than the existing one) costs according to in-house calculations of Fresh Völklingen an estimated € 15-18 million (plus commissioning costs). The construction phase should take 2-3 years. The amortization is expected to be reached in 8-12 years (Zeller 2017).

A **production cycle** lasts for different lengths of time, depending on the type of fish, and covers the entire period. From the arrival of the juvenile fish in the quarantine station to the breeding and harvesting of the adult fish.
- Dorade & sea bass: 380 - 400 days to 400 - 600 grams
- Kingfish: 350 - 420 days for a strength of 3 kg - 5 kg
(Zeller 2017).

One declared aim of the "Fish Farm Project" of Stadtwerke Völklingen at the beginning was to restore some of these **jobs**. But not only the question of the number of jobs, but also of the qualification requirements of the employees arises, since the former industry of the city-coking plants and mining jobs usually required low-threshold qualifications (Peuling 2017). Fresh Völklingen GmbH occupies about 3% of the former Fürstenhausen site (37.5 ha) where about 500 employees were permanently employed in the former coking plant (Zeller 2017). In the Sea Fish Farm are about **20 workers** permanently employed. The proportion of highly qualified employees is noticeable. Although there are also employees with vocational training or as untrained employers in the production, most of the employees have completed and specialized university degrees. With regard to the question of new jobs for former workers of the steel and mining sector, there is much to suggest that only after significant retraining the opportunity to find a new job at the sea fish farm is possible.

A conducted **SWOT- analysis** finds the project to meet goals as well as showcases weak spots, chances and opportunities.

Strengths	Weaknesses
- **Ecological, local production** of fish, short distances = lower CO_2 balance than imported fish - **Brownfield regeneration** on former coking plant area - **Good traffic connections** to the region and within Europe = easy accessibility of the markets - **Technology works**, the world's first inland saltwater aquaculture - **Constant advancement of the system**, high degree of innovation of the private owner company	- **No competent governance** / governance / project development (as a public project) - **Public entity restricted / less flexible as a private investor** - **long building delays**, because prototype - **Stadtwerke Völklingen have almost gone bankrupt** (about 20 - 22 million € loss) - **High initial investment** of approx. € 15-18 million for further plant

- **Private sector operates plant economically** (EBIT beginning of 2018) - Site requirements relatively low, **can be built almost anywhere** in the world - Very **good employment ratio** per hectare compared to the former coking plant - **Powered by 100% renewable energy** - Fish farm has **space to expand** - **Jobs hardly threatened by automation** - Fundamental part of the growing **urban farming market** - **Represents the future of food production** as world demand for fish and overfishing increase	- **High academic quota** among employees, therefore hardly any job replacement for local unemployed - **Only created 20 new jobs** - Small business, relatively few jobs - **Bad image** due to the initial phase - **Specialized product**, not mass-produced at a high price
Opportunities	**Threats and challenges**
- **City and region actively involved in business development** - **Potential for skilled workers is available** (through further training of jobseekers) - **Worldwide interest** for research and economic reasons & requests for planning and construction of the fish farm system - **Increasing global interest in sustainable & high quality food**	- **Depending on globalization**, relocation may be possible for more profitable assets in the future - **No financial support from the municipality** and its own operations due to the budgetary situation - **Location not in a metropolitan area** = smaller local market

From the analysis, some conclusions can be drawn: The plant fulfills the primary objective of the Stadtwerke. It produces fish as a new resource and has created new local jobs. The innovative technology is constantly evolving and working. Since the Stadtwerke has sold the fish farm to a private investor, the plant can also be operated economically. Furthermore, this pilot plant has the potential to serve as a blueprint worldwide due to the low site requirements.

4. Key lessons learned and recommendations

Regardless of the suboptimal project history in terms of bad execution by the Stadtwerke, the project itself can be seen as a success. This is based on the functioning technology of the prototype, on the now economical operation and the sales success of the fish. Furthermore, the facility itself is relatively modest in terms of location and can theoretically be built in most

cities and regions around the world. This convincing advantage paired with the learned lessons of the development phase and the acquired know-how could turn the sale and plant engineering into a sought-after export good of the City.
The production of food cannot be centralized in geographical terms and is best organized locally, also in terms of climate and environmental protection. In times of increasing food sensitization and the ongoing trend in urban farming solutions, this is a forward-thinking design and method. It should be noted, however, that market saturation can also occur in the food industry if demand is over met.
The weaknesses of the fish farm mainly include the history of construction and management of the project. Both major management mistakes were made and the extent of the construction of pilot plants of this size consistently underestimated. This was partly due to unqualified managers, who did not have the necessary expertise in the project planning of such a system and on the other hand, massive financial miscalculations. The question also arises as to whether public-sector companies, such as the Stadtwerke should take on such a project.
Above all, the favourable conditions of the zeitgeist for sustainable and resource-saving technologies should be considered an opportunity for fish farming. The international interest in urban farming, which includes fish farming, is not diminishing and there are many requests for the construction of such facilities in other countries. The sale of the patent or the further production of fish farming systems could further increase value creation in Völklingen as well as have positive effects in the labour market and increase business tax revenues in the city.
A set of recommendations for the Cities in similar difficult structural economic situations can include:

- Investment in the education of jobseekers
- Consolidation of public finances
- Establishment of a (private and public) funding and subsidies coordination office
- Improve public relations and communication
- Strengthen regional cooperation and networks
- Advance brownfield conversion - use potentials
- Expand local (economic) strengths further

On a project level it is to say that:

- Ensure basic and good governance
- Build on existing strengths
- Use projects as an image carrier for the city or region
- Use of the marine fish farming project as a model and learning curve for future developments

One lesson learned is that with future projects of this kind Völklingen will responsible of the relevant actors, interested investors and public companies work cooperatively on further development of this project. Follow up investments such as the construction of a Shushi producing plant in the vicinity as well as other closely related up- and downstream companies are on the horizon. The regeneration of Völklingens economy could have just started to kick off.

5. Conclusion

Classical urban planning reaches its limits when dealing with shrinking cities. There is no universal solution or general recipe for dealing with shrinking cities. These new challenges can only be met in new ways. However, these paths differ from city to city, as the starting conditions in each municipality are also dependent on the individual case and not every city can be developed with the same strategy.

When dealing with shrinking cities, an experimental path is usually chosen, new forms of urban planning and development are tried out, and action concepts are tested for which there are still no blueprints. The way forward is to reach sustainability for future developments. This requires a change of mentality of the city administration. In addition to (new) instrumental challenges, a high degree of openness and communication as well as long-term aspects are perceived as important.

The case study municipality has decided to actively shape the socio-economic structural change. This implies that - as shown - positive as well as negative results can be achieved. The positive effects here are primarily the achieved primary goals of the projects. On the one hand, future-oriented jobs should be created and on the other hand, the urban economy generally strengthened to reach sustainable developments. Additionally, existing strengths should be further developed and promoted. It can be learned from the historical developments that monostructured economies cause difficult situations in communities when this economic sector is in crisis.

The substitute industry as a sustainability strategy to create revitalisation trajectory's in these communities. As a result, jobs have been created on old, existing areas. But at this point, there is a need to look at the size of the Völklingen case study. Only about 20 jobs have been created in a company. This is not (yet) a substantial success that can turn the city's economy noticeably around. The analysis of the case study shows that the replacement industry has been set up with the aim of "recovering jobs". However, these jobs cannot or hardly be filled by the workers who previously worked in the city's industrial sector.

The aspect of sustainability in terms of nature conservation, nature resource savings, CO_2 emissions, to just name a few indicators, is also an important aspect of substitute industries. Especially regarding the urban farming case study of the sea fish farm. As the world's first inland saltwater fish farm it is seen as an important tool against overfishing of the oceans as well as coastal aquaculture, known for controversial methods and rich in consequences (e.g. use of antibiotics in the open sea). The sea fish farm bypasses the current discussion on the (health) threads of plastic waste in the oceans due to being an enclosed system without waste contamination or the need to use antibiotics. The sea fish farm contributes to the growing global demand for healthy fish and environmental protection. In addition, the low CO_2 consumption is to be highlighted in the local, organic production of marine fish in comparison with imported goods.

The time aspect, more precisely the time delay, is rarely taken into account in the substitute industry instrument. Many years or decades can pass between the demise of an industry and the creation of a new employment opportunity. Furthermore, the quality of jobs is shifting, so that new jobs often require a much higher level of education than previous ones.

The recommendations for action that emerged from the analysis aim at cities and project managers to adapt their strategies and continue to play an active role in structural change and to set in motion sustainable developments despite certain setbacks. For the future, the main focus in these communities should be on learning from the mistakes of past projects and incorporating these insights into future initiatives. The transferability of the recommendations is not always given, although partial results can also be transferred or learned from.

In this context, it should be noted that the question "Can substitute industries generate or at least stabilize growth sustainable in a shrinking city, stop the population shrinkage and restore jobs?" could not be fully clarified in this work. In the case study the answer to this question is negative, due to different scales of crisis and the project size.

However, it is clear that the creation of new jobs can compensate for the loss from the mining or the manufacturing industry, but this depends on the type and size of the new initiatives. Although new jobs are often not created in the same number and usually only in changed demand in education quality. The sea fish farm created an equal amount of academic and non-academic jobs. Most of the times substitute industries are focusing on academic jobs, which is not helping the local job market in city's affected by structural changes. The fish farm can be seen as a best practice example in this concern.

However, city planning and development has always been subject to constant change and is constantly confronted with new challenges. As a result, there are always new challenges and repercussions that must be considered when recruiting and locating replacement industries, and whose consequences on the urban environment are still often unknown. Here the result is usually completely open. There is no guarantee of success. An example of the unknown effects is the digital revolution, in which the potential positive and negative effects on cities are still difficult to predict.

Based on the experiences of the city examples presented briefly, it can be concluded that there is no clear answer to dealing with alternative industries. These are neither to be understood as a "panacea" nor as a "symbol of false hope". After all, it is a step in the right direction to anticipate a sincere analysis of the location and the city for the revitalization initiative, since not every municipality has the same prerequisites and potential and consequently cannot rely on the same strategy.

In conclusion, it should be noted that all measures to a certain extent can at least slow down the shrinkage processes. Existing resources can be used to rebalance cities between shrinkage and growth. Even if it is not possible to counteract all the external factors it is nevertheless important to constantly set new innovative and goal-oriented impulses in order to actively shape the future in a more sustainable way.

LUMAT project – integrated environmental management of land resources as contribution to enhancement of urban areas resilience to climate change

abstract

LUMAT project (Implementation of Sustainable Land Use in Integrated Environmental Management of Functional Urban Areas) financed by INTERREG Programme CENTRAL EUROPE – is concerning enhancement of integrated environmental management of land resources in functional urban areas by using ecosystem services approach. Cases of the LUMAT project functional urban areas in 7 countries present solutions of integrated environmental management which can be considered as activities contributing to enhancement of urban resilience to climate change. The project has applied the methodology of ecosystem services analysis and assessment. This approach includes services connected with climate change resilience which is an important element of adaptation of urban areas to climate change.

Action plans presenting examples of solutions contributing to enhancement of integrated environmental management in FUAs include activities for development and strengthening green and blue infrastructure. This group of activities constitute an important factor in climate change adaptation plans for urban areas. In the idea of LUMAT there are actions which are to bring environmental but also social and economic benefits.

One of the action plans concern green and blue infrastructure development in the functional urban area of three cities in Silesian Metropolis in Poland. These cities as other in this metropolis present a densely populated post-industrial area with numerous brownfields and post-industrial sites. The new strategy of development of the cities provides for new goals and priorities in social and economic sphere. At the same time the local authorities are aware of the need for ecological balance of urban areas.

The LUMAT project has offered a possibility for improving this balance by creating a network of green sites including abandoned areas (brownfields, post-industrial sites) but also the existing green areas requiring re-shaping or re-construction. One of the sites has been selected as a pilot action area of LUMAT consisting in full recovery in order to create green park with recreational function. The area is a post-zinc wastes dumping site covering 6,5 ha located in the very middle of the city. The site is surrounded by dwelling houses, garages, workshops and a school building and on the east there is an underground coal mine.

The investment will consist in rehabilitation of the brownfield site located in the middle of the Ruda Śląska city. Phyto-stabilization technology will be used to make the site safe. The investment will create an available open space of a natural, "half-wild" character; due to the progressive greening it will achieve the character of a sub-regional park. The place will become the walking and biking route connection of two districts as key element of the peri-urban green infrastructure.

Synopsis

Project LUMAT is concerning integrated environmental management of land resources in functional urban areas. Cases of the LUMAT project functional urban areas in 7 countries present solutions of integrated environmental management which can be considered as activities contributing to enhancement of urban resilience to climate change.

A Study of Human Ecology and Resources Network

Ge SUN, Shanghai Tongji Urban Planning& Design Institute, China

Abstract

In order to protect people from variable external environment, buildings emerged. Therefore, there are always discussions of the relationship between humans and nature. Nature has its self-restoring equilibrium, however, nature cannot be considered without human participation (Cronon,1996). Due to respond these changes, many designers tried to modify the environment or create artificial works, and some have begun to explore sustainable system in design theory and practice. The relationship between humans and nature challenges the essential theory of architectural and urban design.

How does the city form? Humans gradually get together to a settlement and then occupy the space as their territory. Various settlements connect with each other through channel from point to point. Therefore, the network has been built and the city has formed. As the city developing, it may be constructed following the governmental planning, and mainly represent the capital and political impacts. Some planning strategy and practice think from a traditional top-down system, and try to balance the relationship of human and nature. However, back to the generation of city and the distribution of resources, instead of retracting to a traditional top-down system, a new interactive and bottom-up self-organize algorithm is necessary, to cope with the complicated network system.

Liwa oasis is strongly influenced by the distribution of scarce resources and topographic conditions in the desert, which is a typical city to research on the self-organize algorithm. It is located on the north edge of the Rub Al Khali desert. In addition, energy has become the most important driving force of the expansion of the Liwa oasis in the future. Because the existing Liwa oasis network system is constituted by settlement and nearby sabkhas, and the salt material distribution process, so it is potential to apply as inputs into an algorithm.

This essay will first argue the ethos of new Human Ecology, analyzing the algorithm in nature and the process of biological network in order to explain the distinction between human and nature more details. Secondly, it will focus on how the bottom-up self-organize algorithm transfer to design area. Specifically, it will give design proposals of Liwa, which apply a new algorithm as design method for the future planning. By researching on biological algorithm, applying bio-3d printing technology, developing digital simulation, the biological urban network algorithm will be established. In addition, in order to implement the urban design proposal generated by biological algorithm, it will consider the construction tools and the local matertials. Last, but not least, the biological urban network algorithm is capable to establish the link between the practical requirement of society development and the existing resource oriented network urban morphology, from top-down to bottom-up, from stable to dynamic, from homogeneous to diverse. It is based on this new human ecology, will be determined and discussed.

Key Words: natural systems, human ecology, biological self-organized network Algorithm

1. Introduction

Through relentless choices and changeable evolution of natural selection, the natural forms become perfect and various. The species of animals and plants has a rich biodiversity and keep good metabolic state with the environment. For a long time, architecture has learnt from the forms and structures of nature. Achim Menges (2011) establishes that natural systems reconcile in material structures which operated by internal physical restriction and external forces.

The operation and maintenance of buildings have continual influence on the environment. 'vernacular architecture' is an architecture type which was built by the inhabitants themselves and used local material. The building technologies were the experience by the owners which can adapt the changes of climate and meet their own needs. Vernacular architecture is an example which buildings adapt the nature. With the advent of industrial era, global environmental issues have received widespread attentions, and people's activities can not consider as individuals' actions. Global warming has been presented by Climate Change 2007 in the IPCC Fourth Assessment Report. It is a phenomenon about the rises in global temperature, melting of Antarctic and arctic glaciers and the increases of global average sea levels, which happened since 1750. Human activities have consumed large amounts of natural resources, and at the same time, emitted harmful substances to destroy the nature, including the burning of oil, the coal and fossil fuel. Particularly, buildings may become a medium to expose the fact that humans have caused damage to the nature. Humans have the try to find way to help with the sustainable development of the earth and the interaction between nature and human. There is also a need to change our design thinking of architecture and city, as buildings normally exist for a long time.

Since man and nature both share the common resources for the constructions and architecture always has close relationship with its surroundings, it is obvious that architecture literally becomes part of nature. Most generally, architecture design is not only about constructing buildings and other physical infrastructures, but also about designing and planning from the micro level to the macro level. The coded form in architecture which is the logic in the generation of form is similar or analogous to the genes in nature. Design thinking moves its focus from the form of a static nature to the inner logic of nature system, which is its process of morphology. In order to research on the complex nature system, computers first as research tools, not graphics tools, appearing in the history of architecture and urban design, influence the development of urban planning.

2. Design theory of the human ecology

2.1 the concept of new human ecology

The concept of 'human ecology' comes from 'ecology', but concentrates on the collective behavior of human interaction and the relationship with the environment. Biologists focus on the behavior of organisms and the transformation as the environment changes, while the sociologists did lots of similar research of human groups. From the urban designer perspective, human ecology can be described as a design theory which learn from the collective interaction of biology, but not only focuses on the influence of buildings to the nature as the common cognition.

In the book, 'Occupying and Connecting', Frei Otto(2009) said that urban planning theories nowadays need to follow the change of typical self formation processes. There is a need to research on the 'natural' town transport planning and try to find the way of solving problems by ecological ways. Otto explained that the occupation by a variety of classification standards, but focused on two ways which are 'random occupations(Otto, F 2009)' and 'attractive occupations(Otto, F 2009)'. Otto thinks random occupations means to fight for the largest possible territory. The attractive occupation means the attraction between the occupying subjects. Two ways in occupying processes exist and influence each other. Connection as the way of communicating and exchanging between occupants is as well important and cannot be ignored. Connection focuses on solving the optimal balance between convenient links and the shortest length of roads and the road system is derived and hierarchical. When considering the human settlement, after forming the connection road system, the process of its re-occupation will begin. The road system promotes an uneven regional development, and forms spread tension of settlements.

Therefore, the research framework of forming human settlement becomes from occupying to connecting, and then re-occupying. The theory includes the basic factors of settlement pattern formation mechanism, especially considering the complexity of the city. Figure 1 is a model of the theory of muscle memory in nature by Frei Otto. It can be divided into three stages. The first stage is forming a territory path network which is based on searching for food. The second stage is forming the settlement path network that connects between individual buildings. The third stage is forming the long-distance path network which connects the different habitations.

Figure 1: the model of muscle memory
Diagram reference: Occupying and Connecting, by Frei Otto

Basing on the framework of muscle memory, we can attempt to derivative a new concept of human ecology which focuses on generation and self-organized processes of human groups, emphasize the relationship between machine, human and nature. In simpler terms, the new human ecology tries to make a balance of human activities, buildings and environment, and pay more attention to help the sustainable development.

2.2 the methodology of new human ecology

From the perspective of the general theory of architecture, there is no distinction between nature and artifice. Natural morphogenesis, the development of evolution and process of changes, happens in a complex system, which is the combination of internal generation and external influences and forces, and eventually contains system-intrinsic material and form features. This kind of model which includes complex natural process assists by the computers may emerge the simulation visually and make logic mathematically. The Church Turing (AlanTuring, 1936) hypothesis established that the Turing Machine, which was invented in 1936 by AlanTuring, could repeat both the use of mathematical machines and nature. Thus it is not only help the development of mechanization, but also gives the potential to formulate natural morphogenesis. Another significant theory is presented by Von Neumann, which involves artificial and natural biologies, beginning with the basis of life.

Considering architecture as a material practice, the design process has a hierarchical connection which prioritises the process of formation and then its materialization. This suggests an alternative approach of technology in architecture design, which origins from morphological complexity, except distinguish materialization processes and generation of form. The latent potential of computation suggests that, this kind of analogy of evolutionary architecture needs rigorous geometric logic and reasonable simulation and the digital model can be deployed material characteristics, complex logic articulation in the material and structure systems.

John Holland (1975), gives a crucial system theory in relationship with natural analog model and his examples is about the how to optimize the complexity in unstable environments. Such problems seem to concentrate on the questions of adaptation and do not have a collective name, which could connect with various area, such as ecology, mathematics and also architecture. Accordingly, the coded information of form in nature is due to the genes and natural selection is on the foundation of coded information, which is also influence by the environment. Similarly, the coded manufacturing instruction in architectural model, which is in the real world but reflects the artificial life, is also environmentally dependent.

3. Design practice of the human ecology

As the concept of human ecology has developed deeper and broader, the recognition of the relationship between humans and nature has changed from separation to integration. Designers try to explore on the algorithm of nature and exploit the potential of machine, in order to looking for method of the interaction and long-term influences of humans and nature. This thinking suggests that is there a design method which can establish a sustainable system of the interaction between the collective activities of human and the changes of nature? With such an idea, a design proposal in urban scale proposes in Liwa Oasis city.

3.1 Nomadic self-organized network oasis city

The Liwa Oasis city is located at the Arabian Peninsula, on the north edge of the Rub Al Khali desert. In common sense, desert is defined as the middle of nowhere. However, it is not true, the desert is far more various and beautiful then we imagine. Even in a desert, where is full of sand, the sand also can become an excellent media to represent the various climate and geological condition. The landscape condition is an important factor in whole ecological system. Therefore, due to the diverse condition above, the species distributed abundantly and variously in the desert. Similarly, because of different ecological condition, the species distributed on the dessert is diverse as well. Furthermore, the desert is full of resource, especially energy resource, including fossil energy resource, such as oil and coal, and also sustainable resource, for instance, solar energy and wind energy. The exposure of the diversity of Rub Al Khali desert let us know how interesting and abundant of it, and it give us the motivation and also potential to develop new methodology of urban design in this area.

Unlike the other contemporary urban settlement area in United Arab Emirates, for instance, Dubai and Abu Dhabi, which were constructed following the governmental planning, and mainly represent the capital and political impacts, Liwa oasis is a self-organized territory which is strongly influenced by the distribution of scarce resources and topographic conditions in the desert. Because of this property, Liwa oasis was emerging as an ecological self-organize network system interacted with other resources network. For example, Liwa oasis was built on 16 century, mainly because its location was in the accessible radius of shallow groundwater resource network. Water was the most important resource in that period, because it is necessary for the nomadic people who are living and discovering in the desert. They were “scanning” the territory in the Desert without extract geological understanding, and tried to find the location which can easily access to the shallow underground water through manually digging wells. Some settlements emerged individually alongside the wells, and consequently connected together as a network oasis. Therefore, Liwa was built up as a nomadic self-organize network oasis city, mainly responding to the w ater resource distribution. However, today about 60% water usage in Liwa oasis is provided by the water desalination plants from the coastal area. This change means energy has replaced water as the most important local resource, when this water supplying strategy is actually using energy to replace the water consumption. Under this condition, the existing morphology of Liwa may be challenged.

In addition, in the 2030 master, Liwa is going to tr ansform from a farm area into a m ain tourism destination in the desert. Therefore, its resident population will be increase from around 20,000 to 65,000, and the annual tourist amount is aiming to grow from 30,000 to 90,000. Under this background, energy has become the most important driving force of the expansion of the Liwa oasis.

In the Liwa territory, there is a type of remarkable landscape, between dunes in-land sabkha (salt-plate). This landscape is a main tourism attraction, and also a potential energy source because it’s large reserves of salt. In addition, in the latest 20 years developing history, Liwa was expanding by cleaning and occupying sabkhas, which are normally located at the small basins and protected from the strong winds in desert by surrounding dunes. Because the existing Liwa oasis network system is constituted by settlement and nearby sabkhas, and the salt material distribution process, so it is potential to apply as inputs into an algorithm.

3.2 Biological self-organized network algorithm

Instead of retracting to a traditional top-down system, a new interactive and bottom-up self-organize algorithm is necessary, to cope with the existing complicated ecological network system. For this reason, the pr oject researches and e xperiments with the phy sarum polycephalum slime mold. Slime mold, Physarum polycephalum, is a mold, having an identity crisis as it has not been defined as a kind of mold. In the growing process, oats would be an element to attract the Physarum polycephalum and the formed branches can be efficient networks which is applicable to new design networks for the communication and transportation under a set of constraints of environment problem.

Figure 2 is an experiment of the network formation in Physarum polycephalum, which is similar to the network of tubes around Tokyo. Figure 3 is how slime mold grow exclusively along the shortest path possible between the two pieces of food, which was put at the start and the end of the maze. Until now all the experiments about slime mold were conducted by scientists. They have observed slime mold activities but these have not aimed at simulation for design cities. From the ur ban designer perspective, we want to use the slime mold algorithm into the ur ban design. What we are interested in is to use the intelligence self-organizing algorithm created by slime mold distribution into urban design making a shift for the future cities.This microorganism has similar behaviours strategy with nomadic people when they are searching and c ollecting resources. The behaviour of phy sarum is the combination of num erous cells inside. The interaction and communication of its cells can output a network generating process as optimized as artificial one.

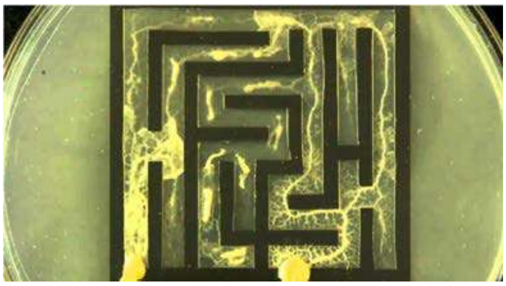

Figure 3: Nakagaki, Yamada, Toth Path finding by tube morphogenesis in an amoeboid arganism
Diagram reference: Science/AAAS

As mentioned in the chapter 2, Frei Otto said the muscle memory in the nature can be divided into three steps, which can leads to the simulation of the natural human settlement networks. It is similar to the growth of slime mold, whist expanding around in the medium, then concentrating on nodes and making a circle to surround the food sources, and last, becoming an optimized network connecting with each other to transfer the information.

Connecting with site, sabkha has a number of salt and water, which should be used for human activities. The network between residence and sabkha can be the analog model object to research. The slime mold, as biological model, can help with the algorithm in the sabkha network. Choosing the sabhka in Rub Al Khali to simulate the network between sabhka and residence. By applying bio-3d printing technology, high-resolution observation device and picture analysis algorithm, the project has developed slime mold as a biological network algorithm, to generate the time-based urban design proposals for Liwa territory. Figure 4 is the bio-3d print machine of some components to push the materials to the petri dish with the injector. Put food resource to the location of sakbha in desert and slime mold in the location of residence in Liwa and a picture of contour map as light source. The project also develops the digital simulation network algorithm from the strategy of slime mold in parallel, in order to provide design proposal in specific area, with higher accuracy.

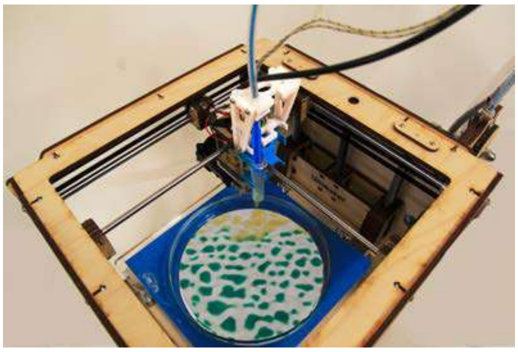

Figure 4: the Bio-3D print machine

3.3 Information process from biological network algorithm

Because the main output from the biological network algorithm are pictures(Figure 5). In this part, the project apply algorithm to convert the picture to density points, and then these points can use to generate the meatball to show the to show the thickness of the slime mold in the picture. Finally, by input these points into shortest path algorithm, we can regenerate the network of slime mold in the biological experiment as in the Figure 6.

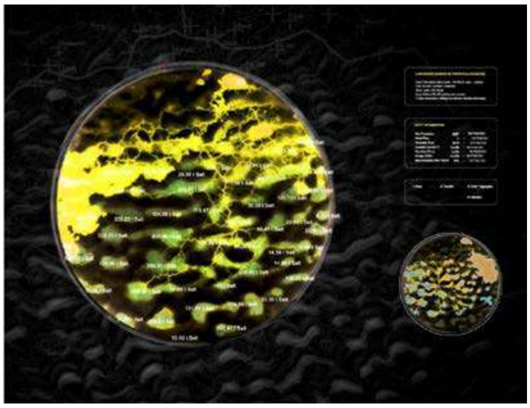

Figure 5: The interface of interpretating the experiment result from biological algorithm

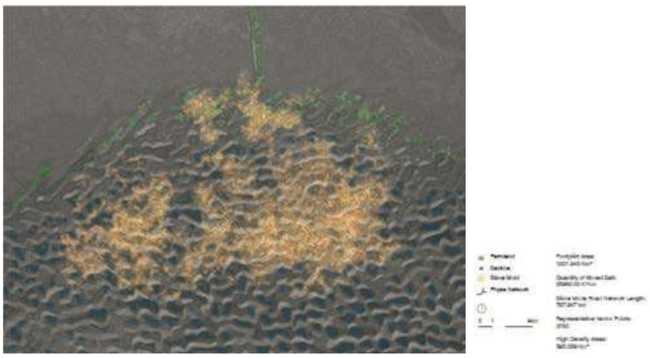

Figure 6: Apply shortest path algorithm to reconstruct the network of slime mold.

3.4 Ecologocial relational model

From above steps, we already can convert the biological experiment results from pictures to vector date and fi t to the site. However, in order to pr ovide a convincing urban design proposal, we need to c ombine the interpretating process with more complex site condition.

For example, In the 2030 master plan of Liwa oasis, the population will become 3 times as in present, from around 20,000 to 60,000, and the main industry in Liwa will shift from farming to tourism. To fulfil the requirements for the increasing population and development of industry, we need different amount of resource and infrastructures. And these resources also has relations in between, which means normally to fulfil the single requirement of one resource we also need to produce extra related resource.

Base on the input-output relation between different required resource, and the population increase target in master plan 2030, the project can build up a mathematics ecological input output model, it can be predicted the general requirements of each resource in each years. Figure 7 shows that the dynamic mathematics model is potential to link to the information interpretating process of the biological experiment, which can help that to develop as reliable urban design proposal.

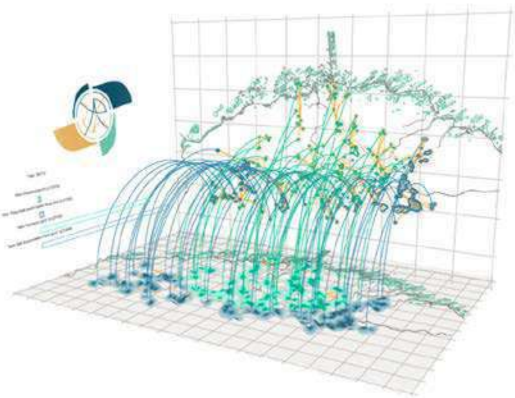

Figure 7: The interface shows the development progress in different year from the biological algorithm

3.5 Biological experiment information interpretation

From the research of the territory, it exposes that the existing morphology of Liwa oasis is expanding by occupying sabkha. In the process of occupying, people need to clean the salt on the surface, to avoid the high salinity environment to damage the building structure.In addition, it can be found energy has become the main force to drive the development, and salt is potential to a source of energy. In the other aspect, the behaviour of slime mold is actually re-distributing the resource on site to improve the transportation efficiency.

To sum up, these condition give us the reasons to translate the process of the biological experiment as and analog model of people expanding the city by re-distributing the salt material and occupying sabkhas. The data from the input-output model is the prameter to control the quantity and progress of this interpretation.

3.6 Physa self-organized network city

By applying physa self-organized biological algorithm, we can generate the urban design proposal contents different time stages, and provide suggestion on programs division, location, and material quantities. These system allow designers cope with the complex territory conditions and also fulfil the society develop requirement. In addition, instead-of traditional top-down city morphology, this methodology allow designers to develop new self-organized decentralized city.

3.7 Autonomous network builder

The Physa Biological Algorithm could be operated and run under different scale. Under the higher than 100 ti me amplification microscope, the cells of s lime mold moved in a v ery organize way. The swarm ovement of cells resulted in an oscillation fluid, and transform the diameters of the tube frequently. This organized swarm behavior was operated under a real time autonomous system. This property give us a new potential to ex tract detail real-time information from the Physa biological algorithm in a micro scale, rather than only observe the pattern of the macro network.

In some condition, salt is a precious resource in desert, and people may manually collecting with suffering of cruel climate condition. Although this scenario does not happen in Liwa now, but when salt is a potential resource of energy, it give us an argument to apply more coefficient way to harvesting salt from sabkhas. In the above research, we found the resource harversting behaviour of cells of slime mold have similarity of nom adic people's collecting activity in desert.

In the other aspect, In order to implement the urban design proposal generated by biological algorithm, swarm robot was introduced as autonomous builders in this system. Because the growing of phy sarum is the m acroscopical representation of the c ollective movement of i ts cells inside, which has the similar mechanism with swarm robots.

3.8 Computational self-organized network algorithm

Because the bi ological simulation has certain limitations in the ac curacy of the data processing and recording, we also manipulated the digital simulation as comparison and supplement. By setting up the agents as the swarm robot gatherer, and emit the collectable particles as the position of sabkha, simulation of swarm robot collection behavior is built up. In this simulation, we can clearly observe and anal yse how the agents collecting materials and interact with the territory. These may provide us more suggestions about how to program the swarm robot and design the salt infrastructure network.

Once decided applied swarm robot as the builder of the urban design proposal, the project needs more detailed information inter of s maller scale and accurate time. The bi ological algorithm is capable in large scale, but has many technical limitation in small scale. In the other aspect, digital simulation has advantage in provide very accurate feedback. Therefore, we extract the mechanism from the behaviour of phy sarum to developed a r elated digital algorithm. These algorithm will run in a smaller scale of ter ritory and m ainly affected by the salinity information.

When the swarm robots carrying materials and moving around Liwa territory, it is potential to construct specific urban prototypes and new landscape. For investigating this possibility, the project researches the energy producing and structure application of the resources, such as salt, fiber, and starch in Liwa territory. The project organizes these investigations as a material system, and connected it into the biological network algorithm, by applying digital simulation as in the Figure 8.

Figure 8: plan view of urban scale

4. Conclusion

Since man and natur e both share the c ommon resources for the constructions and architecture always has close relationship with its surroundings. Vernacular architecture is an example which buildings adapt the changes of climate and meet inhabitants' needs. It is not easy to ev aluate the bui ldings' ecological cost, especially when it needs to c onsider about the whole life cycle of buildings. With the ad vent of i ndustrial era, global environmental issues have received widespread attentions, and people's activities can not c onsider as individuals' actions. Global warming reminds us to pay more attention of gl obal environmental issues which caused damage by humans' activities. Particularly, buildings may act as a medium to ex pose the fact. There is a need to s hift the design thinking from separation to interaction between humans and nature. The new concept of human ecology focuses on generation and s elf-organized processes of human groups, emphasize the relationship between machine, human and nature. It pays more attention to help the sustainable development of earth.

Most generally, architecture design is not only about c onstructing buildings and other physical infrastructure, but also about designing and pl anning from the m icro level to the macro level. It i s important to m ention that the s elf-organisation rules in nature is about the process of metabolism and the pr inciples of th ermodynamics. Natural urban and t ransport planning is perfect as to find solutions to the ecological significance (Otto, F 2009).

In summary, the P hysa biological network algorithm generated design proposal in urban scale, and the digital network algorithm compute the des ign proposal in building scale, meanwhile the s warm builders and the m aterial system are the fi nal implements. These different research components consequently constructed a dy namic ecological network algorithm. This network algorithm is capable to establish the link between the practical requirement of s ociety development and the existing resource oriented network urban morphology, and form a new urban morphology, from top-down to bottom-up, from stable to dynamic, from homogeneous to di verse. This is a des ign approach which can establish a sustainable system of t he interaction between the c ollective activities of hum an and the changes of nature.

Downtown Cairo Urban Regeneration – A Model for Future Urban Regeneration Plans with Energy Efficiency Interventions

Silja TILLNER, Architects Tillner und Willinger, Austria

The Implementation Plan is intended as a future prototype to explore new models for urban regeneration in historic zones that integrate energy efficiency into the plans, thereby linking planning and urban design measures for the improvement of mobility and the public realm with public and private investments in energy-efficient buildings.

1. Background on Population, Living Conditions and Environment

1.1 Population

Egypt is one of the fastest-growing countries worldwide and will continue to grow at such a speed that by 2050 it could surpass many others around the globe countries. If countries are depicted not according to geographic size, but to population figures based on internal growth (not considering migration), countries like India or Egypt gain disproportionate importance compared to their size. [1]

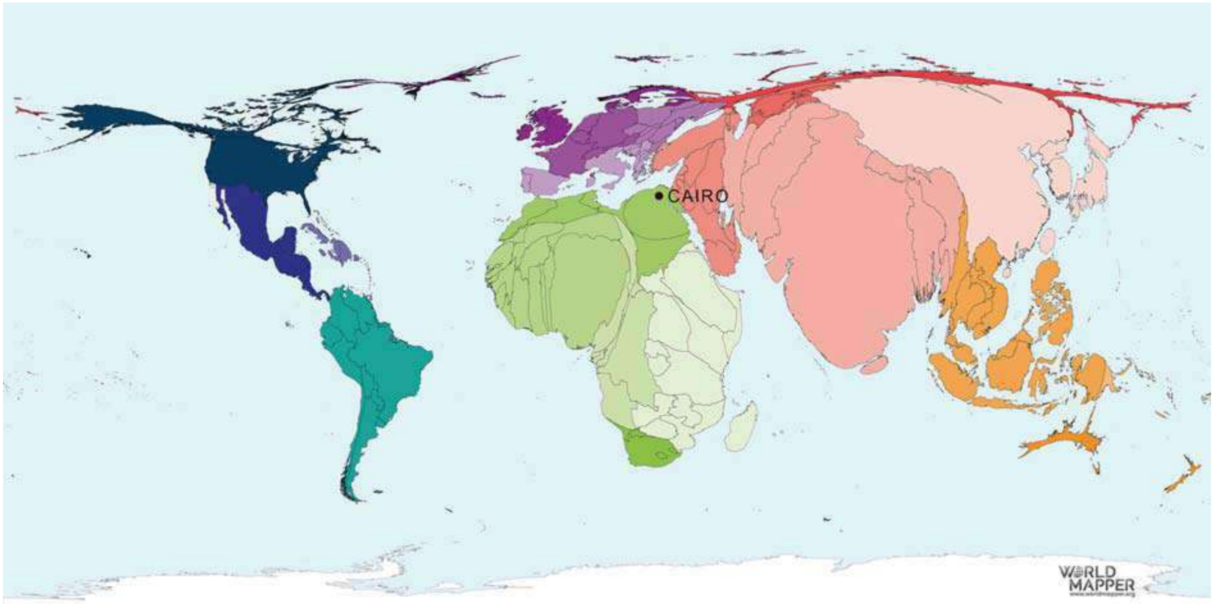

Figure 1: World Map based on internal population growth
Data source: https://worldmapper.org/maps/population-year-2050/?sf_action=get_data

Greater Cairo is a megacity with—considering the contradictory numbers—approximately 27 million inhabitants. Even in 2016, Cairo had an estimated population as high as 12 million, with a metropolitan population of 20.5 million, which made it the largest city in Africa and the Middle East.[2] This unprecedented growth rate has caused negative consequences for Cairo with regard to the environment, living conditions and economics.

Figure 2: Cairo is located in the desert, the fast growth of the last decades caused immense construction on formerly green spaces Data source: https://www.citymetric.com/fabric/cairo-has-dangerous-growth-problem-how-can-it-be-fixed-2865

1.2 Living Conditions

Seventy percent of Cairo's inhabitants cannot afford to live in an apartment, based on the supply of the official housing market, but have to refer to the informal market with all its negative environmental consequences. The informal market bases its supply on illegal land or construction, following three different strategies. Firstly, farmers transform their land zoned for agricultural use into building sites without providing adequate infrastructure, i.e., public transport and utilities (sewers, water, electricity, etc.). Secondly, already densely-built up residential areas are further densified with illegal buildings or additions. Thirdly, illegal structures are added onto the roofs of historic buildings (mainly on buildings from the late 19th and early 20th century in Downtown Cairo) without structural reinforcement or safe access. The government and nearly all private developers, in contrast, focus on the development of new towns in the desert [3] on the outskirts of Cairo to accommodate numbers that have more than tripled since the 1970s, far from public transit and current living quarters. This new town development in the desert is not only negative for the environment, but also for the quality of life of the workforce and their families, who would be separated from their workplaces and social contacts. That is the reason why many of these new housing developments have failed to be accepted. Some young families, however, are gravitating towards the fast-expanding satellite cities in pursuit of cleaner air and to avoid the negative impacts of high noise levels generated by the city, where waste disposal is hugely inadequate and water pollution is a significant issue for many communities.

Figure 3: Informal construction in existing residential neighborhoods
Data source: http://www.mei.edu/content/informal-areas-cairos-silent-urban-revolution

Downtown is currently the administrative center of Cairo and still houses all the government functions, but the ministries will soon relocate to the future capital, "New Cairo,"[4] which is under construction and proceeding fast. After its completion and the relocation of the ministries, as well as of the Egyptian Museum to Gizeh, the future of Downtown will depend on the success of revitalization efforts to make it more attractive as a place to live and work.

1.3 Environment

Cairo has been ranked as the second most polluted large city in the world, according to a report issued by the World Health Organization (WHO), which studied air pollution globally from 2011 until 2015. [5] The WHO report noted that seven million people worldwide die from exposure to polluted air, adding that nearly 4.2 million people died in 2016 from air pollution; pollution from fuel exhaust also resulted in the death of 3.8 million people in 2016. In 2017, the United Nations Environment Programme stated in a report that 40,000 people in different parts of Egypt all died from pollution. The report pointed to the absence of trees within Egypt's capital as leading to the increase of air pollution.

Hosting a population of 19.5 million, [2] Cairo [6] is considered to be the most congested city in Egypt. The Egyptian capital and its neighboring Nile Delta cities suffer from some of the worst air pollution on Earth. Two million cars on its clogged-up streets and a thousand factories surrounding the city cause severe pollution, which is aggravated regularly in the fall when farmers outside the city burn leftover rice husks. High emissions and Cairo's topography—the city lies in a valley surrounded by hills—and the extremely dry climate make the pollution even worse. In the fall, frequent temperature inversions settle over Cairo, stilling the winds and preventing the movement of air. As in other developing countries, the rapid urbanization and weak enforcement of environmental regulations have especially left the poorer urbanites vulnerable to bad air.

Figure 4: Smog over Downtown Cairo – illegal construction on rooftops
Data source: Silja Tillner

Almost all of the city's trees, its most effective dust filters, have disappeared, as has much of the surrounding agricultural land. Every year approx. 30,000 acres of undeveloped land is lost to urban sprawl. Cairo's notorious traffic, the abundance of old cars without pollution measures, the high-rise buildings and narrow streets that trap poisonous air close to the ground have all contributed to the city's consistent ranking as one of the world's most polluted cities. Lately, promising efforts have been taken to reign in the problem.

[…] perhaps, the public and private sectors both appear to have come up with some solutions to the rice straw-burning epidemic. Authorities appear to be slowly reining in illegal agricultural waste fires. An architect, Essam Hosni, has designed building blocks out of the straw, possibly providing an answer to Egypt's lack of affordable construction materials in the process. Potters in the capital's Old Cairo district have taken to packing their delicate wares with rice straw. [7]

1.4 Downtown Cairo – City Form and Function

Downtown Cairo is equivalent to the Khedival Cairo and was once called "Paris on the Nile" at a time when it was an urban oasis full of greenery. The urban lay-out of its formerly tree-lined streets and squares, the landscape design of parks, and the architecture of the buildings was of the highest quality, because the Khedives used the most beautiful European cities in France, Italy, Germany and Austria as models and hired the best craftsmen at that time to plan their city, open spaces and buildings. Downtown is full of valuable historic heritage and still the administrative center of Cairo, but it will change considerably when most of the government ministries move to the new capital.

2. EBRD Project – Strategy for Future Revitalization Projects – Ambition – Team

The Implementation Plan is intended as a future prototype to explore new models for urban regeneration in historic zones that integrate energy-efficiency into the plans, thereby linking planning and urban design measures for the improvement of mobility and the public realm with public and private investments in energy-efficient buildings. The EBRD supports private and public initiatives to revitalize the historic center and save its heritage with a financing model that offers sustainable alternatives to profit-driven private developments.
In parallel to the Government of Egypt's demonstrated intent to redevelop Downtown Cairo, the European Bank for Reconstruction and Development (EBRD) has emerged as an international development partner that is uniquely interested in Downtown Cairo and has taken a proactive approach to supporting the Government of Egypt's efforts. As such, the EBRD has commissioned technical assistance for the integrated and sustainable regeneration of Downtown Cairo by developing a strategic implementation plan for the regeneration of the area, maintaining its cultural and historical heritage, conducting energy and resource audits of major buildings in the Downtown area, and national policy engagement with key public and private stakeholders. [8]

Objectives of the Implementation Framework for Downtown Cairo Urban Regeneration
The Implementation Plan was launched by the EBRD as a future prototype to explore new models for urban regeneration in historic zones and urban fabric. [8]
Work on the Downtown Cairo Regeneration Implementation Plan began in early 2016 and has been implemented by an Egyptian-Austrian consortium of urban regeneration and building energy efficiency experts, led in Egypt by OHK Consultants. This international / local team [9] worked in close collaboration with the Cairo Governorate to develop the Implementation Plan.

Figure 9: Traffic in Downtown CairoDate source: Silja Tillner

3. Analysis of Current Conditions

The analysis of current conditions in Downtown Cairo shows they are a detriment to its citizens: Results from the analysis of the existing situation and the adaptive strategies developed to meet current and future challenges could contribute to the topics weather, water, food and energy. *(See pages 1-4)*

3.1 High Traffic Volumes

Current conditions have high negative environmental impact for the citizens because the high traffic volumes consist of many old and polluting vehicles. Since observations showed that many are mostly passing through Downtown or are drop-off traffic opportunities arise from possible changes in street-hierarchies. *(See page 10-11)*

3.2 Environmental Pollution Heat

Pollution levels have been severe *(see pages 1-4),* but the hot and arid climate, combined with a disadvantageous topography that prevents air circulation through winds, all add to the extreme overheating of the whole city, but especially the urban core in Downtown Cairo. Air-conditioning also aggravates the heat island effect.

3.3 Lack of Public Spaces

Historic parks have been demolished and newly designed open spaces, e.g., the large plaza above the underground parking garage at Tahrir Square, neither provides greenery nor shade. Since 2011, the public realm has been transformed into a high-security zone with few open spaces left for the public; the design lacks planting and instead mostly consists of hardscape and grass. The few remaining green spaces and street trees suffer from a lack of irrigation. Therefore, the Downtown Cairo Urban Regeneration Plan emphasizes the creation of new open spaces and the refurbishment of existing ones with lush landscaping.

3.4 High Energy Consumption

Most buildings (see pages xxx) do not possess passive measures for cooling, e.g., insulation, exterior shading or natural cross-ventilation, but instead rely on air-conditioning which not only heats up the environment, but also generates high energy costs. Since 2016, Egypt had to reduce its massive energy subsidies, which kept prices extremely low for decades, leading to steep rises in energy costs. Finally, because of these high prices there is a new interest in reducing energy consumption and investing in building improvements. Therefore, the Downtown Cairo Urban Regeneration Plan emphasizes energy audits of public and private buildings, the training of local experts, and a set of recommendations for technical building improvements.

3.5 Built Form

3.5.1 Situation

The Urban Morphology Map of Downtown Cairo shows four different patterns of urban fabric that exist in Downtown Cairo. These different patterns developed over the course of time and reflect the planning and building styles of different eras. The orthogonal and radial patterns in particular derive from the original plan for Khedival Cairo, which was developed by European (mainly French) planners and inspired by the Haussmannian plan for Paris. These different patterns generate the diversified and exceptional urban fabric of Downtown Cairo. Its definition, clarification, strengthening and exploration will form the base for the further process and the development of an urban revitalization strategy.

Figure 5: Urban Morphology Map 8) Data source: Architects Tillner & Willinger

3.5.2 Opportunity

This unique morphology presented a great potential for urban design strategies for future revitalization, since it structured Downtown into distinct characteristic areas. The proposals built upon this differentiation thematically with regard to their content, as well as technically concerning proposed measures in the public realm, i.e., streets, squares and parks. The circular squares and connecting diagonal streets especially served as starting points and foci for revitalization, i.e., backbones in a network of measures for creating a pedestrian-friendly environment.

The radial pattern originates from three circular squares and two streets that break the regular orthogonal grid and diagonally connect these squares. Comparable to recent traffic-calming measures in Paris, [13] these circular squares and diagonal streets present an opportunity to create unique places within the Downtown grid. The design measures focus on supporting pedestrians, e.g., widened sidewalks, reduced parking, landscaping, etc.

The orthogonal pattern is characterized by perpendicular roads of different hierarchies and defines rectangular land parcels of similar size. The opportunity here lies in the differentiation of the various street hierarchies. Local, quieter and narrow streets will become pedestrian-friendly thanks to the removal of street parking and the introduction of special landscaping that invites pedestrians to slow down and rest . Wider streets and the linkage to Ramses Railway Station will be strengthened in their business-oriented character, i.e., the movement of pedestrians will be supported while not ruling out vehicular traffic.

Cairo's organic fabric is typical of traditional, older neighborhoods that are more residential in use. Narrow, curved streets and similar building heights define its homogenous organic fabric. The relatively high density and residential character present a challenge for potential interventions; therefore, these districts are considered secondary for regeneration in the future and were recommended for protection, as they provide affordable housing for low-income residents, near their workplaces in Downtown.

The fourth defined structure within Downtown's borders is spaces defined by voids and predominantly large, freestanding buildings like in the area around Tahrir Square or the undeveloped site at Azbekaya. Historically, this typology originated for important buildings, e.g., palaces, theatres or museums (the Egyptian Museum or Abdeen Palace). These undeveloped spaces present yet another opportunity for regeneration, and landscaping could be used to achieve important linkages, primarily to the Nile River and Islamic Cairo.

4. The potential to develop adaptive strategies and become climate-proof is high thanks to existing strengths of Downtown Cairo, e. g. the metro, high-density neighborhoods with mixed-use heritage buildings

4.1 Metro, Railway, Buses

Currently, Downtown is well served with public transport with metro lines, an extensive bus system and the railway station at Ramses Square. Metro Line 3 is under construction and will further improve the public transport network. Usage is high, but the ways to and from the transport stops are highly uncomfortable due to the negative climatic conditions and, particularly for women, are often unsafe. This leads to the high rate in drop-off traffic with especially Uber having become a major form of commuting service. The buses are stuck in traffic with all the individual vehicles and therefore not very effective. Furthermore, they are jam packed and often unsafe for women.

4.2 Density and Mixed-Use

Downtown Cairo is a truly mixed-use city center with retail uses on the ground floors, offices and apartments on the upper floors. At the shop opening hours from 10 am until 10 pm streets are busy with shoppers, especially in the cooler evening hours. Apart from these hours and on major holidays streets are deserted because many apartments are rented, but actually vacant depending on the area; light industrial uses and workshops are also found on ground floors, especially car repair shops, because streets are cluttered with dysfunctional vehicles and not compatible with pedestrian-friendly mobility and street concepts.

4.3 Open Space

The extension of the public realm is limited in Downtown Cairo and there are not enough green spaces. An option for increasing the amount of open space is reorganizing the already existing public space by introducing pedestrian space instead of roadways.
Downtown Cairo's historic gardens have largely disappeared and only a few remnants of the historic public spaces are visible today, e.g. the park connected to Azbekaya still partially exists and is a melancholy reminder of its former historic grandeur. The unique opportunity to again complete the park and bring it back to its original state according to the historic plans and recreate its former splendor will be used by the Cairo Governorate following the DCRP

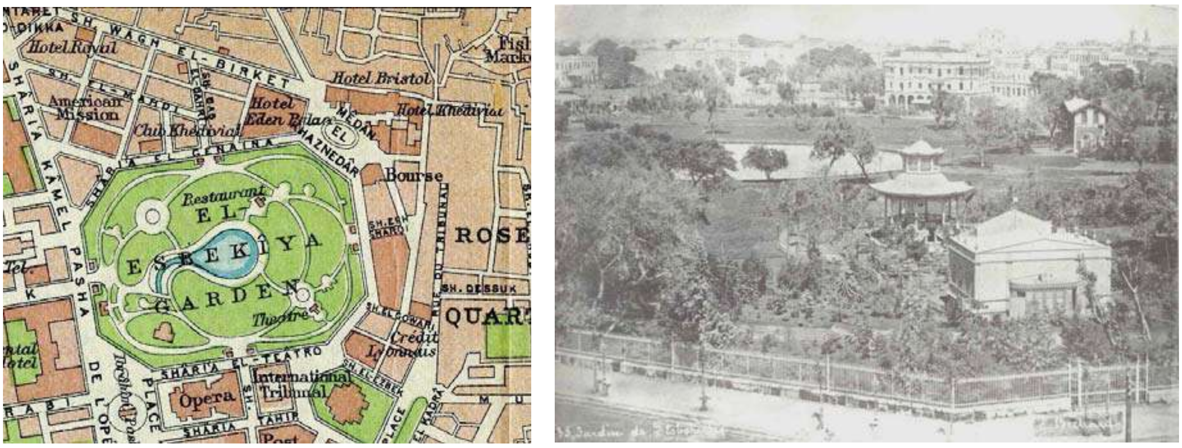

Figure 6: left: Historical map of Al Azbakeyah Garden, right: Historical picture of Al Azbakeyah Garden Data source: National Library Vienna

4.4 River Nile Waterfront

The embankment of the River Nile (see figure 7) and its environment offers an open space resource for Downtown Cairo as a continuous pedestrian promenade that currently suffers from a lack of connectivity. An option is to improve the pedestrian movement and linkage with safe crossings across Nile Corniche, and to include the existing bridges as a part of any new embankment design. By extending the embankment with platforms the pedestrian experience of the bridges can be expanded with safe terraces. A river transport terminal with ferries—like Venice's Vaporetto system—is an additional offer.

5. Vision and Guiding Principles

The guiding principles build on and reinforce existing strengths and address current deficits.

The following measures could lead to a more resilient city that takes into account its limited resources: improvements in infrastructure and resource-efficiency, mobility, landscape and urban design. Downtown Cairo could become a city center with less pollution as a result of a shift in the modal split towards clean public transport, improved connectivity for pedestrians and an overall strategy for a greener Downtown with unique open spaces embedded in its historic ambiance.

5.1 Guiding Principles

Fourteen guiding principles were established to govern the regeneration efforts, providing detailed guidelines for considerations like structure and development form, land use and massing, public realm and pedestrianization, access and mobility, as well as infrastructure and municipal services.

Figure 7: left: Situation Nile embankment now, right: Photo montage with added terrace
Data source: Tillner & Willinger

5.2 Concept Master Plan

The assigned area of Downtown was organized into different "regeneration zones" which share certain characteristics and introduces Strategic Urban Plans for five of these zones, setting a detailed planning methodology and toolset that can be replicated across Downtown.

5.3 Land Use and Massing

Guidelines that determine how the existing urban fabric, both in its massing/morphology and uses, could change in light of existing land and building ownership and historic preservation.

5.4 Public Realm and Pedestrianization

Guidelines that determine the improvement of existing public spaces and the creation of new ones, as well as the strategic conversion of vehicular areas into pedestrian-oriented spaces that encourage a more vibrant cityscape.
With an open space net work, a refurbishment of the public realm related to public transport hubs and connected pedestrian paths in green corridors, landscaping and shading squares, parks and greening flat roofs. The environmental quality as a result of street infrastructure would be improved through better hard and soft landscaping, lighting improvements, and street furniture.

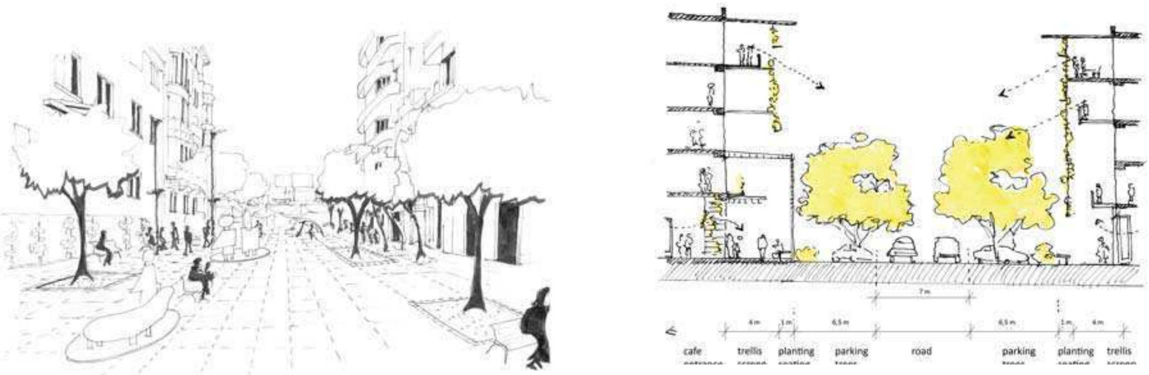

Figure 8: left: Pedestrianized street, right: Section of a "green street"
Data source: Architects Tillner & Willinger

5.5.1 Public Realm Interventions

Streetscape and public realm improvements, a framework of general regeneration interventions and energy efficiency upgrades in the public realm:
The categorization for the urban regeneration of Downtown's streetscape, energy efficiency performance and typology has emerged from project area analysis as well as best practices from the Project Team's 9) urban regeneration experience. Categories cover several regeneration themes. *Streetscape Upgrades* encompass existing public spaces and squares, as well as major north-south and east-west corridors, and entail the refurbishment and improvement of streetscape elements, including hardscape, landscaping, furniture, lighting, signage, and other streetscape amenities.

Pedestrianization involves changes in squares that currently have high vehicular traffic and pedestrianization which entails the removal of vehicular traffic. *(Opera Square - figure 9)*
Public Space Creation encompasses strategic vacant plots or open areas often currently being used as parking lots (Bab al-Louq) and entails their development as public spaces.

5.6 Open Space Strategy

Downtown Cairo , i.e. Khedival Cairo, has comparable density to European cities built at the same time as the building boom of the Gründerzeit in the late-19th century. Therefore, in the areas with intact historical urban fabric, only a few open spaces exist besides public squares and streets, larger ones at the edges of Downtown. The few publicly accessible spaces, e.g., the central green at Tahrir Square, are heavily used in spite of their environmentally disadvantageous situation, surrounded by heavy traffic. Therefore, these undeveloped spaces present a unique opportunity to provide more of these urgently needed resources for Cairo's residents. The goal is an evenly distributed network of green open spaces across Downtown, reachable within a walking distance of 500 meters and connected by landscaped streets, and linkages to the River Nile in the East and the Garden City in the South.

Parks, Squares and Open Spaces

"Open spaces," e.g., squares and parks, in Downtown Cairo, suffer from restrictions on accessibility which were implemented after 2011 . An opportunity arises from transforming vacant sites and reopening currently closed open spaces to the public. Most open spaces have to be redesigned to meet the current needs of the Downtown population.

Figure 9: Data source: left: Silja Tillner, right: Architects Tillner & Willinger 8)

Opera Square

This historic square, once the most prestigious in Downtown Cairo, has seen better days. Its significance, however, lies in being situated along the main east-west entry gateway into Downtown and a connection point to Islamic Cairo. This zone is of extreme strategic importance. Though quite challenged by intensive vehicular use, it lies in proximity to Azbekiyeh Park and the Continental Hotel—key regeneration catalysts—as well as a Governorate office building that has potential for intervention. The iconicity of the square and its historic significance mean that successful regeneration efforts are likely to have a "multiplier effect." Opera Square is to regain its status as a viable public space, rationalizing and optimizing different forms of mobility to catalyze regeneration in the surroundings.

5.6.1 Open Space Zonation

The aim is a greener Downtown with unique open spaces embedded in its historic ambiance with tree-lined streets, parks and shaded open spaces. The zonation characterizes different types of open spaces . Typologies, guidelines and a catalogue of recommendations that define desired qualities and apply to the different zones were developed for each category. The following categories were proposed:

5.6.1.1 Pedestrian-Friendly Streets

These streets will form the backbone of pedestrian circulation and connect important entry points, i.e., gateways, with main attractions. They will offer attractive and safe paths to the stations and will include major shopping streets which are highly frequented by pedestrians.

Pedestrian linkage will be achieved with an attractive, safe, and landscaped network of paths with better street lighting, seating areas, sanitary facilities, bus shelters, etc. Pedestrian-friendly streets have certain design characteristics, e.g. shaded sidewalks due to the planting of numerous new trees, safe wide sidewalks with handicap accessibility and places to rest, Vehicular through-traffic should be reduced by rerouting traffic to more peripheral streets and slowing it on central pedestrian spines and shopping streets with 30 km/h speed limits, traffic lights, and speed bumps. Driving lanes will be reduced and parking lanes eliminated, the space redistributed to wider sidewalks.

Public transport needs to be prioritized, providing attractive and safe bus stops with bus-shelters providing shade, lighting, and surveillance.

5.6.1.2 Pedestrianized Streets

They are proposed on streets that are currently of no significance for the road network and are used more for parking than driving. They will connect to the existing pedestrian network. and will be reserved for pedestrians. Urban design measures, see 5.6.1.1 apply here as well.

5.6.1.3 Existing Pedestrian Network

Existing passageways and pedestrianized streets are continued and connected to new pedestrianized and pedestrian-friendly streets.

5.6.1.4 Urban Square and Circular Squares

Urban squares are connected to the pedestrian network, serving as areas of rest and contemplation within the bustle of Downtown. Landscaping will be introduced to provide shading. Roundabouts are important landmarks and will become exceptional places.

5.6.1.5 Park/Green Space

Currently, Downtown Cairo has very few parks to offer its citizens. There are only a few possibilities within Downtown's densely built-up fabric to create new parks. Landscape design and plant selection should be sensitive to the climate and scarce water resources. The atmosphere should be inviting for families and provide enough spaces for children to play, as well as for rest and contemplation.

5.6.1.6 Connecting Open Space

There are two main connections missing: in the west, to the River Nile and its promenades and in the east, to Islamic Cairo. Specific proposals for Opera Square, Nile see figure 7, 9

6. Access, Mobility, and Transportation

Like in all megacities, transport is a major challenge for the Greater Cairo Metropolitan Area with more than 20 million inhabitants. To guarantee well-functioning and sustainable mobility in cities of such size, an adequate high-capacity public transport system is required. Over the last decades, Cairo's population has been growing faster than its infrastructural and mobility services. Major infrastructure projects, such as the Metro, may have arrived too late. [10] Nevertheless, the introduction of the Cairo Metro in 1987 was a major step towards sustainable mobility. The evolution of the modal share shows the positive effect of the Metro's introduction, creating a significant modal shift toward public transport. After 1987, the modal share of cars decreased significantly. The modal share of buses also decreased while informal transport with shared taxis increased significantly. Non-motorized traffic (mainly walking) accounts for 32% of all trips in Cairo. [11] Compared with European or North American cities, this is a very high share.

While there is broad agreement among stakeholders that mobility solutions offering reduced vehicular traffic must be a part of any regeneration attempt, there is considerable disagreement on the scale, location and form of these interventions. The process of thinking should follow the principles on traffic reduction and pedestrianization in Downtown Cairo, including the fact that 40% of vehicular flow in Downtown Cairo is reportedly “drop-off traffic;” as much as 80% of vehicular flow in Downtown is purely through-traffic. The DCRP is proposing a redesign of Downtown Cairo’s vehicular flow and street hierarchy.
Car Volume and Speed Reduction: Reduce motor traffic volume and traffic speed
The ambition in Downtown is that to optimally reduce both vehicular traffic *and* speed in each street to privilege pedestrians, enhance road safety, improve air quality, reduce noise, and afford a better pedestrian streetscape quality. One way of looking at this is to reduce a street’s current position in the road hierarchy and move it towards the bottom—local streets and roads that have the lowest speed limit (30km/h).

The pedestrian network is mainly defined by the street network, with a few pedestrian zones and passages. The main pedestrian traffic flows have their source at public transport stops, mainly the Metro, with many areas of conflict between pedestrians and vehicules.

7. Specific Measures and Implementation

Five Priority Areas were defined in consultation with the Cairo Governorate, those zones that, if planned and implemented, would have the most catalytic effect on the broader regeneration of Downtown Cairo as a whole were selected.
Priority Area Concept Planning: All five concept plans made concrete and spatially delineated recommendations for regeneration interventions in the following categories:

7.1. Streetscape Amenitization

Streetscape Amenitization encompasses existing public spaces and squares, as well as major north-south and east-west corridors, and entails the refurbishment and improvement of streetscape elements, including hardscape, landscaping, furniture, lighting, signage, etc.

7.2. Pedestrianization Prioritization

Pedestrianization Prioritization involves changes in squares that currently have some degree of vehicular traffic as well as various streets and corridors, and the creation of pedestrianized corridors that entail the removal of all vehicular traffic. Mobility Improvements encompass squares that are currently centers of mobility interchanges as well as various streets and corridors, the optimization of existing mobility patterns, whether through intersection redesigns or shared street infrastructures which continue to allow vehicular traffic, but in ways that improve pedestrian movement.

7.3. Exterior Lighting

Exterior Lighting encompasses the systematic upgrading of exterior lighting to energy efficiency and more durable fixtures, recognizing current inefficiencies of existing luminaries.

7.4. *Sustainability*

Sustainability includes the introduction of key green building interventions such as photovoltaic panels and green façade structures, particularly for governmental and institutional buildings where these interventions can more readily be financed.

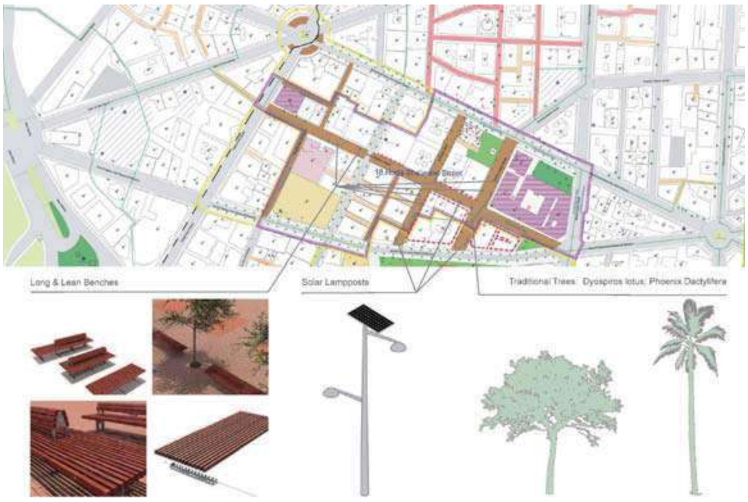

Figure 10: Street furnishing
Date source: Architects Tillner & Willinger 8)9)

7.5. Public Space Creation

Public Space Creati on encompasses strategic vacant plots (often currentl y being used as parking lots) and ent ails their development as publ ic spaces, particularly in the form of extensions to and expansions of adjacent or nearby publ ic spaces and squares. *They were planned in detail in response to local needs and conditions*, e.g. *representative for the measures in these zones* are *Opera Square*, see fig. 9 *and Bab al-Louq. The visison* is to reclaim Bab Al-Louq as a public space, which serves as an “urban interchange” (as opposed to a vehi cular interchange) that links Tahrir Square t o Abdeen Square, and Downt own’s charismatic southern neighborhoods.

Regeneration Interventions

Street furnishings (see figure 10) are provi ded in the area of Bab Al-Louq Square and in the pedestrianized areas near-by. Trees and l andscaping are to be provi ded on the boul evard streets and along the pedestrianized northern edge of the square.

All streets that are to becom e boulevards will feature expanded si dewalks through the conversion of parking lanes. Pedestrian crossings w ill be upgraded at strategic points along busy, e.g. El-Tahrir Streetswith formal pedestrianization on adjacent quieter streets.
Substantial opportunities exist on Opera Square (see fi gure 9). Trees can be added t o the Square, while greenscape can be provi ded on the pl atform, a de-facto, 24-hour pedestrianized zone. Energy-efficient lighting for the open spaces and the façades is intended for the Opera Parking Structure and the Continental Hotel. Green façade features and photovoltaic roof panels are proposed for the Opera Parking Garage.
The introduction of a scul ptural, five-meter, raised platform above the traffic interchange of Opera Square and the reacti vation of the green space di rectly east of the Parki ng Structure will dramatically improve the area.

8. Implementation Framework for Cairo Governorate’s Green Building and Energy Efficiency Efforts in Downtown Cairo Urban Regeneration

Guidelines were devel oped to prom ote building energy effi ciency in Downtown Cai ro’s unique built environment in public and private buildings and in public amenities. Downtown’s framework conditions were st udied, especially its historic urban f abric. The po tential for “greening” buildings in Downtown Cairo was examined.
Rehabilitating the Buildings of Downtown Cairo to Better Standards
This project has m ade efforts to further the development of sustai nable building standards, and has produced a set of guidelines and cases about what is needed t o modernize Downtown’s building stock and make it m ore efficient. Urban sustainability and green

considerations for energy efficient buildings, green walls, landscaping of roofscapes and solar panel installations should be integrated as part of any building modernization.

Public Building Upgrades and EE Retrofitting

Heritage: Many of Downtown Cairo's historic buildings of outstanding value are worthy of being included in a registry similar to European cities with a comparable historic building stock from the end of the 19th and the beginning of the 20th century, e.g.,Paris or Vienna, making heritage in spite of the neglect the single most valuable asset for urban regeneration.

Opportunity

The protection and safeguarding of heritage buildings and districts would lead to a greater attraction of Downtown Cairo for its citizens. Since buildings also tell stories, not only about architecture, but also about people, as was described in the book *Discovering Downtown Cairo* [12], a well-preserved historic district with landmarks along a historic trail would create attractive linkages to the past and stimulate an active interest in the history of the city.
The total building stock in Downtown Cairo is estimated to be 1,492 buildings, of which 8% are government buildings of primarily office and institutional uses 8). As a result of a detailed building analysis and energy audits8) several types of energy efficiency considerations such as exterior treatment, lighting, electromechanical systems and services were identified.

8. Conclusion and Future Outlook

The Urban Regeneration Plan for Downtown Cairo could become a blueprint for future efforts in other cities in the developing world and in Eastern Europe facing similar challenges. The innovative revitalization approach combines classic components of urban design with novel energy-saving and educational measures (which are usually separated), i.e., the energy retrofitting of public and private buildings. The approach is based on valueing what exists – and builds upon it - a sensitive and practical planning method which allows the integration of the needs of stakeholders and leads to a higher acceptance than previous plans.

For Downtown Cairo this implementation oriented plan has, for the first time in its lengthy planning history, offered the Cairo Government and the authorities a practical handbook with strategies, guidelines and detailed proposals including cost estimates. The Cairo Governorate is currently proceeding with the implementation of Opera Square as a catalytic project and will continue with further measures in the public realm and building renovations.

These measures would – if implemented – contribute greatly to reducing pollution-levels and cooling the city center. Downtown could become a sustainable model for other neighbourhoods in Cairo.

District cooling in Sanya Haitang Bay: energy integration in urban planning from theory to practice

Martin TZOU, François Courtot, Jiashuo Xiu, Jingbo Guo, Sijie Liu, Yili Xiong
EDF China, China

Shu DU
China Center for Urban Development, China

Abstract: Cooling demand counts for a high proportion of the energy consumption in hot and humid cities, thus contributing massively to carbon emissions. This situation is amplified in rapidly growing Southern Chinese cities, while integrating energy into urban planning is also a challenge given the complexity of the Chinese Planning system. However, a recent planning case in the new district of Haitang Bay in Sanya, at the most southern point of China on Hainan Island, proves the contrary. The resulting action of the “Smart and Low Carbon planning” of Sanya is the implementation of a multi-energy district cooling system, with the potential of reducing CO2 emissions up to 30 per cent. The case of Sanya not only shows the impact of energy-led urban planning, it also validates the effectiveness of district cooling solutions in hot and humid cities in the context of climate change.

1. Cooling, the new frontier of climate change planning

1.1 The rise of the global building cooling demand

Indoor building environments count for a large proportion among the energy consumed and carbon emitted in today’s world, contributing around 40% of the total energy consumption. Among all types of energy consumption, heating, ventilation and air conditioning (HVAC) systems are the biggest contributors. Providing highly comfortable indoor environments is indeed the inevitable challenge for buildings. In public buildings such as offices, shopping malls, sport centers, etc., energy consumption for cooling can represent over 50% of the energy demands (Pérez-Lombard, 2008).

In hot and humid climates, the well-known traditional building techniques of adjusting to microclimate through natural ventilation are far from fulfilling the needs of modern comfort, and air conditioning in particular is surging. Today, air conditioning already accounts for about 40% of power use in Mumbai, India. More than half of Saudi Arabia’s peak summer power consumption also goes for air conditioning. The Vietnam Housing Management Organization’s has stated that 54% of its energy consumption was used on housing cooling (Huang, 2016).

People living in hot and humid climates tend to use air conditioners more frequently and for longer period of times than in other climates. The high temperature gas discharged by air conditioners worsens the outdoor environment and leads to a vicious cycle of increasing energy use in hot and humid climates. As the tropics and subtropics become increasingly urban, industrial and affluent, energy demands for comfort are evolving differently than they have historically across the global North (Waite, 2017).

Already, HVAC account for 35% of total primary energy in the United States and is expected to reach similar proportions in China within five years. About 87% of US buildings are now air conditioned, and trends in the developing world suggest it is advancing fast down the same route. In this regard, China makes no exception in the trend of growing cooling demands in hot and humid climates, driven by a rapidly expanding urban middle class.

Globally, cooling demand is rising exponentially in cities. Reducing it has become the new frontier of climate change initiatives. The United Nations Environment Program is promoting actively District Energy Systems in cities, describing it as “one of the least-cost and most-efficient proven solutions in reducing emissions and primary energy demand” (UNEP, 2015).

1.2 Growing cooling demand in Chinese Southern cities

Since the opening to market reform in the 1990s and the urban expansion policy implemented subsequently, China has greatly seen its real estate and construction industry booming. With the economic development and the urbanization process, more and more people will be concentrated in this area, and they use more and more energy.

The hot and humid climate zones in China are located in the middle and lower streams of the Yangtze River experience a primarily subtropical monsoon climate and a monsoon humid climate. The area also holds the two most economically developed regions in China: the Pearl River Delta and the Yangtze River Delta, concentrating more than half of China’s population and more than 60% of the country’s GDP.

According to the data of 2017 from National Bureau of Statistics of the People’s Republic of China, the average per capita housing space of residents in 2016 was 40.8 square meters. In cities the same index was 36.6 square meters, which increased nearly five times compared to the 6.7 square meters in 1978, and it continues to expand.

According to the 2017 China Building Energy Consumption Report, China’s total energy consumption for buildings in 2015 was 857 million tons of standard coal, which accounted for 20% of the total national energy consumption. The three most significant factors that impact energy consumption for buildings are: the size of the urban population, the GDP of the area, and the climate zone (Li, 2009).

The overall quality of China’s outdoor thermal environment is also degrading each year. Up to 65% of residential areas in China have a thermal index that is higher than the safety index of 32ºC wet-bulb globe temperature, and 78% are above the thermal comfort index of 28ºC wet-bulb globe temperature (Fang, 2014). Hot and humid areas have longer and hotter summers, increasing the enormous demand of cooling and dehumidification through air conditioners. With the rise of living standards in both urban and rural areas, the energy consumption for air conditioners in buildings is bound to increase continuously, and most severely in the Southern part of the Yangtze Basin.

Regional disparities in energy production and consumption follow economic development; energy consumption per capita in these relatively developed regions is significantly higher than the less-developed regions, with a quality of energy also being above the national average (Zhang, 2008). The energy efficiency map in China follows the same spatial dynamic, going from lower to higher values from West to East (Chen, 2017). Hence, achieving a demonstration program in Southern and Eastern coastal areas in China could make a significant impact.

2. The challenges of energy planning integration in China

In China, the trend of research in decentralized energy as a carbon reduction solution appeared in the late 1990's, and rapidly became a focus as China started to commit itself into climate change issues. From the initiatives driven by green building energy saving programs in 2008, it evolved to comprehensive low carbon energy planning at the scale of cities and regional planning (Zhao, 2012). However, the ambition of integration in the Chinese planning system (or *duoguiheyi*) is confronted to the bureaucratic rigidity and power struggle between administrations, making it difficult to implement (Tzou, Du, 2017).

Currently, two main types of plans co-exist regarding energy in China's planning system. The first, the Energy Development Plan, considers the overall supply and demand relationship and energy strategy at the macro-level of the country. The second, the Energy Engineering Plan monitors at the micro-level of cities and districts the sub-energy systems' infrastructures (electricity, heat, gas).

2.1 Energy Development Plan

Energy Development Plan is a five-year thematic plan developed by the National Development and Reform Commission (NDRC) that involves multiple levels, including provincial the central government level, the provinces, the cities and the counties. The national level focuses on macro issues such as the total energy consumption and its intensity, the energy structure adjustment, the energy development layout, enhancement of energy efficiency and quality, improvement of energy safety, strategy of energy autonomy, innovative developments, etc. In city and county levels, the Energy Development is planned according to the local needs which are different in each area. Ma (2016) considers the county's Energy Development Plan primarily should include aspects such as a reasonable forecast of energy demand, clear development goals and direction, and the main objective and initiatives.

2.2 Energy Engineering Plan

Energy Engineering Plan is a thematic plan developed in the Ministry of Housing, Urban Rural Development (MOHURD), involving levels of cities, counties and townships. The content of the Energy Engineering Plan is similar at each level nationwide, and primarily includes the three main engineering plans which are the city's power supply, gas and heating plans. Although in the "Measures for Formulating City Planning" (MOHURD, 2005) it is required by law the urban overall planning to "ensure integrated objectives and protection requirements such as the ecological environment, land and water resources, energy, and the nature, historical and cultural heritage protection", comprehensive energy planning is rarely present in the current urban planning in China. This reflects that energy issues are not widely recognized in urban planning (Cao, 2010).

2.3 Challenges of urbanization

Urban planning practices tend to consider energy issues in partial and separate ways, following the framework fixed by the system of planned economy. Energy supply is increased when there is an increase of population, energy infrastructure is planned to follow the city expansion. Along with rapid urban development, energy systems have become more disordered and fragmented, while still struggling to keep up with the pace of urban development.

Under the urbanization movement of "Planning for growth" (Wu, 2015), conflicts between energy supply and demand are quite obvious to happen at a local scale. At the beginning of a region's development, the occupancy rate is low and the load is small, therefore energy suppliers will adopt various measures to encourage energy consumption for the purpose of earning profits. When the region is fairly developed and there is a higher occupancy rate, the original planning can no longer satisfy the demand. The energy supply will be pushed to expand. After the energy supply is expanded, a new cycle of consumption begins which will lead to wasting of resources and unreasonable use of energy, thus forming a vicious cycle. This urban planning practice aimed to constantly satisfy the energy demands is today obsolete and is missing its goal of integration.

Besides, the weak position of Energy Engineering Planning in the planning system makes it more influenced by the evolution of land layout and the thematic plan contents, rather than the overall requirements of the energy system. The lack of coordination between each type of sub-energy leads to contradictions and limitations at the implementation level. Planning methods of energy issues in China also lack of maturity, making it more difficult to adapt itself to the more and more complex status of energy in cities (Cao, 2010).

Problems are worsened in hot and humid areas. Unlike heating, district cooling has not become a necessary chapter in urban planning. If district cooling or combined cooling heating and power is not considered, the cooling energy is then usually provided by electricity. The increasingly large power load of air conditioners is however inevitable. Many cities have had to adopt methods such as deliberate power cuts, “abandoning production, preserving air conditioners”, creating a huge load difference between peak and off-peak periods. This has led to a low efficiency in power investment (Long, 2008).

3. Innovative Energy-led Urban Planning in Sanya

Energy experts in China have been calling in recent years for an integrated approach at the early planning stage of cities (Long, 2008). Since the Chinese government has committed itself to the Paris COP21 Climate change agreement, some noticeable initiatives are worth mentioning, showing the trend of energy preservation in planning. In particular, the recent climate change initiative in the city of Sanya can be seen as a successful attempt of planning integration of low carbon energy practices in hot and humid climates.

3.1 The existing energy status of Sanya

Sanya is located at the southern tip of China, on Hainan Island, with a tropical ocean monsoon climate, an annual average temperature of 25ºC and more than 2,500 hours of sunlight annually. With an urban area of 3,200 km2, Sanya is the most touristic coastal city in China, also serving as an important maritime and military base for the South China Sea. In 2015, the local population was 748,900 hab., while hosting 15 million tourists annually (10.6% growth).

In 2015, total energy consumption in Sanya was 1.5 million tce (ton coal equivalent), with an increase of 4.94% from 2014. Thereinto, tertiary industry consumed energy 935,100 tce accounting for 61.96% of total consumption, being the key field for energy conservation. In primary industries, secondary industries and civilian sectors, energy consumption accounted for 6.88%, 15.44% and 15.72% of total energy consumption, respectively.

The energy structure includes electricity, oil, natural gas and coal. As the main energy resource, electricity occupied 56.56% of total energy consumption in 2015. The peak electricity load in 2015 was 566 MW (megawatt), while by the total power install capacity (excluding solar projects) was 162.2 MW, which means Sanya relies heavily on electricity import from the grid.

The existing energy planning

Following the national system, Energy Engineering Plans in Sanya include only the Electricity Plan and the Gas Plan, respectively managed by two separate municipal services. There is no Cooling Plan, and Energy efficiency issues are discussed in the Green building, Industry and Transportation plans. Past energy efficiency initiatives have been hard to implement, due to the lack of a systemic energy planning and the non-existence of relevant regulations and indicator systems, besides the usual difficulties caused by rigidity of bureaucracy.

Challenges of energy conservation in Sanya

Because of the lack of energy management, limited technical maturity, high energy consumption and high emissions, non-optimal consumption behaviors are still very common in Sanya. With the ongoing fast paced urbanization and the increase of urban population, the energy needs in Sanya will continue to grow. The city will face the following challenges:

1) With the particularities of a tropical coastal touristic city, power consumption of Sanya will keep its seasonal features, with peak power demands and a difficult balance of supply and demand;

2) The potential of local power capacity is very limited – Sanya mainly relies on the input of external electricity;

3) The energy structure is quite simplistic; new energy has not been well developed in Sanya.

3.2 Smart and low-carbon energy planning of Sanya

Being the pilot city for low-carbon development in Hainan Province, Sanya has committed to realize an in-depth transformation for the 13th Five Year Plan (2016-2021) and has launched a "Sanya Low-carbon Energy Planning and Action Plan" (Courtot & Tzou, 2016).

Aiming to tackle climate change and reduce CO2 emissions, all aspects of energy in the city are analyzed jointly: the structure of the energy demand (electricity, heating, cooling, hot water, gas), the energy efficiency solutions that can reduce this demand, the structure of the external energy supply (existing mix and its evolution) that contributes to fill this demand, the local potentials for renewable energy, and the complementarities between energy and other urban infrastructure (waste, water, transport, etc).

The urban land planning information integrated into Geographic Information System (GIS), are then combined with satellite image to classify each block by construction time sequence – constructed, under-construction, short term and long term development; and identify urban morphologies, composed of typical buildings.

To evaluate the evolution of energy needs in Sanya, we distinguished 14 typical urban morphologies and 16 typical buildings (Fig. 1).

Finally, the energy demand (cooling, hot water, electricity) of each block at different time periods could be achieved based on the blocks' information (land function, limited height of buildings, FAR, location) and the defined morphologies it belongs to.

Fig 1. Urban morphology classified by energy demand typology

Energy demand evaluation

The evaluation of the energy demand used GIS to integrate the urban planning and geographic information, from both time and space. A mapping of the energy demand (cooling, hot water, and electricity) could be then realized based on urban morphologies, at different time periods (Fig. 2).

Fig 2. Energy demand evolution in Sanya 2016-2030

Buildings are the largest energy consumers in Sanya, with space cooling being the most significant. Today, construction standards applied in Sanya are well adapted to the local climate conditions, leaving only limited improvements to be made on the building envelop.

However, energy demand in buildings will continue to rise as the tertiary sector will develop. Revenues of permanent residents will increase, with a rising need for comfort and domestic equipment. According to studies, cooling demand for permanent residences in Sanya will rise by up to 15% per year in four years.

By analyzing the energy demand evolution in Sanya, three zones with a large upcoming increase of the energy demand and a relatively large share of tertiary buildings were identified. Each of the three zones has its specific load structure and available energy resource, and therefore its specific optimal district energy solution. Haitang Bay is the most energy intensive of these zones that could strongly benefit from high-efficiency district energy solutions (Fig.2).

Local energy resources analysis and carbon reduction actions

Studies have been conducted to identify opportunities to exploit the local energy resources, combining the evaluation of 40 technologies covering local production and energy efficiency solutions. Comparing the results of a set of simulation, cross-checked with collected consumption data, high efficient equipment and adapted human energy behaviors are identified as effective solutions to reduce energy consumption of air-conditioning. While further improving building envelops out of the existing building thermal regulation is found to have only a slight impact on energy consumptions.

A full range of energy efficiency actions, technologies and behaviors have been evaluated and quantified in terms of cost, energy economy, and avoided CO2 emissions. This evaluation is based on detailed local conditions of climate, building thermal characteristics, occupation patterns, and energy usage behaviors. The deployment potential of each action has been quantified in space (building plot granularity) and in time (period by period following the phasing of the urban development).

This approach is based on local conditions and their expected evolutions - population, building stock, energy usage, and natural resources. Individual actions were identified, with cost/benefit analysis and evaluation of the deployment of potential actions.

From a technical point of view, the planning is quantitative and evaluates the potential deployment volume of each action, its emission reduction potential and analyzes the techno-economic feasibility for implementation (Fig. 3).

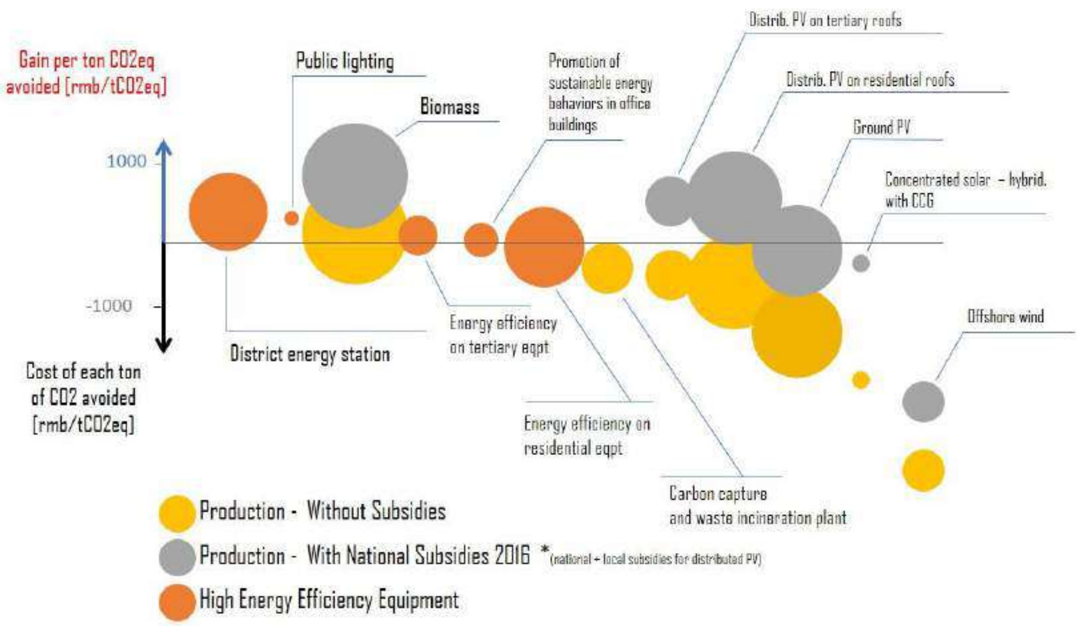

Fig. 3 - Summary of carbon reduction actions

With consideration of natural and economic condition, Sanya has potential to develop roof PV and biomass technology. According to the existing situation in Sanya, high efficiency energy equipment and good energy behaviors could significantly reduce building energy consumption. Meanwhile, district energy system could decrease energy cost and also achieve considerable CO2 reduction in new district and urban renovation zones.

On a side note, the energy-led urban planning practiced in Sanya has inaugurated a new type of “Urban Energy Plan” at a higher position in the Chinese planning system. It should be considered as an extension of the Energy Engineering Plan into urban planning, as well a mean of implementation for the Energy Development Plan, to achieve a reasonable utilization of energy hence the carbon reduction goals.

With sustainable development held as a core principle, the Sanya Low carbon planning is already a case of “best practices” in China, especially because it leads to the implementation of the largest urban district cooling network in China in Haitang Bay.

4. District Cooling in Haitang Bay

Famous for its white sand beach, Haitang Bay is 28km away from the city center in the northeast of Sanya, with a long strip of 22 high-end hotels and an estimated population of 250,000 by 2030. As the main resulting action of the “Sanya Smart and low-carbon planning”, the City government has launched in 2018 a thirty years concession contract to a multi-energy District Cooling project, aiming to provide chilled water, electricity and hot water to users in Haitang Bay, mainly the high-end hotels and public buildings.

4.1 Energy demand and simulation of supply and demand

Energy demand surveys have been conducted in the preliminary phase by inspecting existing hotels’ cooling systems, one by one. Daily utility consumptions of hotels have been collected for an entire year in 2016. The cooling demand is closely linked to outside temperature, not the hotel occupancy rate. This is because all hotels keep the maximum temperature of 26^0 C all year round, even with no occupancy. Similar studies have been made to better understand the behavior habits of electricity consumption.

Based on energy demand curve characteristics of hotels, the electric, cooling and heating demands have been simulated by professional energy demand simulation platform. The planning of new hotel construction and design in Haitang Bay has also been inspected to assess the increase of cooling, heating and electric demand expansion (Fig. 4).

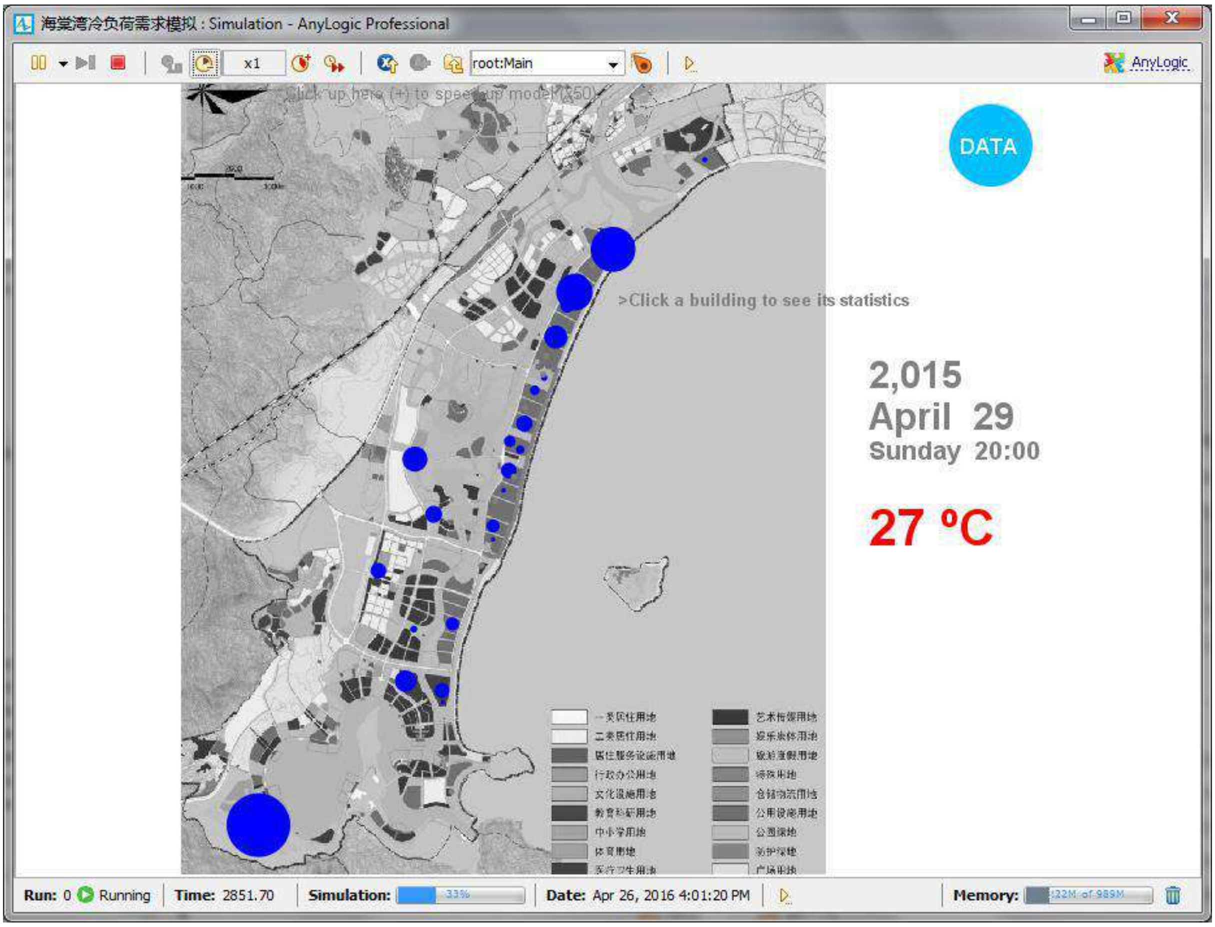

Fig 4. Energy demand simulation in Haitang Bay

4.2 A high CO2 reduction performance

A comprehensive energy saving system has been designed with heat recovery, seawater use, ice storage and combined cooling heat and power (CCHP). Four energy stations with a total installed capacity of 86,400 refrigeration ton (RT) in chillers and 8.8 MW in generators will be built for this project. The average annual cooling capacity is 649,760,000 KWh after completion. Meanwhile, a Smart network would be built on the energy internet for Smart energy production and distribution according to users' demand.

Urban development phasing was also taken into account, each energy station being designed according to the predicted growth of energy needs, to avoid having oversized systems during the early phases of the urban development.

The energy stations are a combination of high efficiency chillers, ice-storage, heat pumps and back-up boilers, with a total installed capacity of 86.400 RT in chillers and 8.8 MW in generators. The coefficient of performance (COP) calculated for the systems raises from 2.35 to 3.2, an increase of 36%, which results from the use of large-scale highly efficient centrifugal chiller (30% more efficient than the conventional chiller), and collective efforts of advanced simulation tools for system design, operation optimization and maintenance of district cooling projects.

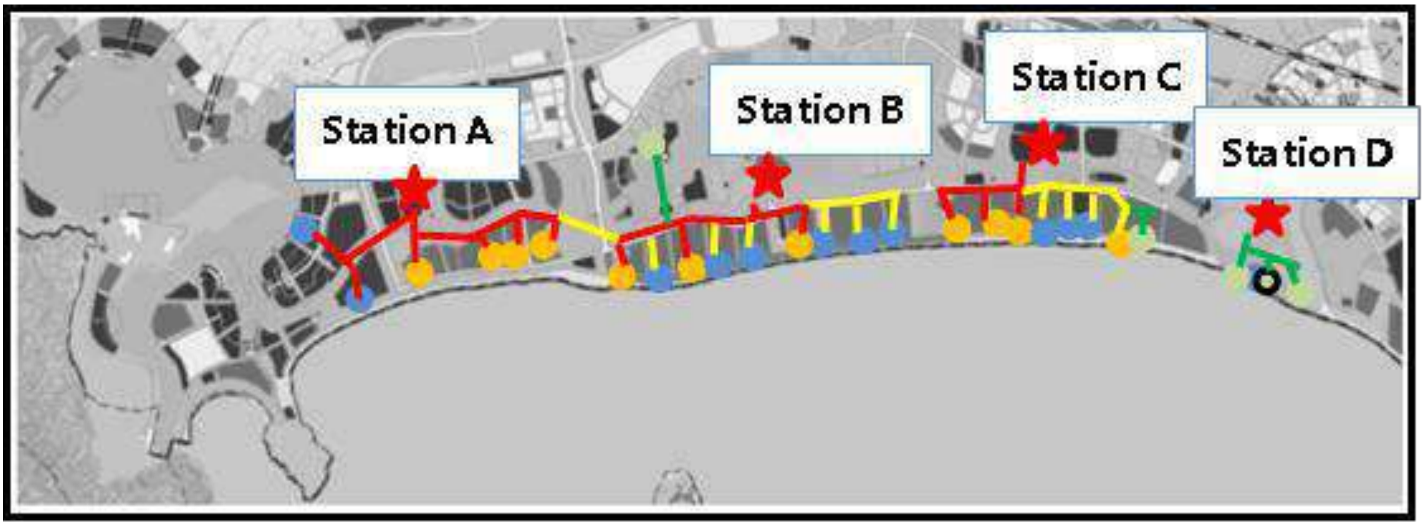

Fig 4. Localization of the four energy stations in Haitang Bay

Four energy stations are linked through an optimized "Smart network" that acts as a back-up during peak loads, ensuring energy efficiency, stability and safety in Haitang Bay. The concept of "Fourth generation network" has been introduced, applying multi-energy complement, big data, cloud service as well as artificial intelligence for the Smart and centralized network control, operation and management (Fig. 4).

Thanks to the CCHP and ice storage, the general electricity consumption would be effectively reduced by half after completion of the four stations, from 276.5 GWh to 115.3 GWh. After completion, 32.553 tons of standard coal could be saved every year. In comparison to the conventional individual central air-conditioning system, 81.802 tons of CO2 would be reduced, counting for 16 per cent of the total amount of emissions of Sanya City according to the 13th Five Year Plan. The system can eventually be optimized with sea cooling or an additional gas fired CCHP and reach 30 per cent of CO2 reduction.

Aside from CO_2 emission reductions, the Haitang Bay district cooling pilot project has also achieved other benefits, including: affordable energy provision; reduced reliance on energy imports and fossil fuels; economic development and community control of energy supply; local air quality improvements; and an increased share of renewables in the energy mix.

4. Conclusion

Satisfying the increasing cooling demand while reducing the CO_2 emissions have become the major challenge of cities in hot and humid climates. With the still growing urbanization rate, the stakes are high in reducing the cooling demand for Southern Chinese cities. In China, another layer of complexity is added with the incoherencies of energy planning handled by different administrations working in silos, making low carbon energy solutions difficult to be integrated at the planning stage of new districts cities.

In this context, the climate change initiatives taken in Sanya lead the path towards new and innovative practices in planning. In line with the CO_2 reduction objectives of the city, the Smart Low Carbon Energy Planning of Sanya successfully integrates energy issues at the early stage of urban planning, delivering guidance to balance the energy consumption and supply from the demand side in the long term, and providing carbon reduction actions.

The main resulting action is the implementation of a District cooling in the most energy intensive luxury hotel area of Haitang Bay. The Smart multi-energy system is tackling successfully the urban energy challenge by reducing carbon emission up to 30%, a first of a kind performance at this scale in China.

Climate change is calling for a more integrated approach in planning. With multi-benefits for hot and humid climates, district energy solutions become relevant parameters for measuring the degree of urban planning integration. On a side note, this trend indicates in a way the end of the “Planning for growth” paradigm in China, opening a new era for more consideration to resilience and energy preservation in urban planning.

Synapse
Cities in areas getting hotter and drier have to find alternative approaches to manage the increased demand for water versus the shrinking supply, while also climate proofing their cities. Water sensitive urban design as an adaptation strategy integrates the management of urban water resources with urban planning.

1. Introduction

Water is one of the most vulnerable and threatened resources in the world that should be protected and managed for the survival and well-being of people. Water is also a hazard that people should be protected from, for too much or too little water threatens our survival and well-being (Rosenzweig, et al., 2015; Prüss, et al., 2002).

Urbanisation and its associated opportunities and challenges has resulted in an increase in the demand for water in cities (UN Water, 2017). While the demand for water is growing, the supply of fresh water is being compromised by climate change, amongst others. Water is predicted to be the "primary medium through which early climate change impacts will be felt by people, ecosystems and economies" (Butterworth & Guendel, 2011). It is thus vital to understand the impacts of climate change on urban water supplies, as well as the vulnerability and exposure of people, infrastructure and economic activities to weather-related hazards, to be able to adapt accordingly. A water sensitive approach is aimed at integrating the management of urban water services and resources with urban planning (Celeste, et al., 2013). As the basis for an adaptation strategy it includes various adaptation actions aimed at regenerating water services as well as reducing the impact of hydrological climatic events (Armitage, et al., 2014). This paper argues that water sensitive urban design should be used to frame the strategy for adapting cities projected to become hotter and drier in future. It discusses a framework to select adaptation actions linked to the risk profiles of cities as part of a water sensitive adaptation strategy.

2. The growing demand for water in cities

Urbanisation poses a challenges to water supply. As urban populations worldwide continue to grow, the demand for water in cities grow due to the sheer increase in the number of people and economic activities. Simultaneously, water consumption per capita (and the resultant quantity of waste water) rises as economic development increases due to changing lifestyles, before it levels off or eventually declines per capita (Yang & Jia, 2005; Popkin, 2006; Anisfield, 2010). In many developing countries where urbanisation rates are high, and expected to remain high for decades to come, much of this growth is occurring in places without hard infrastructure (Bahri, et al., 2016). Informal settlements, extensions on the periphery of cities, and rapidly growing small towns all have to be supplied with water (Bahri, et al., 2016). However, limited resources and capacity has meant that municipalities struggle to keep up with the demands, resulting in growing water service backlogs (Fatti & Patel, 2013; Muller, 2007). Furthermore, ageing water delivery infrastructure is not always maintained adequately, or has in many cases reached the end of its design life, leading to significant water losses through leakage (SAICE 2011; Bahri, et al., 2016; Multikanga, et al., 2009). Many cities thus face the huge challenge of managing current water use as well as planning for increasing future water demand against a shrinking supply, yet current water management and infrastructure tend to be fixed (World Bank, 2018).

Urbanisation poses a threat to water sources. Population pressures may lead to groundwater pollution and a deterioration of stormwater quality. Higher building densities mean an increase in impervious areas and therefore increases in the volume and rate of stormwater runoff, leading to greater flow rates and volumes in watercourses, and increases in risks for downstream flooding and erosion (Armitage, et al., 2014; Wong, et al., 2012). Studies also show that 80-90% of all wastewater generated in cities in developing countries is not properly treated before being discharged into surface water bodies. The collection, treatment and disposal of increasing quantities of wastewater is a major challenge for cities in both developed and developing countries (UN Water, 2017).

All of these issues combined, with increased vulnerability and risk to environmental hazards, place water at the nexus of the development challenge (SADC, 2012).

3. The impact of climate change on cities and water systems

Changes in the climate have significant impacts on the water systems of cities, particularly in regions that will become hotter and drier. The demand for water is increasing while the water supply is impacted by rising temperatures through higher rates of evapotranspiration and decreasing run-off, placing severe strain on already stretched water systems (Engelbrecht, 2017). Changes in the frequency, severity, duration and distribution of extreme weather events can affect the quality and supply of water, sanitation services and infrastructure (Armitage, et al., 2014; Carmon & Shamir, 2010).

The existing water supply and sanitation infrastructure was heretofore designed for different resource availability and water use. Such historical infrastructure is increasingly under greater pressure owing to changes in the climate and demand for water. Changes in the climate may have the following impacts on cities' water systems:

Climate related events and impacts	**Potential impacts on urban water systems**
Storms, flooding and intense rainfall	• Put pressure on or overwhelm the design capacity of existing drainage infrastructure; • Overwhelm stormwater management systems that lead to backups that cause localised flooding or greater runoff of contaminants such as trash, nutrients, sediment or bacteria into local waterways; • Cause stormwater runoff to wash pollutants, sediment and nutrients into water sources. These can threaten drinking water sources, diminish water quality, and complicate water treatment processes; • Lead to, and increase, erosion and larger sediment loads that can cause a reduction in water storage capacity as a result of the rapid sedimentation of storage reservoirs; • Disrupt water services and cause breakdowns in pipelines that distribute water; • Cause sewage contaminated flooding where stormwater drainage and sewerage systems are combined; • Inundate toilets and/or sewage treatment facilities that increases the risk of contamination of the environment;

	• Lead to the destruction or the deterioration of the structural integrity of basic water infrastructure; • Contaminate water sources, leading to increases in the incidence of water-related and waterborne diseases; • Cause a rise in groundwater that puts sewage treatment plants at risk when they are positioned on low-lying ground due to their reliance on gravity; • Cause a rise in groundwater that decreases the efficiency of natural purification processes, resulting in an increase in the risk of the spread and contamination of infectious diseases and exposure to toxic chemicals;
Decrease in precipitation and drought	• Lead to insufficient water resources being available to meet the demand by households and economic activities for the operation and performance of water systems such as to flush sewage systems adequately; • Concentrate pollutants and limit dilution due to lower streamflow; • Increase the drying up of water sources and, for vulnerable communities, a resultant extension in the distances that must be travelled in order to access water;
Increased temperature	• Affect the quality and availability of water supply; • Result in a reduction of surface water availability from an increase in evaporation from reservoirs and lakes and a decrease in stormwater runoff; • Increase water demands for industrial and domestic water use; • Increase the extent and rate of algal growth in nutrient-enriched surface waters; • Impact on how sewage systems operate.

Table 1 – The impact of climate change on urban water systems (Mottaghi, et al., 2015; Wong, et al., 2012; Daniell, et al., 2015; Climate Change Adaptation Resource Center, 2018; NIWA, 2017)

In summary, the potential impacts of climate change on the supply of water in cities include a reduced flow of water posing possible shortages in water, an increase in the demand for and use of water, increased stress on future water supply, the contamination of water through sewage systems, a decrease in surface water, a decrease in stormwater runoff, increases in water tariffs, as well as water related health problems.

"An understanding of the known risks posed by existing climate variability reinforces the need for responses that are robust to both existing variability and future uncertainty, alongside other pressures on resources, systems and services" (Oates, et al., 2014). Cities need to prepare for the widely anticipated consequences of climate change which will put at risk access to safe drinking water and adequate sanitation. Compromising on these qualities will have many secondary and tertiary effects on development, the environment and human health (Butterworth & Guendel, 2011).

4. Adapting water systems to climate change

The upgrading and expansion of the water system is an urgent developmental concern that is also an opportunity to adapt to climate change. The development of new water resources and the adaptation of existing urban water systems to become more resilient will require a range of different solutions, many of which will take time and/or result in substantial costs (Sikaundi, et al., 2016). These solutions will need to respond to issues such as the availability of water resources, the nature and condition of existing water infrastructure, the availability of resources and capacity to develop and manage systems, and existing urban demand patterns for water. These systems must also achieve defined minimum water standards (CSIR, 2018).

Water systems in urban areas can be divided into two categories. The first category consists of water services that provide water for everyday use, for instance for drinking, cooking and cleaning (Sikaundi, et al., 2016). The second category consists of water resources that manage water in catchment areas, urban rivers and streams as well as runoff and stormwater generated within and around urban (Sikaundi, et al., 2016). When adapting to climate change both the water services and the resources need to be addressed. Increased water self-sufficiency should be an objective. By expanding the water mix a larger variety of water resources are accessed to reduce the current reliance on surface water. These can include groundwater, rain- and stormwater harvesting, water recycling and the reuse of grey water (SA Government, 2015). The importance of maintaining and rehabilitating water systems cannot be overemphasised. Maintenance sustain and improve water systems over time, whereas an increase in the backlog in maintenance result in significant wastage and unreliable water services. Upgrades and expansions to the water system can be used to increase water service revenues and provide a firm foundation for further improvements to water infrastructure in urban areas.

When adapting water systems to climate change, Venema and Temmer (2017) names the following principles to be kept in mind:

- Build robustness: Draw upon multi-barrier water protection principles by integrating procedures, processes and tools that prevent contamination/pollution of drinking water in providing infrastructure and services. Decentralisation, mechanical robustness and non-reliance on centralised power/energy sources are some options.
- Promote redundancy: Focus on diversity of water sources for water supply, such as groundwater, rainwater and stormwater harvesting, to mitigate adverse conditions such as droughts and floods that impair the quality and availability of conventional water sources (dams and rivers).
- Resourcefulness: Creative re-use of and retention of water that minimise reliance on conventional water resources and centralised supply networks that are vulnerable to climate change. Rainwater harvesting from roofs and other catchment areas, green roofs and parks for water retention are some options, as well as neighbourhood level bio-retention, vegetated filter strips, permeable pavements and grassed swales to maximise the retention of run-off, nutrients and suspended solids (silt) to be used as alternative sources of water.

In adapting cities to climate change, water-wise cities, water-sensitive cities or water-smart cities are becoming more popular in the discourse. Water sensitive urban design features can be used to adapt places to, and reduce, the impacts of climate change in urban areas.

5. Water sensitive urban design

Water-sensitive urban design is seen as crucial to the delivery of cities of the future (Ministry of Interior, 2011). Many urban areas in hot and dry climates are more likely to experience extreme heat, decreased precipitation as well as more intense and extreme weather events. Hotter and drier conditions will put stress on water resources, while extreme weather events such as intense rainfall will place huge burdens on urban drainage systems leading to an increase in risk of urban flash floods (Carmon & Shamir, 2010; Brown, et al., 2008). Growing urban populations also put pressure on water services and resources, requiring careful planning (ACT Government, 2014). In the past, water systems were designed in a linear way, i.e. sourcing, treating, transporting, distributing, collecting, treating and disposing water. This highly technological approach is resource intensive and results in the fragmentation of the urban water cycle (Armitage, et al., 2014). Cities thus need to adapt their conventional approach to urban water management at the macro-level by adopting a transdisciplinary approach that considers the environmental, social and economic consequences and opportunities of water management (Ministry of Interior, 2011).

Water sensitive urban design (WSUD) is a development framework aimed at integrating the management of urban water services and resources such as stormwater, groundwater, waste water and water supply with urban planning and design (Celeste, et al., 2013; Brown, et al., 2008). WSUD aims to reconfigure cities in a way to enable regenerative water services while also reducing the impact of hydrological climatic events on urban environments (International Water Association, 2016; Brown, et al., 2008; Armitage, et al., 2014; ADB, 2012). This approach emphasises cities as crucial water supply catchments and as crucial places for the provision of ecosystem services. The notion of using wastewater, greywater, recycled water, and harvesting stormwater for gardens, parks and green areas, as well as for sanitation purposes is gaining importance (Maksimović, et al., 2015). By treating all types of water as a valuable resource, a diversity of water sources can be pursued through centralised and decentralised infrastructure. Such diversity reduces the stress on surface and groundwater resources, and introduces new sources of water to the urban water systems (ADB, 2012; Brown, et al., 2008; Wong & Brown, 2008).

The objectives of WSUD are to design, plan and manage urban landscapes to improve water security, climate proof cities, manage and reverse water pollution, improve and protect the health of ecosystems and receiving water bodies, contribute to human wellbeing and public health, to address resource efficiency and energy transition, reduce the ecological impacts that are associated with water management, support affordable living through the reduction of long term costs that are associated with the management of water, and create more liveable cities by linking water infrastructures to aesthetical and recreational land uses (Hoyer, et al., 2011; Armitage, et al., 2014).

Water sensitive urban design include the following practices at various scales:

- Incorporating green infrastructure aimed at capturing and treating stormwater for a range of uses (McCormick & Dorworth, undated);
- Protecting the supply of water against increasing variability of annual and seasonal precipitation and runoff by building additional infrastructure for the storage of water such as storage tanks or reservoirs (ACT Government, 2014; SADC, 2012);
- Developing new groundwater sources, increasing the groundwater recharge potential and decreasing the discharged wastewater to public sewers (Angiello, et al., 2017; McCormick & Dorworth, undated; SADC, 2012);
- Diversifying and improving water supply sources, including the reuse and recycling of water (ACT Government, 2014; SADC, 2012);
- Treating stormwater to be discharged to surface waters or reused and treating wastewater or minimising the generation of wastewater (Celeste, et al., 2013; Harisyanti & Ryanti, 2017);
- Reducing flood risks through the integration of the design of urban drainage solutions with urban infrastructure design (Angiello, et al., 2017);
- Incorporating flood protection infrastructure in the design of developments in order to prevent the contamination of sources of water supply and treatment works (ACT Government, 2014);
- Using inclusive public spaces, multipurpose space and infrastructure and roadside green infrastructure to enhance the liveability of urban areas with visible water (Angiello, et al., 2017);
- Encouraging riparian buffers along streams, rivers, and waterways and maintain floodplains (McCormick & Dorworth, undated);

- Adapting and modifying urban materials of roads, roofs, etc., to minimise their impact on the pollution of water (Angiello, et al., 2017);
- Making use of street trees, rain gardens, green roofs, infiltration trenches, cisterns, rain barrels, vegetated swales, wetlands and porous paving to reduce the runoff from storms and to decrease the pressure on treatment facilities (ACT Government, 2014; McCormick & Dorworth, undated);
- Clearing alien invasive vegetation from infested catchments, and landscaping with indigenous vegetation to further reduce runoff and the need for irrigation (McCormick & Dorworth, undated);
- Using ground and surface water conjunctively, together with water sources at household level such as roof water harvesting in order to mitigate the impacts of disruptions related to weather on any given component of the system (ACT Government, 2014);
- Employing conservation technologies that reduces demand such as leakage management, detection and repair, water efficient fixtures and appliances, water metering and pricing, and pressure management (Fisher-Jeffes, et al., 2012; Elliot, et al., 2011; GreenCape, 2016).

Stormwater management deserves special mention here because it constitutes a big part of WSUD, called sustainable drainage systems (SuDS). Conventional urban stormwater management focuses largely on managing the quantity (flow) of stormwater by collecting runoff and channelling it away from the city as soon as possible to prevent flooding. This has led to the erosion of natural channels and pollution, resulting in environmental degradation (GreenCape, 2016). WSUD approaches stormwater as a resource and asset rather than a nuisance (Mottaghi, et al., 2015). Stormwater design calculations will be affected by climate change in numerous ways such as through the increase in the frequency and intensity of heavy rainfall events, and through changes in the antecedent moisture loading of soils and the average water supply in storage ponds (Shaw, et al., 2005). Stormwater can be transformed from a possible hazard into a resource by capturing stormwater close to its source with infiltration galleries, detention basins, green roofs, porous asphalt and cisterns (Elliott, et al., 2011).

The performance of WSUD can be measured against its efficiency in conserving water in various urban land uses and in irrigated open spaces; against runoff quantity and quality in urban developments and roads, streets and thoroughfares (for example by assessing whether there have been resultant reductions in total pollutant loads as compared to untreated runoff from storms, or whether the capacity of drainage systems has not been exceeded); and lastly against whether WSUD are designed in an integrated way, i.e. whether it supports the relevant development objectives through the engagement of relevant stakeholders at the appropriate stages of planning, designing, constructing and managing WSUD (Government of South Australia, 2013).

6. Framework for water sensitive adaptation planning

Spatial planning, land use and urban design decisions have long lasting consequences for the supply and demand for water services and resources (Rozenzweig, et al., 2015). Both the impacts of the availability of water on land use as well as the impacts of land use on the availability of water have to be considered when dealing with water resources and their management. Water sensitive adaptation measures should thus be identified and integrated with urban planning as early in the planning process as possible (Grau, undated).

It is not usually necessary or possible to apply every WSUD technique there is, but it is also highly unlikely that any single action on its own will suffice to deal with climate impacts. A basket of actions should be selected with the possible impacts of climate change in mind that incrementally reduces the frequencies and volumes of runoff, flow rates and pollution and takes local conditions into consideration (Van Niekerk, 2018; Vermont Department of Environmental Conservation, 2010; Grau, undated). It would be more effective to implement a basket of measures that will combined the mitigation of long term effects with short term adaptation impact. A framework for selecting such a basket of actions is proposed in Figure 1. This framework was developed for South African cities in an ongoing research project called the Green Book (CSIR, 2018), but can be applied elsewhere. The steps below were followed to develop this framework:

1. Potential climate hazards were identified from climate change projections (South Africa in the case of the project). These hazards included coastal flooding, inland flooding, heat stress, drought, and wildfire.
2. The extent of the local urban planning function was defined, and utilised as criteria for selecting adaptation actions from a literature survey. The local urban planning function was extensively defined to include spatial planning, land use management, environmental planning, engineering services, and landscape and urban design.
3. Based on this criteria, a survey was undertaken of existing local and international adaptation plans, strategies and academic literature to compile a wide-ranging menu of adaptation actions. Much of what is proposed as adaptation actions, is simply good planning practice but essential to mitigate the impacts of climate change.
4. Each adaptation action was linked to one or more climate hazards, and also given a property as being a win-win adaptation action, a no-regrets action, or a low regrets action[i]. This property can be linked to the adaptive capacity or vulnerabilities of a place, i.e. if the economic base as well as the population growth trends of a place are in decline, then it is possible to only select those actions that do not involve a huge capital investment, i.e. soft adaptation actions.
5. Relevant adaptation actions were then selected and organised in a framework according to the planning function they fulfil. These were tested with a focus group for their relevance to the local planning function and then refined.
6. The next step was to structure the framework in a hierarchy and to connect adaptation actions to each other in the hierarchy (see Figure 1 below). Thus if you select one action, the linked actions will also be recommended. This is to ensure that a single proposed action is supported within a hierarchy of urban planning instruments. For example, if heat stress is projected to become more extreme in future, one of the adaptation actions proposed under the urban landscape and design category is to design shaded public spaces. The associated actions in the hierarchy are to identify such spaces in the spatial plan, and to protect them through land use management.

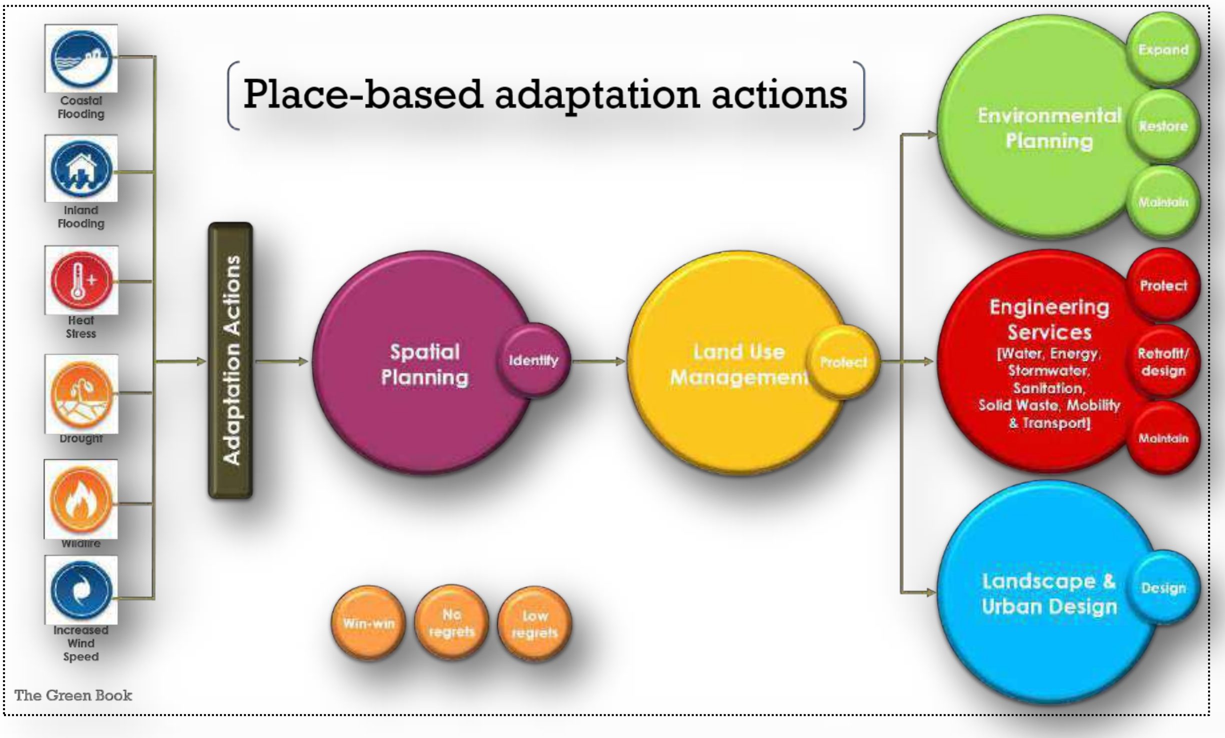

Figure 1: A framework for selecting place-based adaptation actions (Van Niekerk, et al., 2018)

To illustrate how this applies to water sensitive urban planning, say for example a city is projected to become hotter and drier, and at risk of recurring drought in the future. The city's economy is strong and diversified, and the population is growing. Water-sensitive urban design will be crucial to address the future demand for water in the city. Using the proposed framework of adaptation actions, a basket of adaptation actions linked to drought as a hazard will be suggested, each action linked to a hierarchy of planning functions. It is up to the planner then to select all supportive adaptation measures to be integrated into the various related planning instruments. An example would be that 1) the spatial planning instrument(s) is used to identify all the potential water sources in the city as part of a decentralised water provision system; 2) the land use management instrument(s) is used to protect all the potential water sources from development or pollution; and 3) the engineering services function design a diversified water supply system that includes using alternative water sources, recycled water and grey water for non-potable purposes.

The proposed framework assists in selecting the most appropriate adaptation actions as part of a WSUD adaptation strategy, and ensures a single action is supported in a hierarchy of planning instruments, if appropriate.

7. Conclusion

Climate change not only contributes to existing urban challenges, but will also create more problems that will have to be dealt with in the future. It therefore becomes important for planners to be familiar with and thoroughly comprehend the current and potential impacts, to limit and prevent these challenges, particularly in the water sector. Cities are facing the challenge of transforming already fully or over-extended water services infrastructure into systems that can deal with the current and future combined pressures from continued rapid urbanisation and climate change. However, due to the enormity of the urban challenges, the costs of upgrading or replacing old infrastructure to provide immediate services often outweigh any considerations and decisions regarding future climate change. Often cities have limited technical capacity and resources to manage existing water infrastructure, let alone plan and develop new infrastructure that is more sustainable and resilient to climate change. Addressing climate change in urban water systems could therefore be complex, but is an opportunity to address a number of development challenges simultaneously. As water infrastructure may last over 100 years it is important that new infrastructure take into account climatic change that may occur during its lifetime. The development of new water systems and the upgrading of existing systems offer the opportunity to develop systems that are more resilient to future impacts of climate change. It also offers an opportunity to leapfrog conventional wasteful approaches with more effective and resilient systems (Muller, 2007; Bahri, et al., 2016).

Water sensitive urban design should be considered as the basis of city-wide planning instruments in places that are becoming hotter, drier and more at risk of severe climate events. There are numerous potential benefits to water sensitive design for cities:

- Economic benefits include savings on capital costs and costs for water quality improvement, as well as increases in market value from the improved aesthetics that come with some WSUD measures.
- Social benefits include opportunities for the linkages of community nodes through the use of open space, amendable residential and urban landscapes and improved visual amenity. Adapting to climate change is also an opportunity to aim for higher levels of services in unserved areas by leapfrogging the intermediate step of communal services (WHO & DFID, 2009).
- Environmental benefits include the protection it offers for sensitive areas from urban development, contributing to the maintenance of the hydrological balance in cities by encouraging the use of natural processes of evaporation, infiltration and storage, enhancing natural habitats, and supporting the restoration of urban waterways (Van Hattum et al., 2016). Adapting to climate change is also an opportunity to integrate water source sustainability from the outset into new programmes and not as an afterthought (WHO & DFID, 2009).

Given these benefits, this paper proposed a framework for selecting appropriate adaptation actions to be included in a WSUD adaptation strategy that would ensure adaptation actions are not loose standing, but integrated into a hierarchy of planning instruments.

i ***Win-win actions*** contribute to adaptation whilst also having other social, economic and environmental policy benefits, including those relating to mitigation. ***No regrets actions*** yield benefits even in absence of climate change and where the costs of the adaptation are relatively low vis-à-vis the benefits of acting. ***Low regrets actions*** are relatively low cost and provide relatively large benefits under predicted future climates (CSIR, 2018).

Urban surface use optimization for climate resilience improvement

Silvia CROCE, Institute for Renewable Energy, Eurac Research, Italy
Daniele VETTORATO, Institute for Renewable Energy, Eurac Research, Italy

Synopsis

In the current scenario of massive urbanization and global climate change, the urban surfaces and their characteristics have a key role in pursuing resiliency and sustainability objectives at the city scale. This paper discusses the potential uses of urban surfaces and proposes a systemic approach aimed at their optimization. The methodology, which is customizable for different climates, is tested in a residential district of Bolzano (Italy), which is taking part to the European project SINFONIA. In the case study area, several solutions have been systematically applied and integrated, demonstrating the potentialities of such an holistic approach.

1. Introduction

The massive urbanization and the rapid grow of urban population worldwide, estimated to result in more than 6 billion inhabitants by 2050 (United Nations, 2015), are accentuating various energy and environmental issues clearly related to anthropogenic causes. In this scenario, cities are receiving increasing attention; several mitigation and adaptation strategies are proposed to tackle issues related to urbanization and the correlated effects of climate change (Moraci *et al.*, 2018). Green building solutions, water surfaces, and solar active energy systems are just some of the strategies that are being developed and tested to increase the resiliency and sustainability of cities. However, these are often applied as single and sectorial solutions, impeding their integration and the creation of synergies. As a result, the urban surface is becoming a scattered patchwork of solutions, which reduces the capability of cities in responding and adapting to external environmental pressures, and in mitigating the effects of climate change. Furthermore, the lack of a systemic approach generates disharmonized policies and conflicts in the urban surface usage, which prevent the creation of resilient and sustainable urban areas.

This paper aims to propose a systemic approach to the optimization of the urban surface use, and to demonstrate its relevancy in the maximization of urban resiliency and sustainability. The methodology presented contributes to the debate on resilient cities by answering to the following questions: a) What are the best uses for specific surfaces in a city? b) How can different surface usages be integrated to maximize the throughput avoiding conflicts? c) Which criteria should be considered to optimize the urban surface usage?

2. Background

Several studies have demonstrated the link between urban development and climate change, and the unique climate risks, such as urban heat island and flooding, faced by urban areas (Doherty, Klima and Hellmann, 2016; Wang and Wang, 2017) . In this scenario, the urban surfaces and their characteristics have a key role. Indeed, the replacement of natural, permeable surfaces, with mineral materials is responsible of the significant increase of air temperature in urban areas compared to the surrounding environment (i.e. urban heat island effect), and of the land sealing resulting in surface storm-water runoff problems (Tsoka, Tsikaloudaki and Theodosiou, 2017). Furthermore, the low albedo (i.e. reflectance to solar radiation) of materials applied on the majority of the urban surfaces is cause of the increase of solar radiation absorption and of the consequent high surface temperatures observed in cities. The territorial expansion caused by the urbanization increased the land consumption and caused relevant changes in the land use. Therefore, the reduction of green spaces produces a serious environmental degradation, and a decrease of latent heat emission. The latter is cause of the reduction of cooling and further raise of air temperature (Taha, 1997). Heat removal through convection is also prevented by the increase of building heights in urban areas that is responsible for low induced wind velocities. The raise of air temperatures in cities does not only worsen outdoor thermal comfort conditions, but has also negative impacts of human health. Furthermore, it increases the energy consumption for cooling, causing peaks in the electricity demand in hot climate conditions (Santamouris *et al.*, 2016).

2.1 Urban surface uses

In this scenario of increased urbanization and global climate change, it is becoming crucial the capability of cities to: (i) protect people and infrastructures from extreme events like heat waves and floods, and (ii) use their resources efficiently by being self-reliant on energy, food, and water. The use and characteristics of urban surfaces play a key role in addressing these resiliency and sustainability objectives. Five major clusters of surfaces uses are identified as the most promising:

1. Smart coats: consist mainly in solutions aimed at decreasing the absorption of solar radiation in the urban environment. They can be subdivided in two groups. a) Finishing materials or paintings characterized by highly reflectivity to solar radiation and by a high emissivity factor, known as cool materials. These characteristics help decreasing urban surface temperature and minimizing the corresponding release of sensible heat to the atmosphere. Cool materials can be used either on the building envelope or on pavements and other urban structures. The use of reflective materials is associated also to important energy benefits as the cooling load of buildings is reduced (Santamouris *et al.*, 2012). b) Water retentive or porous pavements are applied on ground surfaces to increase evapotranspiration (i.e. water transfer from the land to the atmosphere through the combined processes of plant transpiration and evaporation) and to avoid storm-water runoff.
2. Green: urban greenery contributes to the improvement of urban environmental conditions through different processes: i) direct sun shading, ii) evapotranspiration, iii) mitigation of air movement, and iv) regulation of the heat exchange through the building envelope. In this view, urban greenery solutions can be classified as: a) trees, grass, and vegetation applied in outdoor areas, and b) green building elements (i.e. green roofs and façades). The latter may also produce direct benefits on indoor comfort conditions (Coma *et al.*, 2017).
3. Water: the main purposes of natural water retention measures and artificial water surfaces are to: (i) reduce the impact of urban development by restoring the natural water cycle, (ii) promote in-situ management of storm-water runoff through infiltration (Bortolini and Zanin, 2018), and (iii) remove summer urban heat through evapotranspiration (Santamouris *et al.*, 2016).
4. Urban agriculture: aimed at the production of food, urban agriculture play an important role in the food security and environmental sustainability of a city. As a form of green infrastructure, urban farms and rooftop food gardens contribute to reduce urban heat island effects, mitigate storm-water impacts, and decrease the energy embodied in food transportation (Ackerman *et al.*, 2014).
5. Solar energy systems: within cities, renewable energy can be generated by means of active solar systems, i.e. solar thermal (ST) and photovoltaics (PV), using the surfaces of the building envelope or other elements of the urban landscape (Kanters, Wall and Dubois, 2014).

For each cluster of urban surface use, the main solutions are listed in Table 1, together with the main and secondary objective targeted.

Table 1: Main solutions for each cluster of surface uses. The main (dark green) and secondary (light green) objectives pursued.

USES	SOLUTIONS	OBJECTIVES					
		Resiliency			Sustainability		
		Urban climate optimization	Urban habitats and biodiversity improvement	Urban hydrology and storm-water management	Self-reliance on energy	Self-reliance on food	Self-reliance on water
Smart coats	Cool finishing materials applied on buildings' vertical surfaces						
	Cool roofing systems						
	Cool/reflective pavements						
	Use of finishing materials with different albedo						
	Water retentive paving systems						
	Porous ground materials						
Green	Vertical greening systems						
	Horizontal greening systems						
	Planting and greenery						
	Urban parks						
Water	Sprinklers and water curtains						
	Natural water bodies						
	Artificial water surfaces, fountains						
	De-paving						
	Rain gardens						
	Water squares						
	Aquaculture						
	Aquaponics						
Urban agriculture	Rooftop agriculture						
	Urban farming						
	Vertical farming						
Solar energy systems	Photovoltaic panels						
	Building integrated photovoltaic systems (BIPV)						
	Photovoltaic application in landscape and urban furniture						
	Photovoltaic road pavements						
	Solar thermal panels						
	Road pavement solar collector systems						
	Shelter design						

2.2 *Conflicts and integration*

The majority of the uses and solutions discussed in Section 2.1 are applied independently one from another, highlighting the lack of a systemic view inclusive of synergies and hybridization.

This trend is causing inefficiencies, competition in the use of urban surfaces, and the diffusion of scattered intervention characterized by the absence of a general planning framework. In this scenario, the individuation of the main conflicts and possibilities of integration between different uses is an important step toward the definition of a systemic approach to the optimization of urban surface uses. Table 2 considers the integration of the five surface use clusters discussed in Section 2.1.

Table 2: Conflicts and potential integrations between different surface uses. Rows: main uses; columns: potential secondary uses.

	Smart coats	Green	Water	Urban agriculture	Solar energy systems
Smart coats		? May be used in combination	✗ Impervious surfaces	✗ Use of the same surfaces	? Higher reflected radiation
Green	✗ Use of same surfaces		✓ Increase of permeability	✓ Compatibility	? Research on-going
Water	✗ Conflicting solutions	✓ Microclimate regulation		✓ Compatibility	? Non-conflicting surfaces
Urban agriculture	✗ Use of the same surfaces	✓ Compatibility	✓ Aquaculture and aquaponics		? Use of PV as shading system
Solar energy systems	✗ Use of the same surfaces	? Research on-going	? Non-conflicting surfaces	✗ Use of the same surfaces	

The application of smart coats, mainly highly reflective materials, increase the sealing of urban land; therefore, it conflicts with the surface use for urban agriculture and water systems, which require the presence of permeable soils. In addition, the integration of smart coats with greening or solar energy systems is not possible on the same surface. However, the conflict between the solutions may be avoided when applied on different domains. As an example, cool asphalt applied on ground surfaces is compatible with greening at the building envelope scale. While the increased solar reflection due to the application of cool materials may be beneficial for the energy production of nearby active solar systems (Lobaccaro *et al.*, 2017). Green surfaces are fully compatible with water solutions, as they imply the same heat mitigation processes, and with urban agriculture, while they conflict with solar energy systems. However, recent studies are focusing on the integration of the latter through the application of photovoltaic systems on green roofs (Chemisana and Lamnatou, 2014), and the creation of a multifunctional system integrating building greening and PV (Penaranda Moren and Korjenic, 2017). Water surfaces are compatible with urban agriculture, as they can be used for aquaculture or aquaponics (Al-Kodmany, 2018), and with green solutions. On the contrary, they are not compatible with solar energy production. However, water solutions are mainly applied at ground level, where the shadow casted by buildings and trees reduces consistently the amount of solar irradiation, making these surfaces unsuitable for the installation of solar active systems. Therefore, in the majority of cases, there is no direct conflict. Urban agriculture and solar energy systems are conflicting, since they both aim at using surfaces with good solar exposure. A recent study has conducted a comparison between rooftop food production and energy generation, highlighting the benefits and costs produced by the two solutions applied in Mediterranean climates. The results have shown that, under the modeled conditions, food production is more beneficial than energy production in terms of financial return and local job creation (Benis *et al.*, 2018). Integration between solar energy systems and urban agriculture may be obtained through the application of semi-transparent PV modules on greenhouses roof (Cossu *et al.*, 2016).

3. Methodology

The methodology proposed in this study implies sequential and logical steps to address local climate and morphological aspects for the urban surface use optimization in consolidated urban areas.

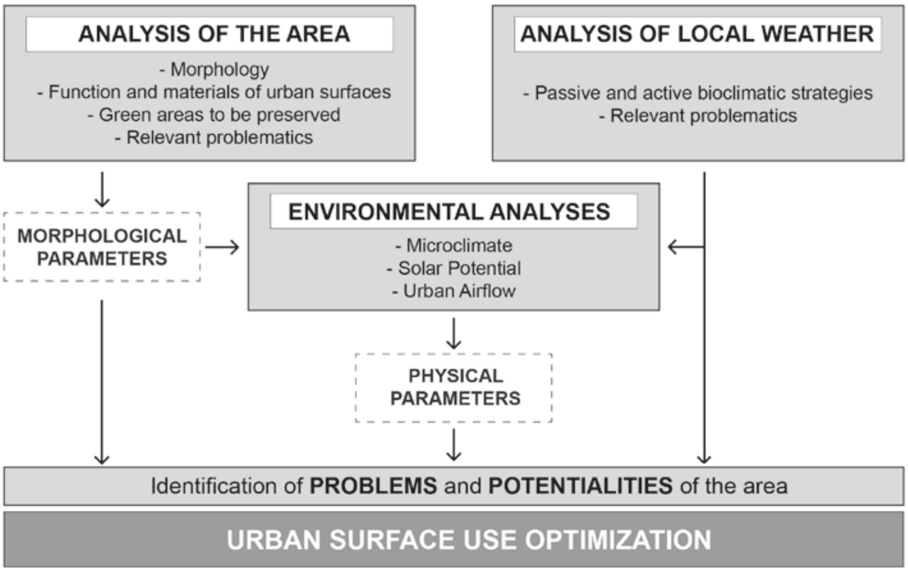

Figure 1: Workflow of the presented methodology.

3.1 Morphological and climate characterization of the area

The methodology, schematized in Figure 1, starts with the analysis of the selected area. The morphology, the function and materials of the urban surfaces are examined with two objectives: (i) outline the main features of the district, and (ii) collect relevant input data for the environmental models. In this stage, the area is also characterized by the individuation of its relevant problematics (e.g. presence of areas prone to flooding, etc.) and positive features (e.g. green areas to be preserved). In parallel, the local weather is analyzed to clearly understand the local conditions and to determine truly responsive passive and active bioclimatic strategies (Lobaccaro *et al.*, 2018). Successively, sets of environmental analyses are conducted on the three dimensional model of the district to: (i) characterize the local conditions and (ii) test responsive solutions, depending on the resiliency and sustainability objectives set for the area. This step includes:

1. Solar potential analyses: aimed at identify the most irradiated areas and the surfaces most affected by overshadowing;
2. Microclimate analyses: focused on the definition of the local climate conditions, the identification of the main problematics of the area, and the verification of the impact of specific modifications in the urban surfaces use;
3. Urban airflow analyses: to evaluate the natural ventilation in the district.

In the final step, the physical and morphological parameters obtained by the analysis process are used as guidelines to define the optimal usage of each surface in the district. One of the strength of the methodology is its replicability worldwide. Hence, since it is based on the three-dimensional model of the analyzed urban district and on the local weather data, the methodology may be reproduced in every morphological and climate condition.

3.2 Tools and indexes for environmental analyses

Several tools may be used as support during the analysis process. In this study, the three-dimensional model of the district was created using the Windows®-based NURBS modeler *Rhinoceros* (McNeel Robert and Associates, 2015). The solar simulations to evaluate the solar potential of the urban surfaces were run using the solar dynamic simulation tool *DIVA-for-Rhino,* a validated *Radiance/Daysim*-based software (McNeil and Lee, 2012) . Finally, the numerical model *ENVI-met*, version 4.0, has been used to analyze the microclimate conditions in the district in the different scenarios. *ENVI-met* is a 3D prognostic microclimate model that simulate the surface–vegetation–atmosphere interactions in urban complex environments with spatial resolution of 0.5 to 10 m and temporal resolution of 5 to 10 s (Bruse and Fleer, 1998). The analyses have been conducted for the 29th July 2017, selected as representative of a typical hot summer day. Finally, the human comfort at pedestrian level in the district has been evaluated using the Physiological Equivalent Temperature (PET), a thermal index developed by Höppe to assess the thermal comfort in outdoor environments (Höppe, 1999; Matzarakis, Mayer and Iziomon, 1999). The value of PET identifies the thermal perception by human beings and the correlated grade of physiological stress; the range from 18°C to 23° C corresponds to “comfort”, above 35 °C to “hot”. PET values above 41°C describe a “very hot” thermal perception related to extreme heat stress conditions (Matzarakis, Mayer and Iziomon, 1999).

3.3 Case study area

The proposed methodology is tested for the urban surfaces use optimization in an existing residential district in the city of Bolzano.

Bolzano (UTM 46°29'53.8" N, 11°21'17.1" E) is located in the north-east of Italy, at a height of 265 m above sea level. The city is situated in the center of south-eastern Alps in a basin surrounded by four mountain ranges, whose significant height impedes balancing currents and moisture. As a consequence, the climate in Bolzano is categorized as moist continental (“Dfb”) according to the Köppen-Geiger classification (Kottek *et al.*, 2006), and is characterized by strong seasonal fluctuations. Due to its location and climate characteristics, Bolzano is often affected by high temperature and heat waves during summer (Papathoma-Köhle *et al.*, 2015), when it is ranked often among the hottest Italian cities. In summer, air temperatures (T_{air}) often exceed 35 °C, with maximum peaks up to 40 °C. Furthermore, a significant increase in the number of tropical nights (i.e. nights with a minimum temperature equal or higher than 20 °C) has been observed in recent years. Until 1995 the tropical nights where less than five per summer, while in 2010 have reached the number of 20 (Papathoma-Köhle *et al.*, 2015). The historical meteorological data series show an increase in the mean annual T_{air} of more than 3 °C in the last 30 years (Lobaccaro *et al.*, 2018). In this scenario, the city of Bolzano represents an interesting case study for its location, its climate features, as well as the need to mitigate summer conditions.

The district selected is one of the five areas in Bolzano taking part to the Smart Cities European project SINFONIA *(Smart Initiative of cities Fully cOmmitted to iNvest In Advanced large-scaled energy solutions*) (SINFONIA, 2017), and it includes two social housing blocks (i.e. buildings S1 and S2 in Figure 2) and the nearby buildings. The morphology of the area is characterized by the presence of five urban canyons: *Via Milano* and *Via Cagliari* from north to south; *Via Brescia*, *Garden*, and *Via Palermo* from west to east (Figure 2). The latter is one of the main roads connecting the eastern and southern areas of Bolzano, while *Via Milano* and *Via Cagliari* are secondary roads. *Via Brescia* is mainly used by the residents to access the underground parking lots, and present a green area with trees running alongside. *Garden* is the central public area between buildings S1 and S2 and it is characterized by grass surfaces and vegetation of different species and dimensions. In the framework of SINFONIA project, whole-building refurbishment and technological interventions have been undertaken. This work aims to expand the evaluation of SINFONIA's impact at the whole district by considering the urban surfaces in a systemic approach.

Figure 2: a) Top view of the case study district. Highlighted in red the two SINFONIA building blocks (source: Google Earth); b) Aerial view.

3.3.1. Scenarios of urban surface use

In this study, five different scenarios of urban surface use have been simulated (Table 3). In the *Baseline* scenario, the morphological characteristics and the albedo of the urban surfaces were maintained unvaried from the actual situation in order to characterize the microclimate and environmental features of the district. Successively, three new scenarios have been modeled to address the main needs of the area, each considering a single use of the urban surfaces. In the *Cool* scenario, materials with higher albedo have been applied on roads and pedestrian paving, at the ground level, and on the roof surfaces, at the building envelope scale (Maleki and Mahdavi, 2016). The *Greenification* scenario implies the modification of the building envelopes, with the application of vertical and horizontal greening systems (Jänicke *et al.*, 2015). While in the *BIPV* scenario, the effect of solar active systems applied on façades and roof surfaces with suitable solar potential has been investigated. The results obtained from the *Baseline* scenario were used as reference values for comparison with the others. Finally, based on the outcomes of the previous scenarios, a final configuration of the district has been outlined. In this *Integrated* scenario, the systemic application and integration of several solutions has been addressed to demonstrate the potentialities of a holistic approach to the urban surface use optimization.

Table 3: Characteristics of the scenarios of urban surface use simulated in the study.

Scenario	Surface	Solutions
Baseline	Roads	-
	Public areas	-
	Buildings	-
Cool	Roads	Cool grey asphalt with albedo 0.40
	Public areas	Cool pavement with albedo 0.50
	Buildings	Cool paint with albedo 0.80 on the roof
Greenification	Roads	-
	Public areas	-
	Buildings	Façades: vertical greening systems Roof: horizontal greening system with grass
BIPV	Roads	-
	Public areas	-
	Buildings	Façades: BIPV on surfaces with suitable solar potential Roof: PV panels
Integrated	Roads	Cool grey asphalt with albedo of 0.40 on the main roads (i.e. *Via Palermo*, *Via Milano* and *Via Cagliari*). Increase of green areas of 10%
	Public areas	
	Buildings	

	Façades: vertical greening systems on (i) surfaces exposed at south, (ii) façades along the roads with higher T_{air}; BIPV on the surfaces with suitable solar potential. Roof: PV panels on the most irradiated surfaces; cool paint with albedo 0.80 on the remaining areas.

4. Results

In this section, the relevant results related to the five simulated scenarios are discussed along with the significance of addressing the use of urban surfaces through a systemic and holistic approach.

4.1 Microclimate conditions in the district

The microclimate analysis of the *Baseline* scenario has been focused on the evaluation of the main climate parameters. Air temperature (T_{air}, Figure 3a), surface temperature (T_s), mean radiant temperature (T_{mrt}, Figure 3b), global shortwave solar radiation (Irr_{SW}), and wind speed (W_s, Figure 3c) have been assessed in selected points for each urban canyon. Finally, solar analyses (Figure 3d) led to the identification of the most irradiated building envelope surfaces potentially suitable for the installation of solar active systems.

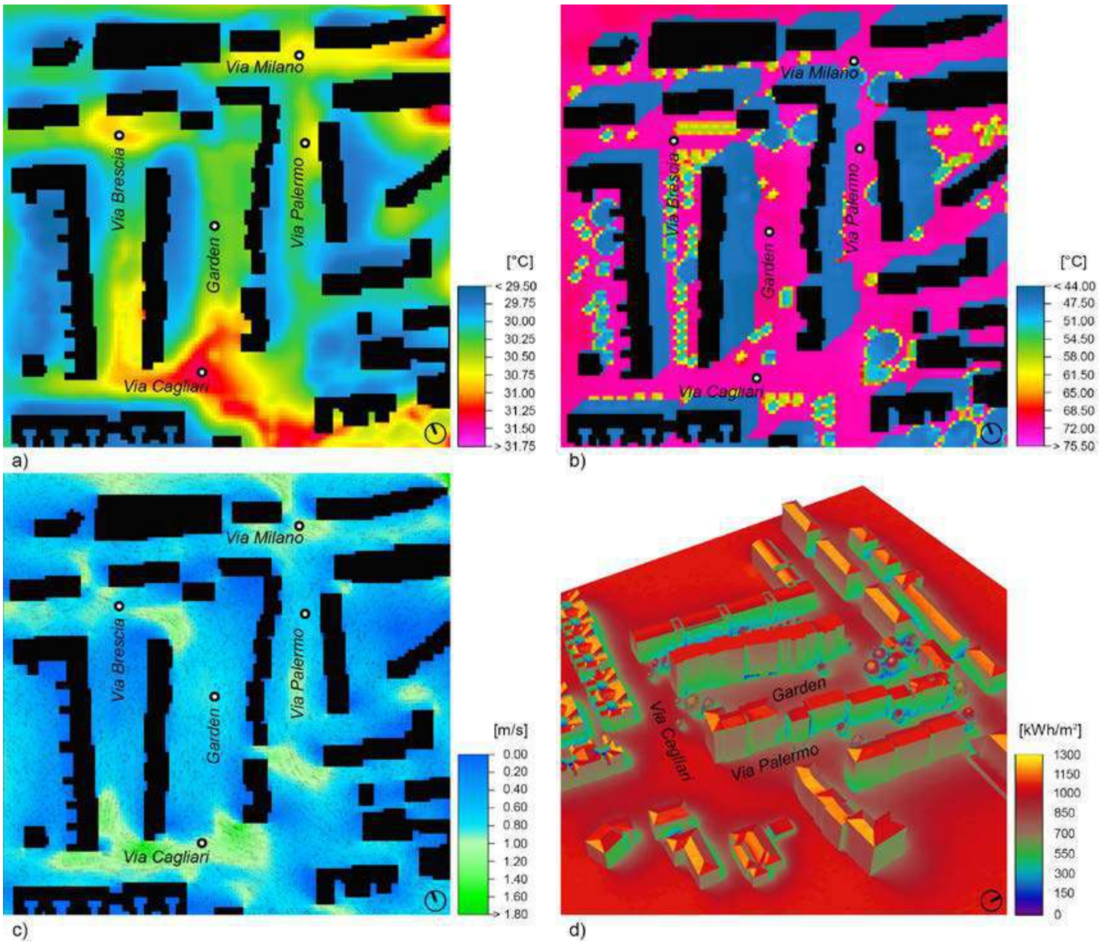

Figure 3: *Baseline* Scenario: a) Air temperature; b) Mean radiant temperature; c) Wind speed and direction vectors; d) Average annual global solar radiation.

The results show that the main problem to be addressed in the area is summer overheating, which is exacerbated by the frequent heat waves, as discussed in Section 5.3. In the analyzed day (i.e. 29th July 2017), the peak of the thermal stress is achieved at 15:00. The hot spots (i.e. areas with high level of thermal stress) are localized in *Via Palermo* and *Via Cagliari*, where T_{air} reaches 30.8 °C and 31.4 °C respectively (Table 4). In both the urban canyons, the T_{mrt} is higher than 70 °C and the PET higher than 50 °C, corresponding to a high level of human thermal stress. The wind flow pattern around buildings (Figure 3c) ensure comfortable and safe wind conditions for pedestrians (Blocken and Carmeliet, 2004).

Table 4: Microclimatic characteristics of significant spots in the urban canyons.

Urban canyon	H/W	Ground material	T_{air} [°C]	W_s [m/s]	T_s [°C]	T_{mrt} [°C]	Irr_{SW} [W/m²]	PET [°C]
Via Palermo	0.60	Asphalt	30.73	0.63	47.62	72.95	990	52.00
Garden	0.56	Loamy	30.27	0.80	42.17	72.34	1 004	50.20
Via Brescia	0.84	Asphalt	30.93	0.77	44.00	63.23	1 006	45.70
Via Milano	1.36	Asphalt	30.77	0.68	47.52	72.24	1 012	51.10
Via Cagliari	0.78	Asphalt	31.38	0.83	44.10	71.43	1 020	50.50

4.2 Effects of the simulated scenarios

To improve the microclimate of the district, two scenarios have been defined based on the most diffused mitigation technologies (i.e. cool materials and green solutions). A further scenario has focused on the district self-reliance on energy by considering the maximization of the urban surfaces' potential energy production. Figure 4a shows the air temperature difference between the baseline and the *Cool* scenario. The cooling effect of the albedo increase is visible mostly at the c enter of *Via Palermo*, *Via Cagliari* and *Via Milano*. The maximum cooling effect of 0.4 °C dissipates by reaching the limits of the roads and the central areas of the district. The increment of the ground surfaces' solar reflectivity produces an average decrease of surface temperature by around 2.6 °C, but causes at the same time an increase of T_{mrt}, which produces a consequent worsening of thermal comfort conditions at pedestrian level. This is demonstrated by an average increase of PET by 0.5 °C. Regarding the *Greenification* scenario, the vertical green façades and vegetated roof does not produce a significant cooling effect in *Via Palermo* and *Via Milano* hot spots, while T_{air} is reduced at the center of *Via Brescia* and *Garden* by up to 1 °C. In *Via Palermo*, the air temperature is slightly increased (i.e. ΔTair = + 0.6 °C) due to the reduction of wind speed caused by the presence of vegetation at both sides of the urban canyon. However, considering the overall effects in the district, this scenario leads to a significant improvement of thermal comfort, reducing PET by around 0.5 °C. Finally, the *BIPV* scenario does not pr oduce relevant modifications in the microclimate conditions of the district; in this scenario, PET is slightly reduced by about 0.3 °C.

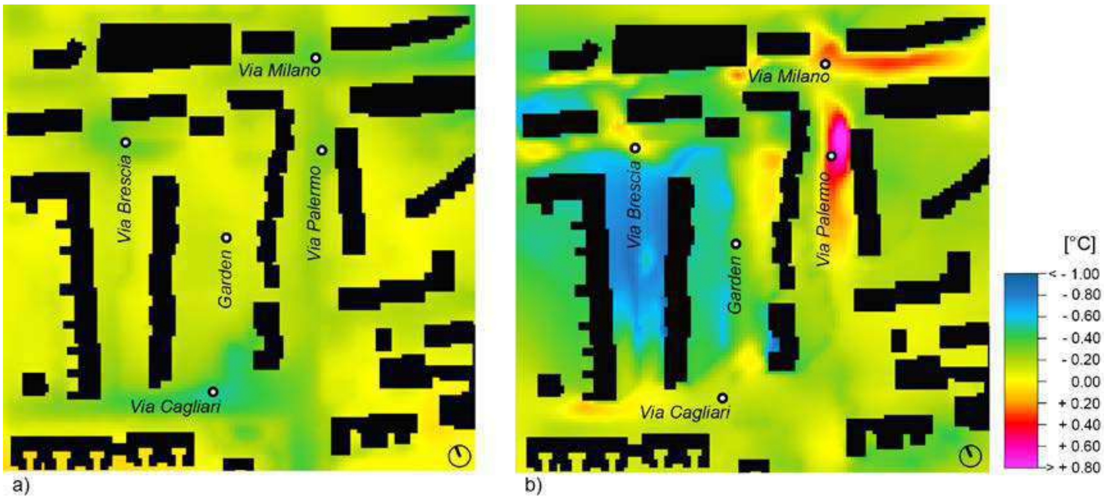

Figure 4: Comparison between *Baseline* and simulated scenarios - Absolute T_{air} difference: a) *Cool* scenario; b) *Greenification* scenario.

4.3 Final scenario of urban surface use optimization

The final configuration of the district (i.e. *Integrated* scenario) has been outlined based on the result of the *Baseline* scenario (Section 4.1) and of the simulated scenarios (Section 4.2). The urban surface use has been defined with a systemic approach. The objective set has been double: (i) to improve the microclimate conditions by combining some of the mitigation strategies previously analyzed and the increment of vegetated areas, and (ii) to increase the energy self-reliance of the district by taking advantage of the surfaces with a good solar exposure (Figure 5a). In terms of microclimate conditions, the air temperature is reduced in all the hot spots (Figure 5b). Furthermore, the combination of increased relative humidity, and decreased surface and mean radiant temperature, produces a reduction of PET in all the urban canyons (Table 5). The more significant improvements in term of outdoor thermal comfort are registered in *Via Palermo* (ΔPET = - 1.4 °C), *Via Milano* (ΔPET = - 2.6 °C), and *Via Cagliari* (ΔPET = - 0.8 °C), which resulted to be the canyons with the higher thermal stress in the *Baseline* scenario. Finally, in the *Integrated* scenario, the installation of solar systems on building envelope surfaces with suitable solar irradiation (i.e. $Irr_{SW} \geq 950$ kWh/m^2) has been considered. The sum of the suitable areas on façades and roofs covers 6 500 m^2, with a corresponding annual solar potential of 6 320 MWh/a.

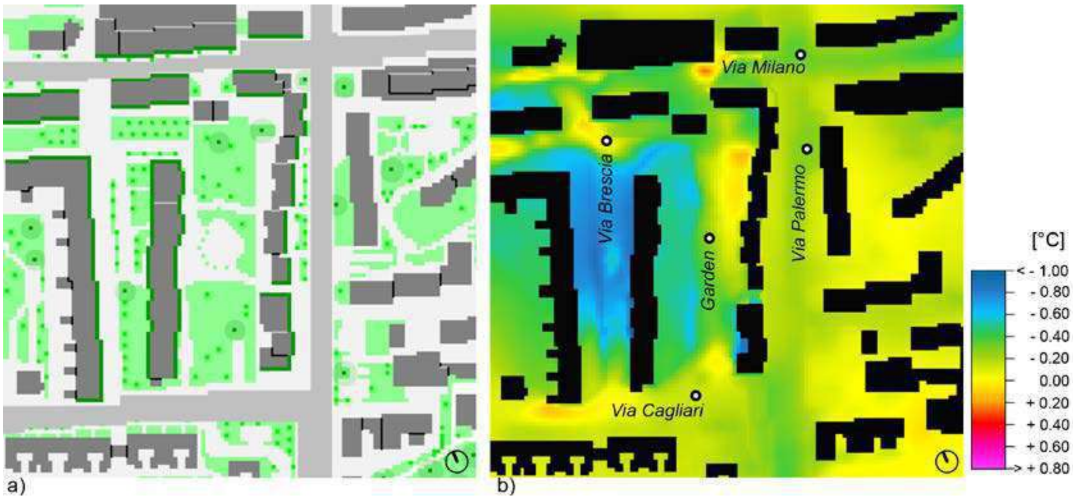

Figure 5: a) Final configuration of the district; b) Comparison between *Baseline* and *Integrated* scenario - Absolute T_{air} difference.

Table 5: Absolute difference of the main microclimatic parameters at 1 m a.g.l. in the *Integrated* scenario compared to the *Baseline* scenario.

5. Conclusions

The main purpose of the study was to develop and test a systemic approach aimed at the optimization of the urban surfaces use in consolidated urban areas. The preliminary discussion on the main uses, their conflicts and potentialities for integration, highlighted the lack of a systemic approach for the optimization of urban surfaces. In this scenario, a methodology is proposed to systematize the results of morphological, climate, and environmental analyses. In the first step, the analysis led to the identification of the main negative and positive features of the district. Successively, the solutions to be applied have been defined based on the main resiliency and sustainability objectives set for the area. Optimal uses of surfaces have been identified in terms of (i) outdoor microclimate and thermal comfort, and (ii) solar active strategies. The final configuration, in which several solutions have been systematically applied and integrated, demonstrate the potentialities of a holistic approach to the urban surface use optimization. The thermal stress in the district is reduced, with PET values up to 2.5 °C lower than in the *Baseline* scenario, and the potentialities of the most irradiated surfaces have been exploited by installing solar systems. Future developments of the study will address (i) the effect of other solutions for surface use and, (ii) the definition of quantitative thresholds and guidelines for the optimization process. Furthermore, the possibilities and potentialities for the inclusion in urban planning instruments of indications on the surfaces uses will be investigated.

The study on the performance of sponge city construction based on land use planning——cases of Canghai new area in Wuzhou

Fujun XIA, Shanghai Tongji Urban Planning & Design Institute, China

Abstract:
There is still deteriorating trend of China's urban water environment, heavy rain and waterlogging disasters are still multiple. In addition to the concept of rainwater management is relatively backward, the overall planning of land use planning and road planning, green space system planning and other special planning is not organic combination, lack of the fast and efficient feedback mechanism. Meanwhile, the Ministry of Housing and Urban of China issued the "sponge city construction performance evaluation and assessment methods (Trial)" also emphasis on post-evaluation and assessment, can not be an early stage of the effective assessment of the planning stage.
The two aspects of urban storm water disaster prevention and surface runoff, which are closely related to the land use planning, are chosen in this paper as the main research object, the concept of sponge city construction performanceis defined, the specific evaluation index is selected, and the calculation function is put forward, with the typical case study, the space Model simulation, statistical analysis and other research methods, through the GIS analysis, CAD, Civil 3D and PCSWMM modeling, practical case and ideal model comparative research and other technical means, the sponge city construction performance is studied qualitatively and quantitatively, and mainly on quantitative study.
There are two main results in this study: a method to quantify the performance of sponge city construction based on land use planning is explored in this paper through the application of the assessment model, and comparative evaluation of multiple plans in the early stage of planning. Based on the land use planning, some strategies to improve the performance of sponge city construction are put forward.

Key Word:
Sponge City, Quantitative assessment, Model, land use planning

Most cities in China today face a variety of water crises: water shortage, water pollution, urban rainstorms, increased surface runoff, falling groundwater levels, shrinking and even loss of aquatic habitats (Wang Hao, 2011). These problems which are systematic and comprehensive are not caused by a single water sector or a functional department. If we want to solve these "water problems," we need a more systematic and integrated solution. The "sponge city" theory is based on the basic characteristics of China's water conditions and the "water problems" it faces. In the construction of the sponge city, what can be done in the planning field and what kind of contribution can be made is still unclear.On July 10, 2015, the <Measures for the Evaluation and Assessment of Sponge City Construction Performance (Trial)> issued by the Ministry of Housing and Urban-Rural Development of China was also mainly to evaluate the performance of China's sponge city construction. Once the city is built, it will become a fact. After-the-fact evaluation can only evaluate the quality of the previous plan, but there is no way to change the existing facts. Therefore, it is particularly important to make an effective and reliable assessment of different planning schemes before the construction of the sponge city, and to select better schemes and further optimize them.

1. Sponge City Construction Performance Evaluation Method and Simulation

1.1. Definition of Sponge City Construction Performance Concept

The performance evaluation content of this paper is mainly in the urban planning land use planning, which belongs to the program evaluation before the implementation of the plan. The selected indicators are the urban storm flood control and surface runoff. The definition of the sponge city construction performance concept is based on the above considerations, and the concept can be defined as: land use planning to prevent floods in urban storms and to control the comprehensive ability of surface runoff.

1.2. Sponge City Construction Performance Evaluation Function

The performance evaluation of sponge city construction includes two major indicators: urban storm flood control and surface runoff, and urban storm flood control includes whether there is heavy rain or not, and the total accumulated water time and total water volume in the flood water in the flood season. According to the item index, this study uses AHP(Analytic hierarchy process) to conduct qualitative and quantitative evaluation and decision-making on the evaluation of the final sponge city construction performance. The sponge city construction performance hierarchy is shown in Figure 1.

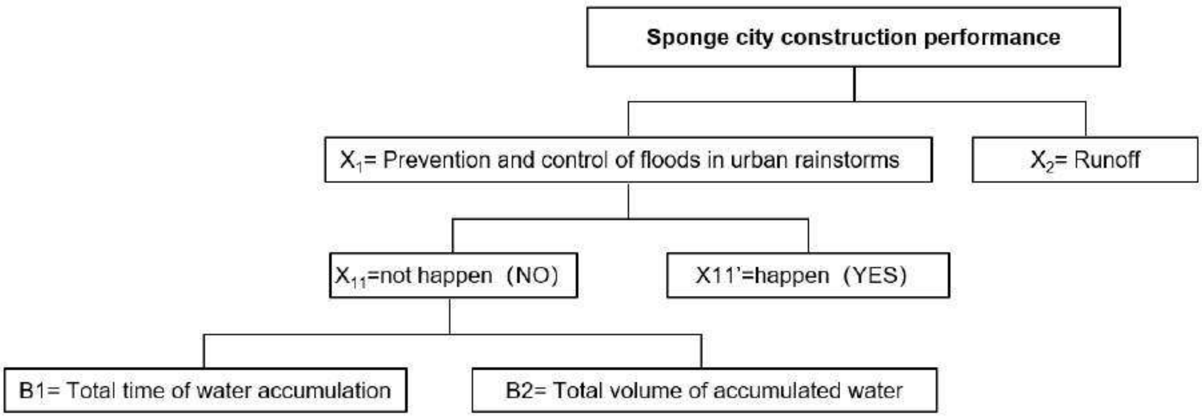

Figure 1. Sponge City Construction Performance Hierarchy
Source: author paint

1.3. Experimental Platform and Tools (PCSWMM software)

SWMM developed by EPA is a dynamic precipitation runoff simulation model, which is mainly used to simulate the time and long-term water and water quality simulation of a certain city. The evaluation software PCSWMM used in this paper is the commercialized software developed by the Canadian Institute of electronic water Resources based on the SWMM model.

1.4. Multi Scheme Model Simulation Method and Process of Sponge City Construction Performance

Through model simulation, a set of effective methods to observe and compare the multi scheme of land planning is set up in the early stage of planning, and the difference of the construction performance of the different land use scheme can be reflected as true as possible so as to select the better scheme and optimize it.

1.4.1. Establishing a multi-scheme model

The establishment of a multi-program model first requires the introduction of basic data, including geological data, climate data (including temperature, evaporation, wind speed, etc.), hydrological data (including rainfall, evaporation, etc.), terrain data and other data. The second is to introduce different land use planning schemes into the model.

1.4.2. Model simulation output data analysis

The total surface runoff of each land use plan, the total time of flood disasters and the total amount of floods were compared, and the performance index of sponge city construction was obtained. Then, the sponge city construction performance evaluation function was used to compare and score each plan, and better plan was selected and optimized.

2. Empirical Study on Performance Simulation and Evaluation of Sponge City Construction

2.1. Case Overview

Wuzhou is located in the eastern part of Guangxi China, located in the middle reaches of the Pearl River Basin, with an area of 12585 square kilometers and a population of 3.4 million. The research object of this paper is located in the south side of Cangwu County, Wuzhou City. The specific location is shown in Figure 3. It has been invaded by heavy rain and flood for many years.

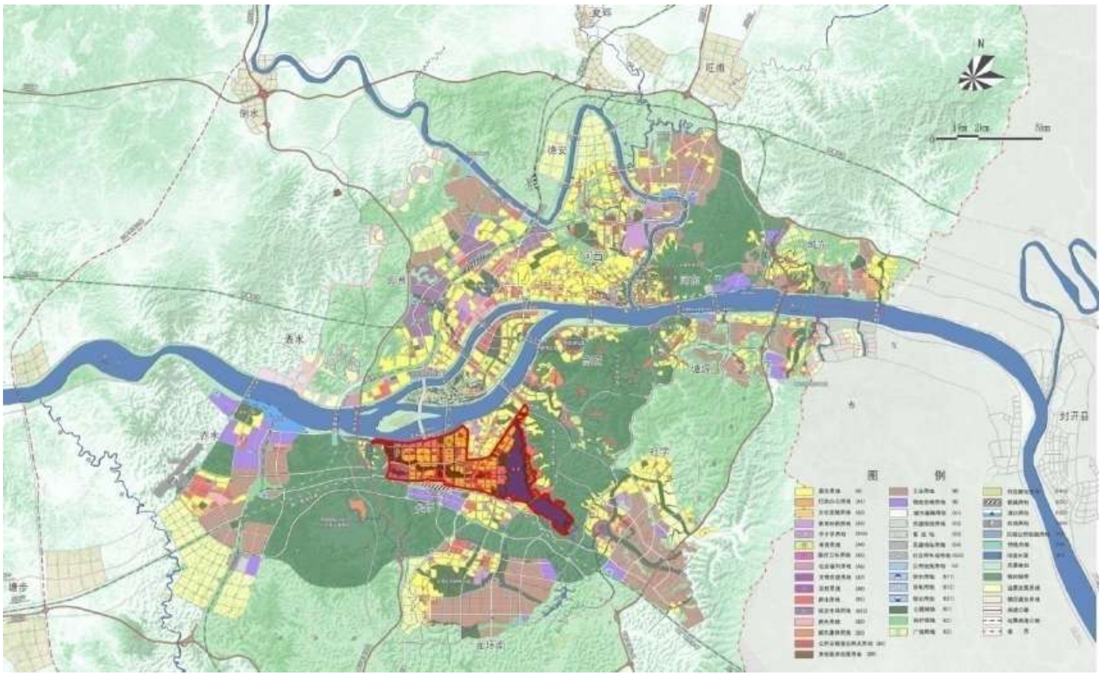

Figure 3. Location map of the study area
Source: author paint

The research in this paper is mainly aimed at the prevention and control of urban flood disasters and the surface runoff in different rainfall day study areas, especially the heavy rain days, and the evaluation of the performance of sponge city construction in different land use planning schemes. Therefore, the historical rainfall data within the study area is especially important for this study. According to the statistics of rainfall from 1959 to 2010 in the study area (the data is not classified because of the confidentiality of the data), the statistics are shown in Figure 4.

2.2. Sponge City Construction Performance Model Simulation

In this paper, two sets of representative rainfall data of Wuzhou Rainy Day (Rainstorm Day and Light Rain Day) are selected, and the rainfall data of two rain days are recorded in the three-season land use planning model, and six different scenarios are obtained. .

Table 1. 24-hour rainfall on two rainy days

2.3 Analysis of model simulation results

(1) There are differences in the performance of sponge cities in different land use schemes.

(2) High green land ratio does not necessarily represent low surface runoff.

(3) The area of green land does not play a significant role in terms of prevention and control of rainstorm waterlogging.

(4) The size of the water area does not necessarily play a decisive role in the prevention and control of rainstorm waterlogging disasters.

(5) Water density plays an important role in the prevention and control of rainstorm waterlogging.

3. Urban Land Use Optimization Strategy

3.1. Set Up an Ideal Model

The research area of this paper is very large, there are many types of land use, and the geological conditions are also very complicated. Therefore, the surface runoff obtained, the time of flood disaster, the total amount of flood and other data of the model simulation are a result of many factors. It is difficult to determine which specific factor plays a decisive role in a certain result.

A series of ideal models are established, that is, without considering the changes of topography, soil characteristics, groundwater conditions and erosion, only certain presets and changes are made for the variables to be studied, and the model output data is collated according to the research purpose, trying to figure out the relationship. According to the research needs, three sets of ideal models were established to study the pre-development and post-development changes of the site, the role of the green space system and the difference between the urban functional land.

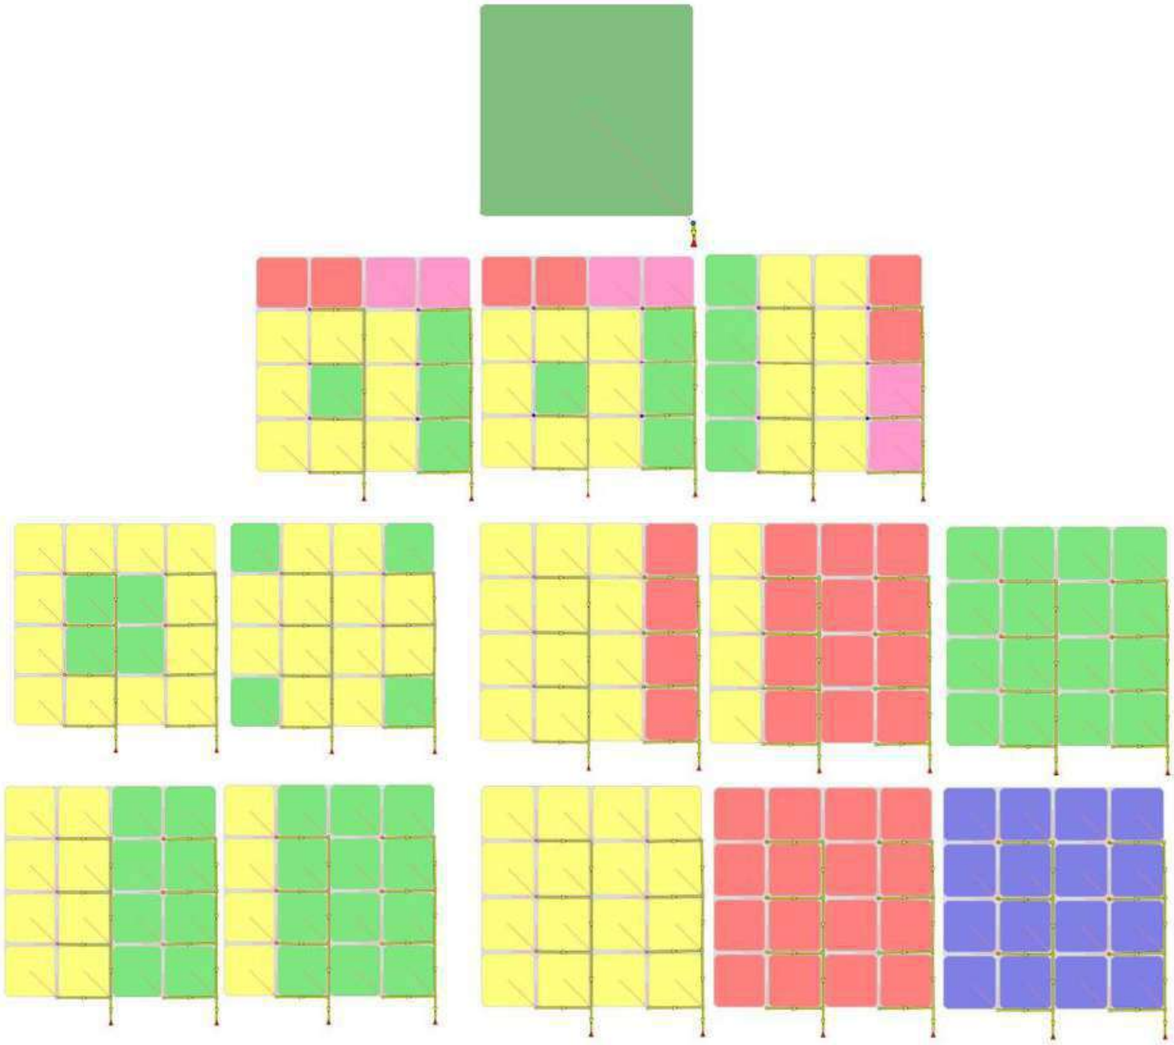

Figure 8. ideal model diagram
Source: author paint

3.2. introduction of LID (low impact development) control technology

Three LID technical measures of ecological detention unit, green roof and rainwater garden were introduced, and program 3 were introduced to establish model simulation to compare the effect of LID control measures on the construction performance of sponge city.

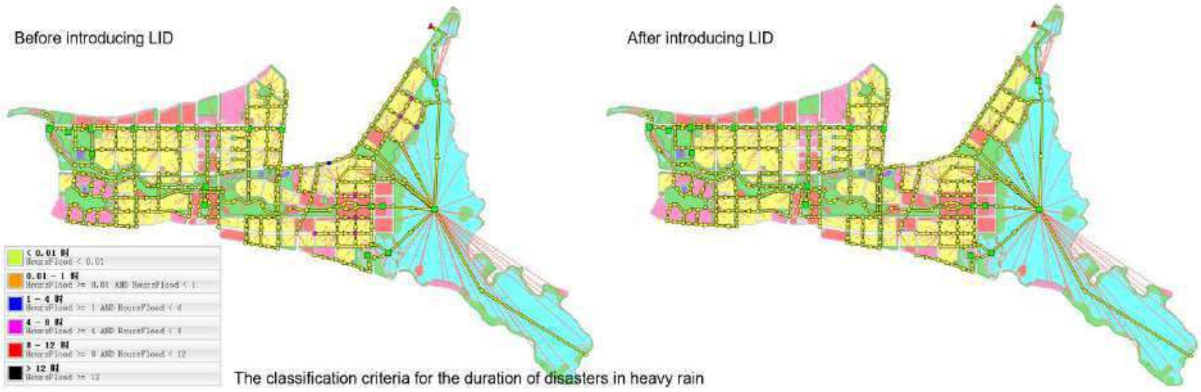

Figure 9. contrast map before and after the introduction of LID
Source: author paint

3.3. Model simulation conclusions and land use optimization strategies

3.3.1. Model simulation conclusions

(1) The LID control technical measures have no obvious influence on the evaporation amount and the infiltration amount under the conditions of constant temperature, wind speed and land structure.
(2) LID control technology measures can greatly control the total amount of surface runoff, and the effect is more obvious on light rain days.
(3) After the development and construction of the cities, the surface runoff will be increased due to the increase of the surface impervious rate. However, the surface runoff may be reduced to some extent or even lower than before the development if the LID control technology measures are introduced reasonably.
(4) The different proportion of urban functional land area will affect the surface runoff and urban rainstorm waterlogging disaster prevention and control, so the urban land area ratio has an impact on the construction performance of the sponge city.
(5) The functional land of the city has little effect on the evaporation due to the impervious rate, but it has an effect on the amount of infiltration, surface runoff and total flood, and with the increase of impervious rate, the amount of infiltration decreases and the surface runoff Increase, the total amount of floods increased.
(6) Green land is more conducive to increase the amount of infiltration, reduce the total surface runoff, and improve the ability to control surface runoff; however, in the prevention and control of flood disasters in heavy rain, the green rate does not play a significant role; In the green space system layout, centralized layout and decentralized layout have their own advantages and disadvantages.

3.3.2. Land Use Optimization Strategy

The delayed water body can effectively improve the construction performance of the sponge city. The natural rivers and lakes or artificial excavation should be used as much as possible in the planning, but at the same time, the water density of the urban river network should be reasonably improved.
In the drainage planning, the rainwater should be discharged into the natural water body as soon as possible; when the funds are allowed and the planning is feasible, the rainwater pipe diameter should be increased as much as possible, and LID technical measures should be introduced;
Urban planning does not necessarily pursue high green rate; in the layout of green space system, centralized layout and decentralized layout have their own advantages and disadvantages.

4. Research Results and Applications

4.1. Theoretical Results

There are mainly two theoretical results of this research: preliminary exploration of the performance evaluation method of sponge city construction based on land use planning perspective and empirical research, through the specific indicators of sponge city construction performance evaluation, and the application of sponge city construction performance evaluation model to form a set of methods to quantify the performance of sponge city construction, making the study of sponge city more rational; This paper propose a strategy to improve the performance of sponge city construction based on the perspective of land use planning.

4.2. Research applications

This paper focuses on the urban planning stage of sponge city construction, focusing on the overall planning land use planning level in urban planning. Through the construction and operation of the simulation model, this paper try to propose a method that can quantify and evaluate the performance of sponge city construction, and analyze it. The optimal scheme is selected through this method. This paper proposes a strategy to improve the performance of sponge city construction based on the perspective of land use planning, which can be used to optimize the scheme of the design stage of land use planning.

Investigation of Regional Coordinated Development Based on Watershed Comprehensive Management for Greater Beijing Region

Ningjing XU, Tsinghua University, China

Abstract:

This paper is to provide a feasible plan for the ecological and economic coordinated development of the Greater Beijing Region in the predictable future by comprehensive management in ecological watershed units. In order to solve the problems of economic development and ecological protection and prove its feasibility, we would like to point out the following aspects for the relevant department to pay attention to: 1) we would like to break the regional boundary and establish a comprehensive management unit with natural basin as a partition; 2) we would like to develop different development patterns according to the different potential of the small watershed unit. To answer for this need, we have brought about the small watershed unit development model based on the following four systems: the water environment system, the leading industrial system, the urban system and the traffic system. In conclusion, it is of primary importance to capital's ecological barrier by coordinated development of the economic and ecological in West Beijing Corridor.

Key words: Regional Comprehensive Management; Watershed Comprehensive Management; Small Watershed Unit; West Beijing Corridor; Ecological Security

(Supported by Beijing-Tianjin-Hebei space planning series of courses in School of Architecture, Tsinghua University)

1. Introduction

1.1 Background

The Greater Beijing Region has entered the process of world urban development due to its special status, rapid population growth and economic and social development, and is now forming a world urban special zone. In recent years, Beijing and its surrounding areas (especially in the northwest) have begun to suffer from such ecological and social problems as bad atmospheric environment, shortage of water resources and unbalance of economic development. There are ecological barriers around the world's megacities. For Beijing, the western area of the Greater Beijing Region is located in the buffer zone between North China Plain and Inner Mongolia Plateau, where a natural valley corridor lies. The valley corridor in the western area of the Greater Beijing Region (hereinafter referred to as "the West Beijing Corridor") is on the Windward and Upstream side of Beijing, where most of the Yanghe River Watershed flows through.

The urban belt in the corridor is highly related, but its economic development levels are far apart. Taking Zhangjiakou (the city which Yanghe River Watershed mainly flows through) as example, the analysis results show that the per capita GDP of Zhangjiakou ranked ninth in the 11 cities of Hebei and was 28.8% of the per capita GDP of Beijing in 2017(Zhu et al., 2017). Approximately 21% of the Greater Beijing Region has encountered water shortage problem, and the groundwater resources are seriously consumed. The region is in urgent need of water resources. Miyun Reservoir and Guanting Reservoir are two important reservoirs in Beijing, of which 96% of the Guanting Reservoir is derived from Yanghe River Watershed. 40% area of the two major reservoirs is in Zhangjiakou. Yanghe River Watershed is an important water conservation area, and its ecological environment is directly related to the ecological security of Beijing's water source.

1.2 Study Area

The Greater Beijing region includes Beijing, Tianjin and Hebei province generally, but the surrounding areas of Beijing tend to be regarded as “Poverty Belt Around the Capital City” with Zhangjiakou city, Chengde city and part of Baoding city in it as most of the Poverty Counties are in that belt. the uncoordinated development is considered to be the biggest contradiction in the Greater Beijing Region, which is an important background factor for the whole study.

Especially in the northwestern part of the Greater Beijing Region, it also assumes the function of ecological barriers of the capital, so that the economic development of the part is restricted. The northwestern part of the Greater Beijing Region is an area of concentrated contradiction between ecological protection and economic development, where is the study focus.

The West Beijing Corridor is the core zone of Yanghe River Watershed which belongs to Haihe River Basin as the major groundwater source for Hebei Province, which is the key area of the study.

Guanting Reservoir is located downstream of Yanghe River Watershed, at the junction of Beijing and Hebei province, which act as an important water source of the Greater Beijing Region. The management of the small watershed unit that Guanting Reservoir lies in is a typical case of the comprehensive management of inter-governmental watershed.

2. Necessity Demonstration of Comprehensive Watershed Management

2.1 Empirical Study on Integrated Watershed Management

Since the 1930s, many transnational or cross-administrative rivers such as the Tennessee River, the Mississippi River, the Blackstone River, the Volga River, the Thames River, and the Amazon River have all undergone comprehensive rectification and development and have achieved great achievements (Wang, 2010). The initial motivations for water environment management in these basins are inconsistent, either for the distribution of water resources, for the treatment of water pollution, or for flood control, but the successful experience of watershed management in river basins provides a consistent inspiration. The first is to establish a unified management organization and ensure its authority through relevant legislation; the second is the coordination of overall interests and local interests.

The integrated management of the Tennessee Valley in the United States originated in 1933.The promulgation of the TVA Act resolved the most important issues in energy, environmental management and economic development, such as power generation, flood control and reforestation, and has now formed a comprehensive watershed management and sustainable development goals. Since the establishment of the Tennessee Valley Authority in the 1930s, the hydropower project, the nuclear power station and the development of clean energy, the social and ecological environmental benefits of the area are all upholding a sustainable and dynamic development view (Tan & Wang, 2002). It gives us three inspirations: (1) to establish a comprehensive watershed management organization; (2) to change the way resources and environment development, focus on the improvement of resource and environment use efficiency, control population growth within the region, and change from extensive to large It is a fine type; (3) to avoid the “path dependence” of river basin development, change the phenomenon of single heavy industry development as the main body, and advocate industrial diversification.

The planning of the Black Rock River Canyon in the United States is a typical of natural corridors development mode. Blackstone River Gorge has good resource condition, and the industrial sites and cultural relics have shaped the uniqueness of this place. In the special management plan "Reflecting on the Past, Looking to the Future", specified the objectives of interpreting history, educating the citizens, balancing heritage and economic development, and promoting the revitalization of the basin, which will develop in the three periods are short, medium and long under the big development goals (Wang & Sun, 2001). Its inspiration lies in the key nodes along the river research and development, the restoration and reconstruction of the river structure, the encouragement of cultural festivals and exchanges, setting development goals in stages, and the full use of the social and economic value of natural resources.

2.2 Requirements of Integrated Development of the West Beijing Corridor

Starting from the comprehensive watershed management is of great necessity to improve the regional integration. From the perspective of the corridor itself, the continuous Yanghe River valley is connected in series with every important city on the West Beijing Corridor. Every aspect of the problem must be solved through comprehensive watershed management.

Firstly, at the ecological level, there are problems such as lack of water resources, poor water quality, and imperfect water resources compensation mechanisms.; Grazing causes a large number of grassland and forest vegetation to disappear, resulting in hydraulic erosion of soil and desertification. Although recovery has begun in recent years, the overall ecological environment condition is still lower than the policy target. To maintain soil and water and make good use of the high-quality ecological resources in the corridor, we need comprehensive watershed management. Secondly, at the level of industrial economy, the existing ferrous metal industry, traditional electric power, and chemical industry in Zhangjiakou have greatly damaged the water quality of the watershed (Hebei Province Government, 2016). However, from the economic perspective, the West Beijing Corridor is still in relative poverty. To achieve industrial transformation and economic development on the basis of ecological conservation, we need to solve it from the overall perspective of the watershed. Thirdly, at the cultural level, starting from the Qin Dynasty (221-206 BCE) as a passageway for the people, the Ming Dynasty (1368-1644 AD) as a part of the Zhang-Ku Avenue, the West Beijing Corridor has superimposed the culture of different historical periods on it, forming the multicultural context of the Corridor, which influenced the development of settlements point in the valley. To carry out unified development and avoid homogenous development and vicious competition also needs to be solved from the overall perspective of the watershed.

In conclusion, most of the problems in the West Beijing Corridor are centered on Yanghe River Watershed, and It cannot be solved in a single administrative area. Therefore, comprehensive watershed management is chosen as the focus of regional planning.

2.3 The West Beijing Corridor Development Prospects

The sustainable development commitments at the global level, the coordinated development at the regional level, and the planning policies for water security are all relevant to the comprehensive management of the northwestern watershed in Greater Beijing Region.

Habitat III the Quito Declaration promotes the development of inclusive, safe and sustainable resilient cities actively (United Nations, 2016). *The National Development and Reform Commission's 13th Five-Year Plan* strengthens water security, promotes river system remediation, maintains basic ecological water demand, enhances water storage capacity, and scientifically implements cross-border river development and management. At the same time, it is required to improve the regional coordinated development mechanism, innovate regional cooperation mechanisms, and strengthen coordination and cooperation in inter-regions and the whole basin (the State Council of the P.R.China, 2015). *The "Beijing-Tianjin-Hebei Collaborative Development Plan"* emphasizes comprehensive management of river basin and promotes the construction of water ecological civilization. The basin and regional issues are very serious, such as the shortage of surface water in the Beijing-Tianjin-Hebei region and the water allocation in the upper and lower reaches. In the context of regional coordinated development, the sustainable use of water resources requires the three forces of the Beijing-Tianjin-Hebei, and innovation and reinforce of integrated river basin management are needed (The Political Bureau of the P.R.China, 2015).

In addition, the requirements for easing Beijing's non-capital function, the development of natural and cultural tourism around the capital region, and the construction of transportation facilities such as the Beijing-Zhangjiakou high-speed railway have brought new opportunities for the development of the West Beijing Corridor. The goal of integrated development will be achieved through comprehensive planning of the Yanghe River Watershed.

3. Development Problems of the West Beijing Corridor

The unique location advantages, the accessibility of the transportation system, the long history and the rich resource endowment have made the advantages and potential of the West Beijing Corridor. However, Zhangjiakou is within the poverty region around the capital; Ecological development and economic development are extremely unbalanced.

3.1 Protection of Ecologically Sensitive Areas Restricts Urban Economic Development

The biggest conflict of the region lies between ecological protection and economic development. There has been an increasing hidden danger for extensive development, showing low efficiency in concentrated use of lands, which has now become the restrictions of regional development. Taking regional ecological capacity into consideration, there are obvious issues concerning unsustainable resource utilization, ecological deficit, which means the current energy consumption mode needs to be urgently transformed.

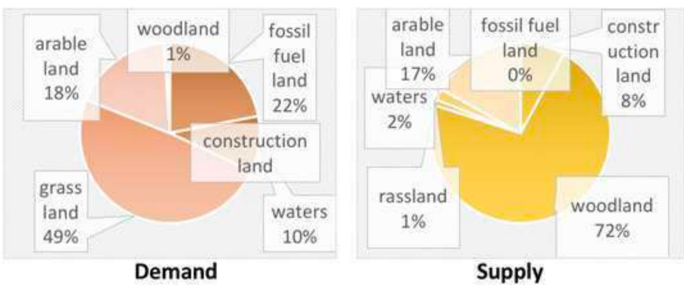

Figure 3: Water Demand and Supplyin the West Beijing Corridor

Source: drawn by the author with data source from Wu&Zhang,2011 & Dong et al., 2013.

1) The Greater Beijing Region in in short supply of water resources. As an important ecological water conservation area, the water resources management problem in the West Beijing Corridor is highlighted, with difficulties to coordinate development between regions. The West Beijing Corridor is the main water supply and the main ecological conservatory in Beijing. However, due to the water utilization mode of the upper stream area is not sustainable, the Guanting Reservoir has stopped the supply for drinking water. As a result, it is difficult to well coordinate the water resources for the Greater Beijing Region.

2) There are contradictions in the construction of Yanghe River conservancy project. It is against the regional sustainable development to carry out the rubber dam projects, or other waterscape projects which harden the riverway and hinder the migration. Slowly-upgraded sewage treatment projects are also considered improper. Located at the juncture of Beijing and Zhangjiangkou, the Guanting Reservoir enjoyed the total volume of 4.16 km3. The water volume has reduced from 1.9 km^3(at the beginning of the construction in 1954) to 0.1 km^3 (in 2015) during the second half of the last century (Zhang, 2008). Nearly 160 km^2 of water surface has been reduced to only 30 km^2 to 40 km^2(Zhang, 2008). The village around the reservoir is densely covered. The retracting lands are mostly turned into farmlands and the original plants have been seriously damaged.

3) Inefficient management of the Greater Beijing Region sand source. The regional coordination strategy requires that anti-sand barriers should be built for the West Beijing Corridor. However, there has been extensive desertification and soil erosion within the region, with the proportion of light desertification being 35% (Wang, 2012).

4) Ecological barrier is faced with soil erosion. The expansion of urban construction lands has become contradictory for the protection of forestry lands and basic farmlands. Smart growth of urban construction lands is still to be explored and the proper layout for farming and forestry land is still to be optimized. The overland runoff is not sufficient, showing serious consumption of underground water and unsustainable of water resource application.

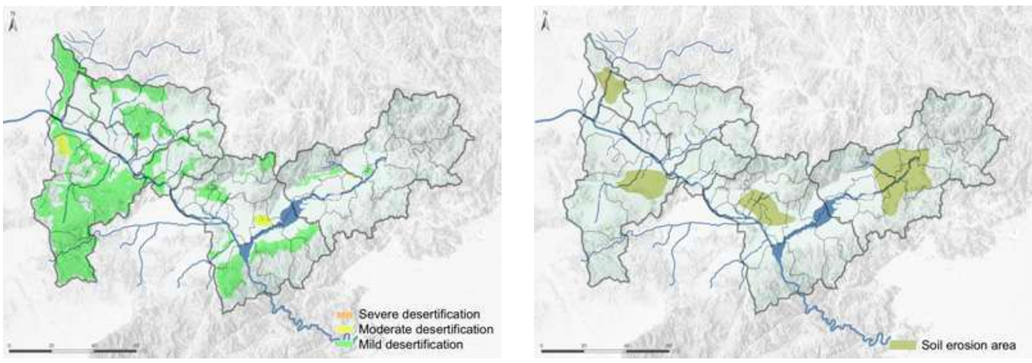

Figure 4: Desertification and Soil Erosion State in the West Beijing Corridor

Source: drawn by the author.

3.2 Imbalance of Urban Development to be Coordinated

There has been an imbalance development of the urban nodes in the West Beijing Corridor, showing a distinct trend for homogeneous development. The exploitation and utilization of resources is not intensive and there lacks communication and coordination between neighboring nodes. The current urban system is scattered, the population agglomeration effect cannot be being achieved well. Most villages are faced with poor geographical conditions and belong to ecological protection areas. Besides, the upper stream of Yanghe River is mostly for agricultural use, while the middle stream for industrial use and the lower stream for both industrial and agricultural use. Most of the industrial and urban life sewage has been discharged to Yanghe River, manifesting the conflict between human activities and the sustainable development of the waters.

1) The limitation of government's rights and obligations due to the administrative borders. The division of administrative units restricts the overall development. It is difficult for the government of these divided units to well communicate with each other and there lack effective ways to solve regional conflicts. the West Beijing Corridor should be considered as a complete district to solve the problems including aging, relatively low labor quality, hollowing villages and population loss, etc.

2) Industrial extensive development consumes much energy and water. The industrial parks which are based on black metals and traditional electricity and chemical support are of high consumption of water and energy but low output value, causing soil and hydrological environmental pollution and the incompatibility with current water resources. The sewage discharge and water resource consumption lead to water quality damage and the water level decline and water area reduction, so there will be a shortage for underground water resources.

3) Low efficiency in agricultural development leads to massive pollution. As the urbanization drive proceeds, there will be increasing pressure asserted by agricultural pollution on the waters of the river. The scattered villages have posed challenges when it comes to the concentrated management of farmlands. The infrastructure processing sewage in the villages and towns is weak. Without proper treatment of swage of life and production, the water resources have been severely polluted.

In conclusion, the traditional mode which considers the administrative units separately ignores the importance of regional interactive development. The separation of administrative units cannot be disconnected geographically. The Yanghe River Watershed is a complete eco-system and the rights and obligations for this area is difficult to be defined for different administrative units.

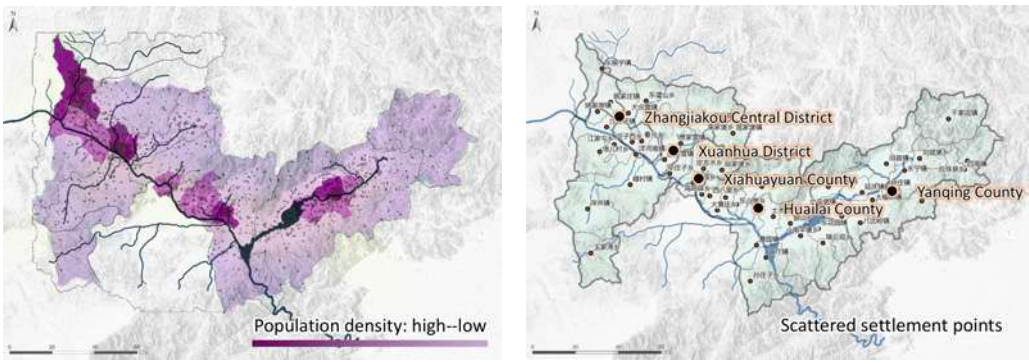

Figure 5: Population Density and the Scattered Settlement Points

4. Exploration on the Comprehensive Development of Small Watershed Units

Water-shortage is the core issue of the development of the Yanghe River Watershed. It is of practical significance for disharmony between regions and realizing the coordinated development of river management, industrial layout, agricultural layout and urban construction by breaking through the administrative boundary and coordinate administrative interval cooperation with "small watershed" as a unit.

By applying the theory and method of watershed ecology, the water gathering ground of the river surrounded by the divide line is subdivided into nine watershed units. According to per capita ecological carrying capacity, it is estimated that about 1.725 million people can be carried in the watershed; And now there are 1.888 million people existed in the watershed, in order to ensure the sustainable development, it is necessary to guide and control the population distribution in the watershed properly.

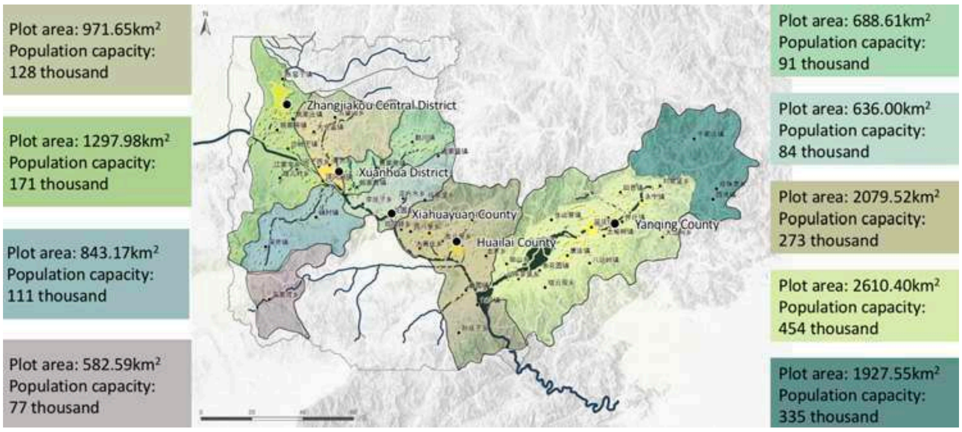

Figure 6: Population Capacity of Each Small Watershed Unit

Source: drawn by the author.

In terms of management strategies in small watershed units, the foregoing mid-term and long-term program in further is divided into two aspects: respectively the management of water environment and the planning of the space. On the management of water environment, practical action plan is supported by administrative system, and space planning based on watershed environment after renovation is fully implemented which involves urban system, cultural tourism resources and the industrial layout etc.

4.1 Water Environment Management

On the management level, in the cross-region comprehensive management of Yanghe River Watershed, the concept of "Watershed Circle" should be established, as well as at the level of Beijing and Zhangjiakou government cross-region comprehensive control department should also be established. Taking the small watershed as a management unit, under the mutual participation of Zhangjiakou and Beijing government, enterprises and the public, in the use of means of administration, market and law, coordinating, systematic, and sustainable management has been applied to well coordinate the resources in the small watershed units, so as to promote the coordinated development in the watershed as a whole.

The policy of "River Leader System" should be implemented, and the main person in charge of the party and government of the main watershed unit should hold the post of “River Leader”, who shall be responsible for the treatment of river pollution. River Leaders should coordinate to deal with the regulation problem of trans-boundary watersheds unit to achieve the division of responsibilities and rights. In addition, the comprehensive management mode of watershed units requires the synchronization of urban river regulation and urban development. Taking the river as a whole system, the management of upstream and downstream, main flow and tributaries are taken into account comprehensively, hence realizing the effective regulation of the whole Yanghe River Watershed.

When it comes to techniques, on the basis of ecological sensitivity factors, the status of towns, villages residential areas, water bodies, nature reserves, and farmland should be combined to obtain the construction suitability evaluation; and by drawing ecological red line, clear define and standardize the range of construction and development. According to land use assessment, on the premise of present distribution situation of towns, village farmlands, reservoir and protection zone, five types of areas are divided, including town construction area, farm area, tourist area, protected area, and key protected area. Also, there will be requirements related to the construction and activities of each area. Among them, protected areas accounted for 68.98%. Through the planning and improvement of agriculture and forestry, changes in land use have increased the area of woodland to achieve the ecological functions of wind prevention, soil fixation and water conservation.

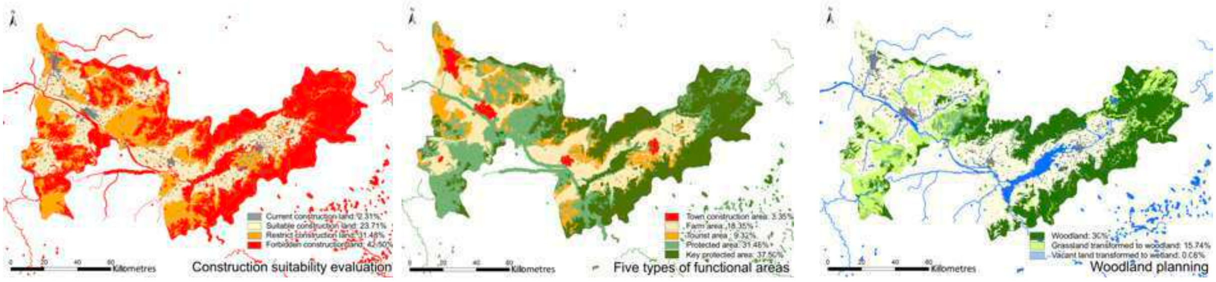

Figure 7: Construction Suitability Evaluation, Five Types 0f Functional Areas and Woodland Planning

Source: drawn by the author.

In terms of rural source pollution control, the technology of sprinkler irrigation, drip irrigation and micro-irrigation should be taken, and make effective utilization of water resources reasonably, choose good, less water-intensive crop varieties, reduce the planting area of high water-intensive crops. At present, settlement points located around the Guanting Reservoir watershed unit generally adopt the old flood irrigation method, which result in the relative serious waste; The reduction potential of pollutants in the corresponding planting industry mainly comes from the scientific and reasonable use of pesticides and fertilizers. Measures should be taken to improve the utilization rate of fertilizers by soil testing and formulated fertilization and changing fertilization methods. Adjust the planting structure to prevent the pollutants flow into the water.

Build a perfect ecological system, improve the effectiveness of protection, protect the diversity of regional species, and form the landscape pattern with characteristics.

4.2 the Layout of Leading Industries

Integrated watershed development needs eliminate high-energy and high-pollution industries such as black metal mining and processing, traditional power supply and chemical products manufacturing in the watershed, optimize and upgrade traditional leading industries such as manufacturing of specialized equipment, food, general equipment and tobacco, and foster new industries such as new energy and automobile manufacturing. The development model is the combination of production, study and research and industrial agglomeration. In this way, the four major industrial agglomeration areas will be formed. Zhangjiakou Central District and Xuanhua District in upstream is focused on manufacturing industry; aerospace equipment and environmental protection industry develop in Huailai District in middlestream; and new energy resources develop in Yanqing District in downstream. Finally, according to the water supply in the watershed, the location and area of the current industrial park in the watershed will be adjusted respectively. The main trend is area reduction.

Moreover, construct multiple and compound ecological leisure roads and provide diversified choices for different types of tourists and residents. Build four travel lines of hundred-mile galleries, Great Wall leisure lines, Beijing-Zhangjiakou railway and the green road along the Yanghe River in the watershed, and form differentiated leisure areas run through by ecological recreation corridor. Differentiated functional status promotes the integrated development of the whole watershed.

4.3 Urban System Planning

Combine urban development potential with the conclusion of the ecological carrying capacity, three types of small watershed units would be divided, respectively the integrated development watershed units, the coordination of urban and rural ecology units and natural ecological conservation units, and on account of three types of small watershed units, respectively the measures of optimizing and improving quality, the coordinated development and ecological protection are proposed.

On the basis of classification, the development function of central settlements inside the watershed units should be further cleared. Yanqing District in downstream as international tourism and leisure area, Huailai District in middlestream as the important transport junction in the west area of Beijing, Xiahuayuan District in middlestream as regional culture tourism city, Xuanhua District in upstream as the famous historical and cultural city, and Zhangjiakou Central District in upstream as the finance and information center in the northwest area of Hebei Province, will be realized. That will achieve differentiated linkage development. Based on the areas mentioned above, the development structure of connecting watershed units is determined by using the landscape system pattern and realize the interconnection and interaction of core nodes, and symbiotic mode of harmonious development of the upstream and downstream watershed units.

The combination model of central-cities +key-towns + general-towns is adopted in the development of watershed units. Efforts are taken to encourage the clustered linkage development of key-towns, as well as to perform appropriate tourism development projects and attract foreign business and investment, motivating the industrial development. In general-towns, the increase of land use should be strictly restricted, promoting environment-friendly recreation and ecological education, and encouraging non-permanent and non-development projects.

In conclusion, the land use pattern should be further optimized in terms of land layout, with emphasis on regional coordination and comprehensive development inside watershed units.

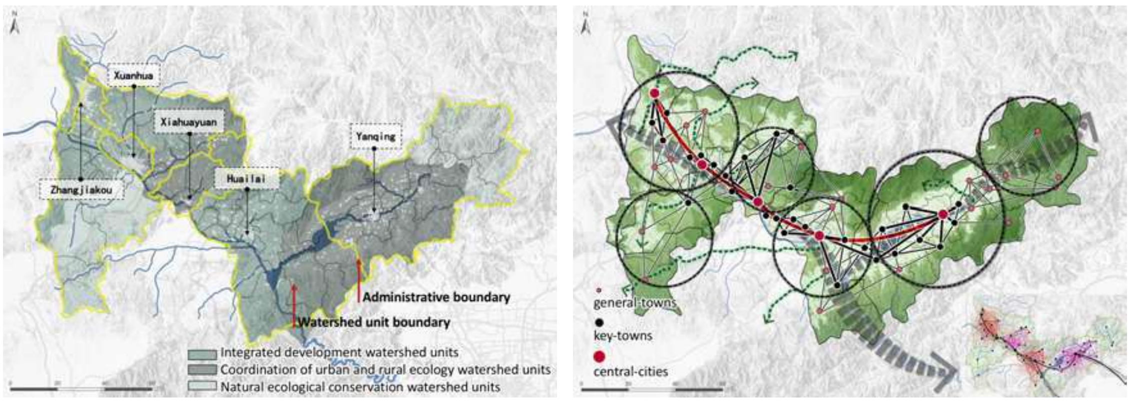

Figure 8: Devided Small Watershed Units and the Guanting Watershed Unit Town Development Mode

Source: drawn by the author.

5. Exploration for Small Watershed Units---Taking the Comprehensive Management of Cross-Border Watershed Around Guanting Reservoir as Example

Guanting Reservoir is an important water source in the capital area. According to the administrative boundary division, 70% of it is in Zhangjiakou and 30% in Beijing. As Guanting Reservoir and its surrounding area are faced with serious water pollution, it's necessary to consider the development within the complete watershed unit. To coordinate the two administrative regions from the perspective of watershed units is of great significance to the protection of water source area and the construction of water source conservation area.

Figure 10: Different Boundaries by Administration and Watershed Unit

Source: drawn by the author.

In the integrated planning of the watershed units, the development of Guanting Reservoir is positioned as a regional ecological leisure area, where the tourism service industry has been mainly developed with many green industry demonstrations. In this watershed unit, the impact of major events brings opportunities. The 2022 Winter Olympics promotes the gathering of ski resort and other tourist service facilities, and the 2019 Garden Expo will accelerate the construction of landscape ecological corridor along the river.

From the perspective of ecological carrying capacity of the watershed unit, the current population in the watershed unit has not reached environmental saturation yet. However, except for the dramatic increase of tourists caused by major events, there is still much less space for growth. In the aspect of ecological development, firstly, it's necessary to form ecological corridor system in the watershed unit based on regional national forest park, forest green land, river ecological green space around Guanting Reservoir, and the urban inside green space, as well as to supply the channel for the migration of wildlife in the watershed unit. Secondly, the management mechanism of the overall watershed unit should be improved by implementing the systematic supervision of the boundary greenbelt, riverbank boundary facilities and sewage treatment at the administrative boundary. The sustainable development of water resources can be realized through integrated management of water pollution from upper stream, middle stream to lower stream. According to different geographical features, the upstream urban development area is the concentrated location of the reservoir, and the sewage is treated in a belt and plane shape; The middle stream urban development area is also the downstream area of the reservoir, which is treated with belt-shaped sewage; The downstream is the non-concentrated area of the township for the treatment of point-shaped sewage.

In the aspect of policy, ecological compensation measures should be perfected. It is recommended that the central committee and the Beijing municipal government should provide compensation to relatively poor cities such as Zhangjiakou to alleviate the limitation of economic development caused by the development of ecology from two aspects: capital and resources. Meantime, the appraisal system should be established to achieve a relatively equitable distribution of benefits.

6. Conclusion

Comprehensive watershed management emphasizes that in the process of developing and utilizing water resources, it is necessary to adhere to the organic combination of two values. On one hand, it must serve the purpose of economic development; On the other hand, it must maintain the basic ecological balance of the watershed. For this purpose, comprehensive watershed management must break through the barriers of administrative divisions. The upper, middle and lower streams of the Yanghe River Watershed should be comprehensively managed based on their different water environment issues to achieve the goal of ecological-production-life integration development from the whole watershed. This can also change the current development model of the government. Comprehensive watershed management is not just a regional master plan. It should also be subdivided into the various urban and rural settlements. The division of small watershed units makes the problems of various parts more detailed, thus realizing the implementation of watershed planning and a sustainable living environment that meets the needs of the Greater Beijing Region.

Abstract

In recent years, worldwide extreme weather is constantly appearing. The extensive development and construction of cities had changed the original water system that caused the frequent occurrence of urban water disasters and the worsening of the water environment until the planning and construction of the Sponge cities vigorously promoted in China that the problems with urban water systems were gradually easing in 2014. In this paper, through four points of view are ecological toughness, technical toughness, social toughness and economic toughness that make a scientific top-level design of Sponge city construction. Meanwhile, it points at three key problems as the urban flood control and drainage, regulation of diffuse pollution and utilization of rainwater resources in an urban tenacity development perspective, based on the key points as the simulation technology of urban rain and flood and the LID optimization technique method to discuss the technical methods for supporting the implementation of Sponge cities. According to the Sponge city construction in the new area of pilot cities - The conceptual planning of the sponge city in the extension area of Jixi in Jinan city as the research case; put forward the planning strategies of ecological pattern construction, systematic planning and c onstruction guidance of the sponge city in system, also explores the extended industrial development and the construction of tenacity mechanism of the Sponge city that attempts to provide a new thinking and path for the study of the sponge city planning and construction.

Keywords: Sponge City, New Urban Districts, Toughness Development

1. Background

The promotion of "new normal" accelerates the pace of urban transformation and development, which makes its development demand shift from "scale and quantity" to "efficiency and quality". The construction of the extensive development of the city has changed the original water system of the city, and the problem of water system in the city has become increasingly prominent. Since 2014, China has vigorously promoted the construction of sponge city to solve the problems related to urban water environment, water ecology and water resources. Experts, scholars and relevant administrative departments in the field of urban planning and construction have made many useful attempts and explorations in the planning and research of spongy cities.

In order to enhance the resilience of the city, several pilot projects have been set up in China to carry out the construction. Unfortunately, 19 of the 30 sponge City trials in China appeared water logging in 2016, which led to various controversies in the civil and academic circles. At the same time, it is found that the research scope of the pilot sponge city is limited by the sort out and review of various problems in the process of the planning and construction of the domestic sponge city. It often ignores the top-level design problem of sponge City, especially for the study of water system planning in larger scale regions and cities (Zhao zhiqing, Wu Zhongyang & Wang Zuowei, 2018). Under such circumstances, the construction of sponge city under the guidance of urban resilience thinking is particularly important.

However, most of the research focuses on the planning and construction of spongy cities. They are more inclined to specific municipal engineering measures, and the focus is to solve the problem of urban water logging (Wang C H, Blackmore J M, 2009). Therefore this paper puts forward the top layer design of the construction of the planning strategy of the spongy city by taking Jinan Jixi extension area as the research object, taking the problems arising in the process of the planning and construction of the sponge city as the guidance, and through the methods of urban flood defense and drainage, the control of non-point source pollution and the resource utilization of rainwater (Shao Yiwen, Xu Jiang, 2015).

2. Methodology

2.1 Range of Study

Jinan was selected as the first batch of sponge pilot cities in 2015.It selected the old city area of 39 square kilometers in the central area as the pilot area of sponge city construction (Fig.1). The scope of this plan is to select the JiXi wetland, Emei area and West Railway Station area in the western part of Jinan as the demonstration area for sponge city construction. The conceptual planning is the top-level design of sponge city. It is a commanding plan in the implementation process of the spongy city planning and construction in JiXi extension area, and provides the top level positioning and technical support for the follow-up control detailed planning, construction detailed planning, construction management, acceptance and maintenance work (Zhao zhiqing, 2016).

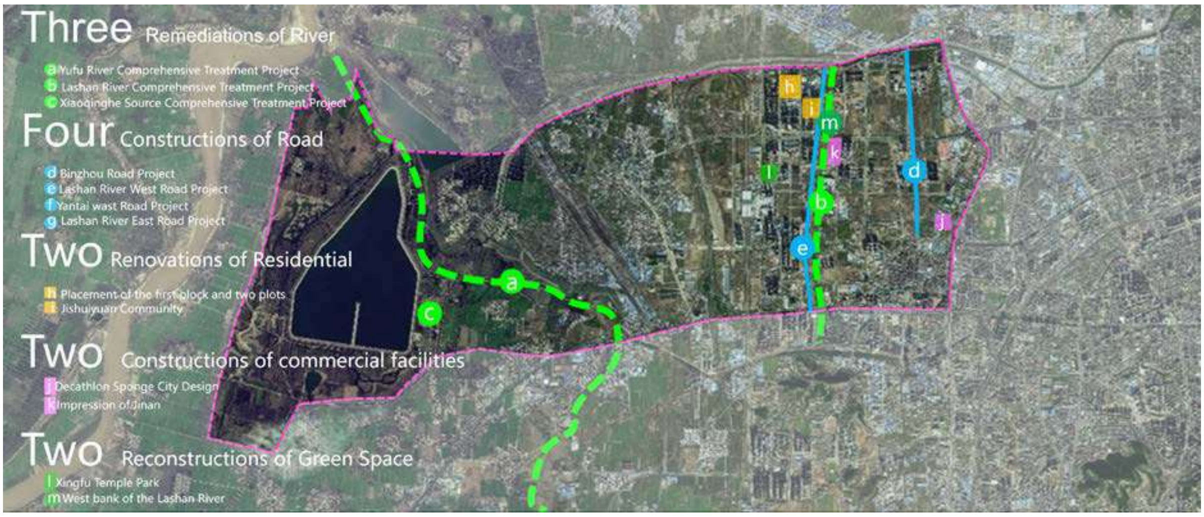

Figure 1: Current status of existing projects
Source: graphing by author

2.2 Situation Questions

(i) The utilization rate of unconventional water resources is low. The regeneration and utilization of sewage has not yet formed a complete system, and the utilization of rainwater resources has just started. There are only rainwater collection and utilization facilities in some housing estates, such as Ji Water Royal Garden District, Forest Landscape Villa district and part of the street.

(ii) There is a hidden danger of water logging in JiXi extension area. The data show that there is no water accumulation point in JiXi extension area, but its rainwater pipeline system is not perfect, the recurrence period is less than 2 years. The poor scheduling of the construction of rainwater pipe network in the west station area and the unsound pipe network in Emei area have hidden dangers of water logging.

(iii) The sewerage network system has not yet been constructed in Emei area. The effect of the direct discharge of sewage and the non-point source pollution result in poor water quality of the Mount Emei River and its downstream Small Thanh Ha. The non-point source pollution of urban water and rainwater surface runoff is more serious.

(iv) The ecological nature of a few river course shoreline is not good. The maintenance of the ecological nature of Small Thanh Ha, La Mountain River and Jade Character River is good. There is no maintenance measure for Mount Emei river bank line, so ecological shoreline restoration is needed.

(v) The risk of flood disaster is low, and the prevention and c ontrol system needs to be improved. On the south side of the Jinxi extension area, there is a flood by-pass of the La Mountain River. It introduced the flood upstream of the Small Thanh Ha into the west to the Yellow River river system and reduced the potential flood hazard. However, the rainstorm in Jinan is characterized by heavy rainfall, high intensity, obvious locality and very concentrated time history distribution. It should strengthen flood control and improve the resistance to flood disasters in the JiXi extension area (Bates S, Angeon V., Ainouche A., 2014).

2.3 Urban Toughness

Resilience thinking can solve various problems in the construction of sponge city with a new research angle, and construct a more stable urban ecological pattern from a macro perspective in order to solve the problem of poor systematic and single research scale (Adger, W. N., 2000). It establishes the overall framework of the sponge city construction system with the ability to deal with the rain and flood risk from the meso scale, and makes the construction of the sponge City collaborate highly with the special planning between the other urban subsystems, which enhance the integrity of the construction project and make it no longer blindly rely on the facilities to solve the water system problem (Bai, X., 2007). It builds the facilities of the sponge city from the micro scale, and at the same time deploys and promotes the implementation and management of the construction of the sponge city, in order to enhance the stability of the economy and control of the sponge city. The following will be di scussed from four perspectives of resilience: ecology, engineering, economy and society (Fig.2).

Tenacity Thinking		Spongy City	Approach	Planning Concept
Ecological toughness	Water system toughness	Water ecology, water environment and water safety planning	Water area control and protection, water pollution control, flood control and drainage facilities planning, "Matrix -- corridor -- plaque" protection strategy	**Dominant recessive combination**——Basin perspective; surface and underground;
	Tenacity of green space system	Construction of urban green space system in sponge City	In the low-lying area of the city, sponge type green space is set up. Retention infiltration green space, Midway transmission type of green space, receiving storing type of green space.	
Technicial toughness	Technical toughness	Planning of municipal rainwater, sewage and water system	Introduce advanced pipe network system and perfect the current system	**General and special combination**——Normal rainfall and extreme climate co-ordination; flood detention, flood diversion and flood discharge co-ordination;
		Revetment improvement and rainwater utilization	Restoration and protection of ecological coastline	
	Measurement toughness	The control index of land use runoff in each block	Quantitative index control	**Micro control and global idea**——The index is refined to the plot, the unit is divided into control thinking, and the promotion area is balanced.
Sociology toughness	Management toughness	Construction management and control	Set up a sponge city management team and set up an expert think tank.	**Resource integration**——Mutual support and interconnection ensure the common operation and rapid response among departments.
	Synergistic toughness	Public participation	Coordination of governments at all levels, neighborhood organizations, community organizations and private sectors	**Cooperative inclusion**——Further develop professional subregional network to achieve the common vision of building resilience cities
Economic toughness	Potential toughness	Planning scheme of extension industry in sponge City	Sponge city culture tourism, sponge City Culture Exhibition	**Layers of progressive**——From building monomer, green space, street to functional area unit, the urban culture and industry will be improved comprehensively.

2.4 Data Specification

According to the DEM elevation and landset8 satellite remote sensing image data provided by the local survey service, it has carried out the analysis of the area on the slope, elevation, vegetation cover and heat island, and locked the main aggregation area of the site problem. Local rainfall data are derived from local Yearbook chronicles. In order to ensure consistency of the research foundation, these data sources chose the same year to minimize the possibility of invalid data as far as possible.

2.5 Statistical Analysis

The rainfall pattern in Chicago is composed of the maximum rainfall intensity of different duration under a certain recurrence period. The determination of rain pattern is based on the IDF relation curve at a specific recurrence period. The determination of the rainfall pattern in Chicago includes the determination of the comprehensive rainfall peak position coefficient and the determination of the rainfall graph model in Chicago (Trinh D, Chui T.,2013).

(i) The annual maximum rainfall process samples of the every duration of rainfall were segmented at intervals of 5min to calculate the rainfall peak position coefficient $r_i = t_i / T_i$ (r_i is the peak position coefficient of the rainfall, t_i is the peak value time of the rainfall , and T_i is the duration of rainfall.

(ii) First, it carries on the arithmetic average of the rain peak position coefficient of the annual maximum rainfall process samples of the every duration of rainfall, then weighted average of each diachronic peak position coefficient according to the length of each diachronic time and calculates the comprehensive rainfall peak location coefficient *r*.

(iii) It designs the rainfall recurrence period (*P*) and the duration of rainfall (*t*) based on the comprehensive rain peak position coefficient *r*, and substituting it into the rainfall pattern in Chicago derived from the rainstorm intensity formula to calculate the instantaneous rainfall intensity before and after the rain peak and the average rainfall intensity in each period. Thus, the rainfall pattern in Chicago corresponding to a certain recurrence period and the duration of rainfall is finally determined.

The rainfall pattern in Chicago makes the design of typical rainfall process based on the statistical rainstorm intensity formula. It describe the time when the peak of rainstorm occurs by introducing the rain peak position coefficient *r*, and divides the time series of rainfall duration into two parts: pre peak and post peak. The instantaneous intensity of the pre peak is $i(t_b)$, the corresponding duration is (t_b), and the instantaneous intensity of the post peak is $i(t_a)$. The corresponding duration is (t_a).The instantaneous rainfall intensity before and after the rain peak can be calculated by the following formula：

$$i(t_b) = \frac{A[\frac{(1-n)t_b}{r} + b]}{[(\frac{t_b}{r}) + b]^{n+1}}$$

$$i(t_a) = \frac{A[\frac{(1-n)t_a}{1-r} + b]}{[(\frac{t_a}{1-r}) + b]^{n+1}}$$

3. Results

3.1 Basic Data Analysis

The overall topography of the area shows the South High and North low . The altitude of the south side of the site is mostly between 30-35 meters, while the altitude of the most other areas are mostly between 20-30 meters (Fig.3). The land in JiXi extension area is relatively flat, and most of the slopes are between 0.3-5.0% (Fig.4).The proportion of the whole green space and the underlying surface of the water body can exceed 40%.The JiXi extension area has excellent natural resources and comfortable living environment (Fig.5,6).

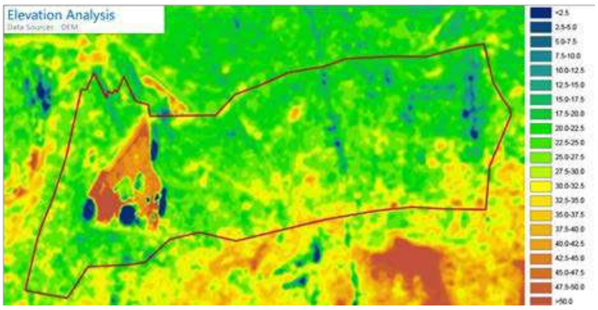

Figure 3: Elevation Analysis

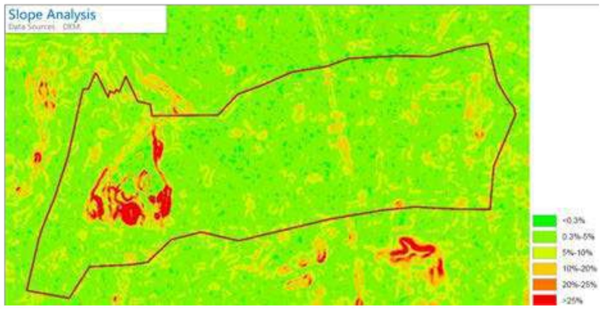

Figure 4: Slope Analysis

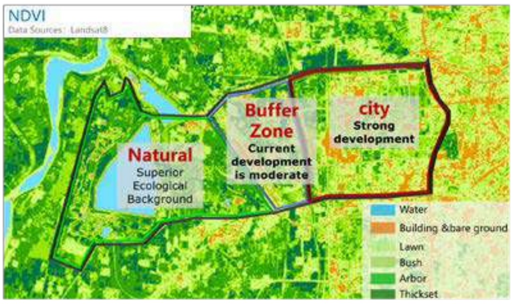

Figure 5: NDVI Analysis

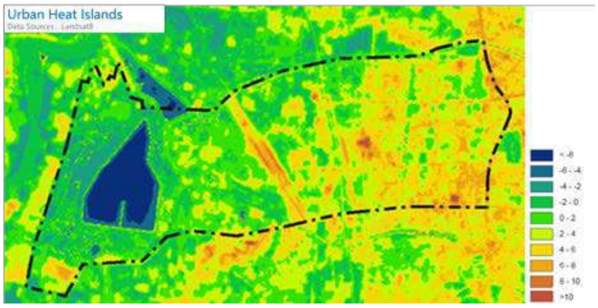

Figure 6: Urban Heat Islands Analysis

Source: graphing by author

According to the statistical data, the local rainfall has the characteristics of uneven distribution of precipitation, large variation of inter annual rainfall, seasonal variation of precipitation, and large annual average water surface evaporation. According to the rainstorm intensity formula before and after the peak, the maximum intensity of Chicago rain pattern at different recurrence periods is shown below the following picture. The maximum intensity of a 2 year rainstorm is 2.656mm/min. The maximum intensity of a 100 year rainstorm is 5.941mm/min, and the composite rain peak coefficient is 0.347 (Fig.7, 8, 9).

3.2 Flood Control and Drainage

The urban low-lying areas are easy to gather rainwater. Therefore, sponge type green spaces should be set up in the low-lying areas of the city to collect, store and retain rainwater. Depressions type I: water depressions. Protection requirements: coordination of general regulations and regulatory rules must be preserved. Depressions type II: waterless depressions. Protection requirements: according to the actual situation, the depressions should be used as green land, lake or other land, or construct the LID facilities (Fig.10).

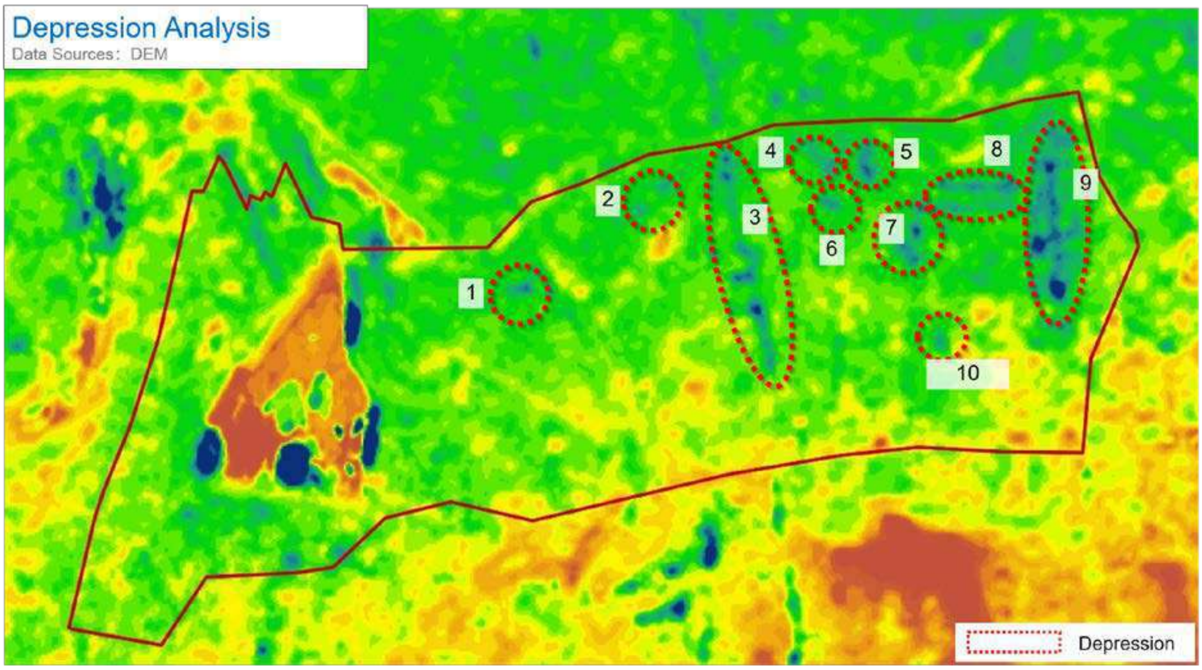

Figure 10: Depression Analysis
Source: graphing by author

3.3 Pollution Control

(i) Increase the ecological purification facilities. Setting up ecological purification facilities in streets and communities, including vegetation buffer zones, grass planting trenches and rainwater gardens, so as to beautify the environment and reduce runoff source pollution.

(ii) Perfect drainage pipe network. The current situation of rainwater network construction is not perfect. There are lots of shanty towns in Mount Emei area, and the density of rainwater and sewer pipe network is low. Part of the road which was not constructed in the West Railway Station area resulted in incomplete pipe network. The pipeline network should be constructed in stages according to the actual situation, so as to reduce non-point source pollution.

(iii) Put up the initial rain discard flow devices. In the rainwater pipeline, the initial rain discard flow device is added, and the initial rainwater is treated and discharged to the river to reduce the pollution of the rain water after washing the pollutants to the river system.

(iv) Sewage interception. Improve the sewage pipe network system, shut off the sewage straight discharge port, discharge all the sewage into the sewage treatment plant, and prevent the sewage from being directly discharged into the river water system (Fig.11).

Figure 11: Classification of Pollution Control
Source: graphing by author

3.4 Runoff Unit

In order to connect the implementation scheme of the spongy city in the JiXi extension area, and to provide support for the implementation of the follow-up construction projects (Fig.12). Facilitating the further deepening of the runoff control indexes in the construction land of the control units, the control units can carry out independent runoff monitoring (Table.1).

4. Methodology

4.1 Framework of the Resilience Structure

In order to avoid a series of problems, such as poor systematic scheme, single research scale, and fragmentation of construction projects, this plan divides the construction of the spongy city planning system into three levels, which are the ecological pattern planning of the sponge city, the system planning of the sponge city and the planning of the construction of the sponge city (Alexander D E, 2013). In these three levels, it joins the guidance of resilience thinking, and solves the problems in the process of the planning and construction of the traditional sponge city, and makes the construction system of the sponge city more flexible (Fig.13).

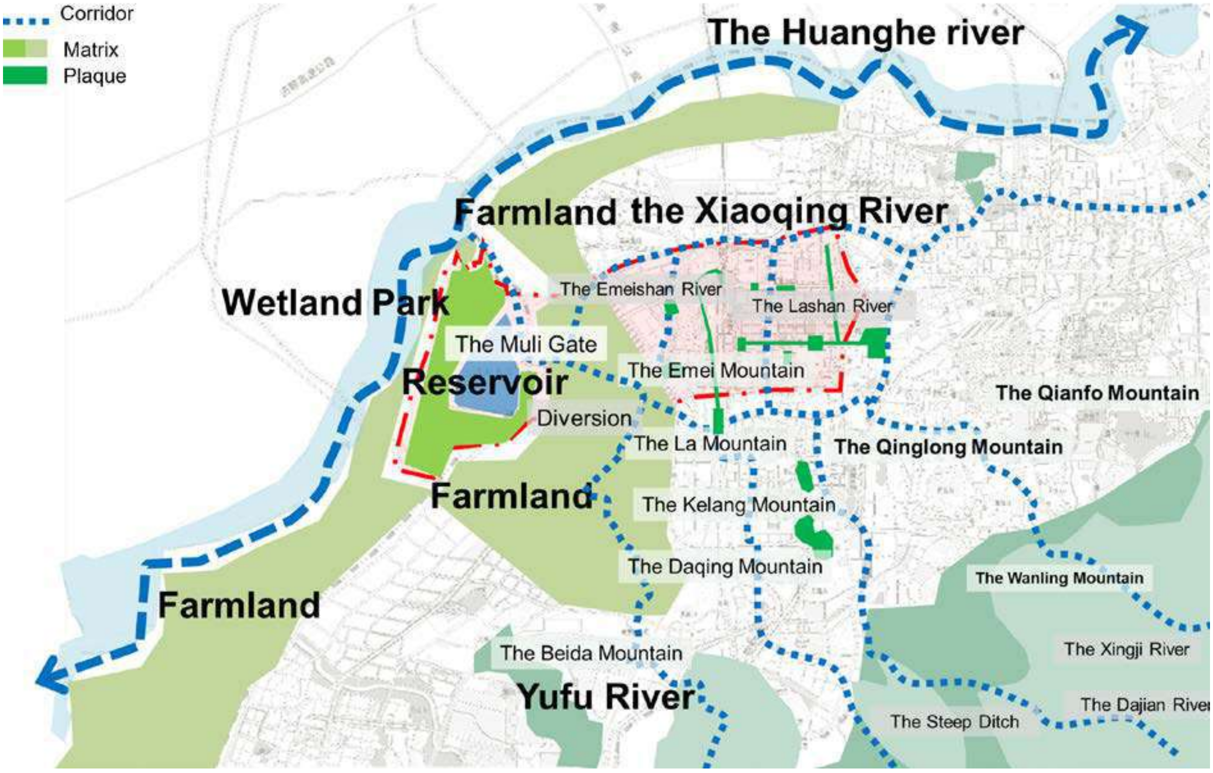

Figure 13: Framework of the Resilience Structure
Source: graphing by author

4.2 Maintenance of Derivative Industry

The development of sponge city extension industry can bring some economic benefits to sponge city construction, and promote diversified industrial development in the promotion area. This plan has utilized the natural resources in the JiXi extension area and the landscape design of the sponge city construction project. At the same time, it combines the six major groups of owners' main group business (including ecotourism, cultural industry, health industry, etc.), and puts forward to develop the two major industries of the cultural tourism and cultural exhibition in spongy city in JiXi (Jabareen Y, 2013).

4.3 Dynamic Supervision and Control

The planning and control system of sponge city construction in JiXi extension area includes three aspects (Huang Xiaojun, Huang Xin, 2015): organization guarantee, technology control and management implementation. The main control phase includes the whole cycle from planning to implementation of the construction .It guarantees that in any stage of the construction of the sponge City, there will be a c lear department responsible, reliable technology to provide security, corresponding regulations, and c an quickly deal with and solve the problem, so as to ensure the stability of the construction system of the sponge city (Fig.14).

Figure 14: Dynamic Supervision and Control
Source: graphing by author

5. Methodology

On the basis of four aspects of urban resilience, through integration analysis of resilience, flood control, pollution source control and runoff unit control, we can conclude: a. the rigidity of sponge facilities is the foundation of urban toughness. b. the implementation of the whole process of resilience is important to the project. c. dynamic supervision and control is the guarantee of urban resilience. In the current practice of sponge City, the new tenacity mechanism and renovation methods are constantly optimized. At the same time, the development of urban and ecological environment system involves many complicated factors, and other types of data should be expanded. The decision making method mentioned in this paper still needs supplementary and practical feedback, which is also needed for further work in the future.

TECHNOLOGY AND INFRASTRUCTURE: Clean, Green, Smart and Resilient

Making Lagos a Cool City: A Study of Transport System and Travel Behaviour

Wale ALADE, University of Lagos, Nigeria
Mobolaji OLASENI, Yaba College of Technology, Nigeria
Femi ADENIJI, University of Lagos, Nigeria
Bukola ALADE, Bells University of Technology, Nigeria
Juwon OLASENI, Vistaplan Consulting, Nigeria

1. Introduction

Transport plays a pivotal role in the socio-economic and political development of nations all over the world. It is a catalyst which facilitates access to various services and opportunities. Scholars (Alade, 2009, Daramola and Adeniji, 2009, Fadare, 2010, Badejo, 2011 and Filani 2011) have recognized the role of transport in the efficient performance of cities. However, urban transportation systems in most developing cities are far from ideal with congestion being the most visible and frequently mentioned transport problem which results from high level of motorization and other factors such as poor road infrastructure and inefficient traffic management.

According to UNEP (2010), transport is the second largest sector contributing to global carbon dioxide (CO2) emissions from fossil fuel combustion and of the 23 per cent of global CO2 emissions from the transport sector, road transport accounts for 73 per cent, followed by international shipping and international aviation. However, the transport sector is not receiving enough attention in global climate change mitigation efforts, even though, according to UNFCCC (2011) it is the sector where emissions have increased the most (by 14 per cent from 1990-2008) and, in a business-as-usual scenario, are expected to grow by 25.8 per cent by 2020 compared to 1990 levels.

The impact of transport on the environment cannot be underestimated. Mitigating the effects of climate change in the global north has been profound, however, not much has been done in the south. In Lagos, the largest city in West Africa, efforts are ongoing to respond to global action on climate change through investment in transport infrastructure with appropriate measures including policies to encourage more use of public transport and non-motorized transport options. This study examines the transport system and travel behaviour in Lagos and the efforts of the government in promoting environment-friendly transport with a view to using the outcomes to make policy recommendations that will make Lagos a cool city.

2. Literature Review

2.1 Urban Transportation System: An Overview

Transportation can be broadly categorized depending on what is being transported, the mode of transportation, and the governing regulations and other institutional dimensions. In relation to what is being transported, three subsectors in transportation-moving passengers, freight or information- make different demands on transportation systems (Mehrotra et al., 2011). The impact of greenhouse gas emissions as well as measures to mitigate or adapt these emissions can vary widely depending on how passengers, freight and information are transported. Again, transportation in terms of mode of travel can be broadly categorized as occurring by land, air and water. Land-based transportation systems are generally those with the highest utilization in urban centres and can be sub-divided into rail and road-based transportation.

Kahn-Ribeiro et al., (2007) noted that road vehicle accounts for more than three-quarters of the total energy use in transportation and is consequently associated with greenhouse gas emissions. The combination of what (or who) is being transported and mode adopted for transportation is significant because it gives a measure of the amount of greenhouse emissions by modes and types of uses. As a result, the measures of emissions in turn helps to devise adaptation and mitigation strategies. Finally, the type of regulation and management of the urban transport system have a critical role to play in the reduction of vehicular emissions.

2.2 Transportation and Climate Change

The transportation sector accounts for 23% of global energy related greenhouse gas emissions in 2010 and some scholars project that emission levels for this sector could increase by greater than 70% by 2050 (Sims et al., 2014). Transportation, therefore, needs to play a pivotal role in efforts geared towards global climate change mitigation (UN-Habitat, 2009; Voukas and Palmer, 2012; IEA, 2013). However, the importance of the transportation sector goes beyond carbon emissions. Transport networks connect people with employment opportunities, health care and education, shapes communities and provides means of bringing goods and services to the market. In other words, efficient and accessible transport is not just sine qua non to economic growth, but also fundamental to the well-being of humans.

Historical low investment in public transport infrastructure and low capita incomes epitomised by low and middle-income countries in Africa have resulted in dependence on walking, bicycle and motorbike (Oyesiku, 2001; Abduhamoud et al., 2011; Voukas and Palmer, 2012). The implication of the foregoing is that car-centred transport systems require more land, promote urban sprawl, increase congestion, raise expenditure on energy and generate air pollution that causes respiratory illness, particularly among vulnerable groups such as infants, the elderly and physical labourers (Goodwin, 2004; Litman, 2004; UN-Habitat, 2009).

UN-Habitat (2009; 2010b) observed that dependence on private vehicles can also contribute to the development of two-layered transport systems, where those without access to vehicles are forced to depend on non-motorised transport (NMT) modes and informal public transport options, often resulting in greater exposure to air pollution and risk of traffic accidents. This compounds social and environmental inequalities. On the other hand, multi-modal transport networks that include well-connected mass transit infrastructure (buses, trams and trains) and NMT options (pedestrian walkways and cycling lanes) are less energy and emission-intensive, promote more compact forms of urban growth and are socially inclusive (Kenworthy, 2006; Rode et al., 2014). However, these transport networks require substantial upfront capital investment, strategic urban planning and sophisticated technical and management capabilities, which at times are beyond the capacity of governments in low and middle-income countries.

3.0 Materials and Methods

The study is both qualitative and quantitative in approach. The qualitative approach examines the transport system in Lagos by reviewing the Strategic Transport Master Plan and other transport study reports of Lagos Metropolitan Area Transport Authority (LAMATA) to highlight the character and challenges of the city's transport system and government's investment in transport infrastructure that aligns with climate change mitigation. The survey of travel behavior covers 1953 households in 32 neighbourhoods in three contrasting residential density areas using systematic sampling technique. Structured questionnaire was administered on household heads to obtain information on their previous day travel characteristics. Data were analysed descriptively and the results were used to highlight the climate change implication of urban travel in the city.

4.0 Results

4.1 Lagos Transport System

The transport situation in Lagos reflects its megacity status. It is estimated that some 6million passengers' trip are recorded daily within the city. About 70% to 77% of these trips are bus based public transport, while the rest is largely by cars. The rail and water transport accounts for less than 1% of the trips (LAMATA, 2014). Organized public transport services exist in the form of Bus Rapid Transit (BRT), the LAGBUS and the corporate Taxi scheme which were introduced a decade ago as part of government efforts to make Lagos a global and competitive megacity. The BRT was introduced to replace the private sector driven mini-buses known as Danfo and Molue. It was estimated that there are between 75,000 and 90,000 such buses in Lagos metropolitan area.

The BRT Scheme came into operation in 2008. It is expected to operate along eight routes using specially designated BRT lanes running through the city, with the aim of expanding to other routes in the future. The BRT scheme is estimated to transport about 10,000 passengers in each direction per hour during the peak travel times. The Lagos Metropolitan Area Transport Authority (LAMATA) is the government agency established to deal with the multitude of transport problem in the state and oversees the BRT scheme. The LAMATA BRT corridor covers about 22kilometres in length. The system is run by two operators, Nigerian Union of Road Transport Workers (NURTW) Cooperatives and LAGBUS, a Lagos State Government owned Asset Management Company which contributes about 180 high capacity buses for the implementation of the first phase Mile 12 to CMS BRT Lite system.

Motor parks or public transport garages abound all over Lagos Metropolis. These facilities are poorly designed, badly maintained and poorly located. In some cases, bus stops are located too close to interchanges or at a point difficult to access from primary corridors. The bus stops that are commonly utilized are operated inefficiently, because bus drivers maintain no order and there are no pre-designed bus stops serving destinations. This results in large number of bus passengers milling about, searching for buses and the opportunity to board a bus before it has entered the bus stop. The operation of the Lagos State Traffic Management Agency (LASTMA) has impacted positively on traffic situation in Lagos. Total time wasted in traffic is estimated at 3 Billion hours annually. Saving just 20% is equal to 1 Billion USD of economic benefit to Lagos (ROM Transportation Engineering, 2010). Activities of LASTMA has reduced the excessive total travel time on journeys being made on major corridors in Lagos metropolis.

The transport situation in Lagos is expected to get better with the expansion of the BRT scheme and the completion of the light rail transit. The rehabilitation of inland water ways and introduction of private sector ferry services with the new taxi scheme are also efforts directed to enhance urban mobility in Lagos. To consolidate these efforts, some agencies and institutional framework were put in place. These include the establishment of LASTMA, State Traffic Safety Advocacy Programme, Lagos State Drivers Institute and Motor Vehicle Administration.

4.1.1 Lagos Transportation Challenges

Lagos is rapidly expanding and is expected to have a population of over 30 million people by 2030 and overtake Cairo as the biggest city in Africa. Unfortunately, Lagos does not enjoy the privilege of adequate urban and transportation planning it deserved in its initial stage of urbanization. Consequently, the city has experienced proliferation of slums, degradation of urban areas and facilities, and transportation problems affecting all modes manifesting in the form of congestion, poor accessibility and mobility, inadequate road and terminal infrastructure, distressed public transport system, weak traffic management and safety and security challenges among others. Congestion is a major challenge in Lagos megacity and occurs daily along major corridors.

In a report submitted to LAMATA by ALG Transportation & Logistics (2013), it is documented that the public transportation system in Lagos state is inadequately regulated and structured. Besides, the public transport system is highly fragmented comprising many un-regulated routes and dominated by the use mini-buses (Danfos) leading to an inefficient public transport service which compels people to depend on private transport, resulting to a chaotic transportation which aggravates congestion.

It is further noted in the 2013 report that the industrial status of in Nigeria accounts for the growing number of freight vehicles along the main transport corridors in city and the freight vehicles share the existing road infrastructure with passengers. Similarly, the absence of an organised non-motorised transport (NMT) infrastructure, the lack of integration of transport and land use, weak regulatory mechanism among others are factors that worsen the transportation challenges in Lagos. The 2013 report concludes that, there is need for an urgent urban and transport development plan in Lagos, to address the continuous degradation and congestion of the transport system. The report also emphasizes that the results of “No action” will not only lead to the extension of the current congestion levels of Lagos but will also result in the loss of a unique opportunity to develop the Mega-city as the key-economic hub of Africa.

4.1.2 Non-Motorized Transport (NMT)

NMT, especially walking, is the most common form of mobility in Lagos, particularly for low-income households. According to the Lagos STMP (2004), around 30% of Lagos mobility is on foot or by bicycle. The interaction between pedestrian and vehicles in Lagos is unplanned and dangerous. In other to achieve an inclusive and sustainable transportation system in Lagos city, there must be recognition of importance of NMT. This does not seem to be the present situation as there are few segregated traffic facilities for pedestrians (e.g. walkways, zebra crossings, footbridges, underpasses and signs) and no pathways for bicycle riders. As a result, pedestrians are frequently forced to walk on the carriageway sharing roadway with motorised transport, which implies a low level of road safety.

Furthermore, the use of junctions as non-regulated commercial areas has been identified as one of the critical issues of urban mobility in Lagos. The encroachment on the roadway available for pedestrians by commercial activities represent a general challenge in all of Lagos urban core. The inadequacy of space for pedestrians is also a challenge in Lagos public transport system. There is a perceived lack of provision of proper accessibility to bus stops/terminals. Invariably, this results in increased rate of traffic accidents involving pedestrians in relation to unsafe bus stops.

A close examination of Lagos urban transport system also reveals restrictions to pedestrian mobility. For instance, highways and primary roads represent significant obstacles to pedestrian movement due to the absence of proper infrastructure facilitating the crossing of such barriers. The absence of road infrastructure also leads to poor pedestrian mobility. For instance, the present lack of East-West connections within the Mainland Central area isolates neighbourhoods and restricts the efficient movement of people and goods. A close examination of current improvements in road infrastructure shows that provision for NMT in being neglected. The absence of a comprehensive transport policy in favour of NMT may be responsible for this trend.

4.1.3 Vehicular Emissions in Lagos Metropolis

The urban transport system in Lagos metropolis is a significant source of environmental pollution. In terms of industrial activities and economic development, Lagos is one of the fastest growing megacities in the world (Kotin and Cox, 2013). Over 70% of the industries in Nigeria, consisting more than 7,000 medium and large-scale manufacturing industries are located within the city. Lagos is the most industrialized city in the Economic Community of West African States (ECOWAS) sub-region (Komolafe et al., 2014) and is home to about 60% of total non-oil enterprises in Nigeria. Consequent upon the agglomeration of these industrial infrastructure, Lagos city is the highest consumer of energy, which is predominantly fossil-based, thus making it one of the largest contributors to greenhouse gas emissions.

The industrial profile of Lagos is noteworthy in view of the close relationship between industrial activities and transportation, especially freight transportation. Manufactured goods from the industries and raw materials for production are transported to and from industrial complexes through an inefficient road transport system that involves the use of trucks and heavy-duty vehicles. This method of conveyance, largely due to the poor transportation system and lack of credible alternatives to road transportation, has resulted in more vehicles on the road and greater environmental pollution from diesel engines. According to Lagos Air Quality Monitoring Study (2008) vehicular emission is the major source of pollutants in Lagos, contributing approximately 43% of ambient air pollution. This study also recognizes that vehicles in Lagos contribute to over half of the greenhouse gas emission from the transport sector in the country.

In the past ten years (2001-2009), the number of vehicles in Lagos State has increased to 234% (LAMAMTA, 2014) without commensurate increase in roadways which further compounds congestion in the city. The increasing traffic congestion in Lagos also makes driving conditions more polluting. The two main reasons for this growing congestion is the lack of a good network between the hinterland and ports and inadequate transport planning in new areas. The former leads to freight movement within the city and attendant friction with passenger traffic while the latter complicate commuting trips thereby resulting in the adoption of private transport as an alternative in most cases.

According to LAMATA (2009) over 70% of the vehicle fleet in operation within Lagos are 15 years old or more (see figure 1). Most of these vehicles comprising of cars, buses and trucks, are second-hand imported vehicles that do not meet the emission standards of their countries of origin. Furthermore, the general vehicle maintenance culture is often poor and is usually limited to essential maintenance and repairs to keep the vehicle on the road. Inadequate or non-existent vehicle maintenance result in gradual decline in engine performance, leading to less efficient fuel combustion, thereby increasing emissions.

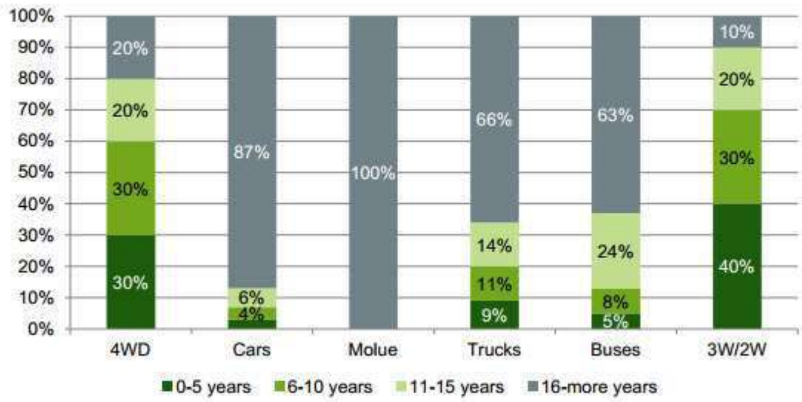

Figure 1: Vehicle classification by age in Lagos
Source: LAMATA, 2009.

These old poorly maintained vehicles are known as "super emitters" which are responsible for about two thirds of the CO_2 emissions in Nigeria coming from transport activity. According to the *Assessment of Emissions from Road Transport (AERT)*, around 85% of the "Lagosian" vehicle fleet works with old engines. A finding of this study is that an average car plying on the roads of Lagos approximately meets the EURO-II emissions standard which was already in place in 1996. EURO-II emissions standard are 3 to 4 times higher than the current standard in the continent.

Vehicle type	Cars		Buses		Euro 2
	New	Used	New	Used	
CO	3.00	14.96	8.07	12.45	3.28
HC	0.006	0.22	0.006	0.17	0.34
NOx	0.07	1.2	0.15	0.36	0.25
CO_2	22.92	165.9	107.9	229.2	130

Table 1: Comparison between emission factors for vehicles using petrol as measured in 2008 and Euro standards (g/km)

4.1.4 Lagos Climate Change Adaptation Strategy

Lagos is not taking the back seat in respect of climate change. The Lagos Climate Change Adaptation Strategy (LAS-CCAS) recognizes multimodal transport - the introduction of mass transport system comprising a combination of bus rapid transit (BRT), rail and water transport services - in Lagos a key measure for climate change mitigation and adaptation (Lagos Strategic Transport Masterplan, 2014).

The rationale for the introduction of multimodal transport is hinged on their larger passenger capacity and lower emission rate than those of private vehicles. As shown in the table below, the private car is the major emitter per passenger-kilometre when compared to other means of transport. The emission levels of motorcycles are close to the Danfos level and more than the BRT, rail transit and bus, the most environmentally efficient modes of transport. The table below further reveals that the BRT is the most efficient of these means of transport, considering emissions per passenger. Private vehicles prove to be high pollutants in comparison with mass transit buses, due to their low occupancy rate. Furthermore, less buses are required to move large populations when compared to private vehicles. Thus, the total emission per passenger in public transport is lower than in private transport.

Additionally, the AERT (2009) proposes that current emission standards are set at Euro 2 (for used vehicles) and Euro 4 (for new vehicle), as well as a series of law enforcement measures concerning inspection, maintenance and certification, including a change in fuel use from diesel/petrol to CNG which will yield substantial environmental benefits from cars and buses. These represent feasible objectives for long-term transport planning in Lagos megacity. AERT recommendations can serve as basis for defining an environmental policy geared towards mitigating environmental impact of transport.

- Transport planning and demand management to implement:
  - Substitution of 20% of cars/SUV (Sports Utility Vehicles with enhanced bus services like BRT.
  - One-way streets
  - Establishment of certification centres for vehicles on emissions
  - Encouragement of Non-Motorized Transport (NMT)
- Promotion of NMT facilities, which could produce a 10% reduction in motorized trips.
- Switching buses to operate with CNG (can reduce the Emission Factor for CO_2 by 28.7%, 30.4% for CO, 0.06% for NO_x and HC and 100% for PM10)
- Limiting the age of second-hand vehicles imported into Nigeria.
- Setting emission standards to EURO-IV to limit emissions from vehicles.

4.2 Travel Behaviour

Five trip characteristics were analysed to present the travel behaviour in Lagos. These include trip frequency, trip purpose, trip mode, trip time and trip length. These are presented to highlight the travel behaviour implication for climate change in Lagos.

4.2.1 Trip Frequency

Analysis of trip frequency in this study covered all purpose trips. Further, “a trip” was defined as a journey made to a destination for a purpose notwithstanding the number of modal interchange. As shown in Table 2, majority of the respondents (97.0%) made at least one trip in a day, while 3.0% made no trip. Those who made just a trip represent just 1.0%. Further, 51.1% of respondents made two trips, 31.3% made three trips, 11.9% made four trips while 2.6% made more than four trips in a day. This implies that apart from the trip originating from homes and home bound trips, respondents usually take an additional trip different from the major trip purpose for the day. Such trips may include shopping, social and religious. The aggregate of all trips made by the respondents was 4565 trips. Thus, the average number of trips made by a respondent per day is 2.6 trips. This is approximately three trips per respondent per day. This figure is like what obtains in other major cities across the world.

Table 2: Trip Frequency

Number of Trips (a)	Frequency (b)	Percentage	Total Trips (a x b)
1	18	1.0	18
2	913	51.1	1826
3	541	30.3	1623
4	213	11.9	852
5	36	2.0	180
6	11	.6	66
No Response	53	3.0	-
Total	1785	100.0	4565

4.2.2 Trip Purpose

Six major trip purposes were identified in this study and they include work, shopping, school, social, religious and others. Others as a trip purpose include those trips made to obtain services like medical, banking, auto repairs and so on. Work and school trips are regarded as non-discretionary trips while others are regarded as discretionary trips. As demonstrated in figure 5.4, 67.0% of respondents made non-discretionary trips (work and school), 30.0% of them made discretionary trips (other types of trips apart from work and school) while only 3.0% of the respondents had no trip purpose since they made neither discretionary nor non-discretionary trips. It is further revealed in figure 6.1 that 56.1% of the respondents made work trips, 7.8% made shopping trips, 10.9% made school trips, 11.4% made social trips, 6.3% made religious trips and 4.4% made other trips. This implies that majority of the respondents made non-discretionary trips than discretionary trips.

4.2.3 Trip Mode

This study reveals that different modes of road transport were used by the respondents for all the trips recorded. Table 3 shows that 97.0% of respondents used one mode or the other for their daily trips while just 3.0% made no trip during this study. Further, the table revealed that car and bus were dominantly used by respondents for their various trips, 44.0% of respondents used car while 33.2% used bus. It is further revealed that 6.7% and 7.7% of respondents used walk and motorcycles/3wheelers respectively for their daily trips. Only 3.9% and 1.5% of the respondents used taxi and the newly introduced bus rapid transit respectively. The use of rail by respondents was low as less than 1.0% used the mode. These results suggest that car and bus are the two major modes of travel in Lagos. The implication of this is that the proportion of respondents who rely on public transport (motorcycles, 3-wheelers, taxi, bus and rail) for their daily trips (46.4%) is almost the same with those who rely on private transport (44.0%). The predominance of low occupancy vehicles (car and bus) and near absence mass transit (bus and rail) in Lagos are pre-conditions for traffic congestion.

Table 3: Trip Mode

Trip Mode	Frequency	Percentage
Walk	119	6.7
Motorcycle/3 wheelers	136	7.7
Car	786	44.0
Taxi	70	3.9
Bus (Danfo/Molue)	593	33.2
Bus Rapid Transit	26	1.5
Rail	1	.1
No Response	53	3.0
Total	1785	100.0

4.2.4 Trip Time

Analysis of trip time of respondents as shown in Table 4 revealed that majority (65.9%) of respondents made trips that were lesser than one hour while 31.2% of respondents made trips of one hour and above. Further, the table 20.0% made trips of between 1 – 2 hours. Respondents whose trip time was above 2 hours represent 11.2%. As earlier observed, 3.0% of respondents had no response. Consequently, the mean trip time for this study was 1.86 hour. This suggests that majority of households in Lagos spend relatively long time in traffic for most of their daily trips. Thus, this becomes a major travel challenge in Lagos and many other large cities where urban travel is undertaken by low occupancy vehicles.

Table 4: Trip Time of Respondents

Trip Time	Frequency	Percentage
<1Hr	1176	65.9
1-2Hrs	357	20.0
2-3Hrs	96	5.4
>3Hrs	103	5.8
No Response	53	3.0
Total	1785	100.0

4.2.5 Trip Length

As shown in Table 5, 47.5% of respondents made trips lesser than 5km. Further, the table revealed that 18.3% made trips of between 5 -10km. Those who covered between 11-20km and above 20km represent 15.7% and 15.6% of respondents respectively. Thus, 49.6% of respondents travel above 5km on daily basis. The mean trip length from this analysis is 3.8km per person per day. This suggests a fairly-short trip length among residents although about 31% travel above 10km per day.

Table 5: Trip Length

Trip Length	**Frequency**	**Percentage**
<5km	847	47.5
5-10km	326	18.3
11-20km	280	15.7
>20km	279	15.6
No Response	53	3.0
Total	**1785**	**100.0**

5.0 Conclusion

This study has examined the character of transport system and travel behaviour in Lagos and concludes that Lagos is still far from being a cool city and may take a relatively long time to become one. This is because the socio-economic development of the rapidly growing city with a current population of about 20 million is driven by road-based transport. Public transport system in the city is dominated by informal services. Organised public transport system is relatively young and very limited in network.

Vehicle population has increased by 234% in the last 10 years and over 70% of the vehicle fleet in operation are 15 years old or more, thus, the transport system in Lagos metropolis is a significant source of environmental pollution. This situation is worsened by the fact that over 70% of the industries in Nigeria are located within the city. Analysis of residents' travel behaviour reveals unsustainable travel pattern as more than 90% of daily trips is road based, average trip time is approximately 2 hours over an average trip length of 10km suggesting a high level of road congestion. Massive transport infrastructure is ongoing, but still largely road based. Development of rail transport is rather slow compared to the travel demand in Lagos.

The government is conscious of the climate change implication of the existing transport system and travel pattern and has made efforts to develop *The Lagos Climate Change Adaptation Strategy (LAS-CCAS)* which recognizes multimodal transport as a key measure for climate change mitigation and adaptation. The multimodal system will be mass transit driven (bus and rail). Other climate change adaptation strategies include setting current emission standards at Euro 2 (for used vehicles) and Euro 4 (for new vehicle), as well as a series of law enforcement measures concerning inspection, maintenance and certification and promotion of NMT. A major concern in all of this is the slow pace of policy and plan implementation. For Lagos to become a cool city, it is important that a workable transport policy is legislated with a strong political will to implement the strategic transport master plan. There is also the need to professionalize the transport sector for capacity building. There is the need to change the transport orientation of the people towards NMT.

Challenges and Best Practices for the planning of Zero Emission Neighborhoods and Smart Energy Communities – the case of seven Norwegian cities

Daniela BAER[1], Brita NIELSEN[2]

SINTEF [1], Norway
NTNU [2], Norway

Abstract

Designing more sustainable neighborhoods as implemented in the concept of Zero Emission Neighborhoods (ZENs) and Smart Energy Communities (SECs) is a complex challenge and requires a leap from segmented planning approaches to holistic planning. Seven neighborhoods in Norway are currently under planning and development into a ZEN/SEC and used as cases in this paper to extract the significant barriers to the design and implementation process of sustainable development. After presenting the main challenges on a general level, we will focus on stakeholder collaboration as this is pointed out as one of the key challenges in our research. We will show how Norwegian cities cope with challenges within stakeholder collaboration and present best practice solutions from the case cities.

However, the findings show, that the sustainability of the neighborhood requires tools that can encourage also the integration of spatial qualities and sequencing to ensure sustainable behavior as well as an early and ongoing collaboration with stakeholders. A participatory approach with municipalities, utilities and private developers was taken to suggest a solution to this. The paper will end with the presentation of a planning tool, the SEC Planning Wheel with a Core of Community (CofC) Fund mechanism, which aims to be a guideline for city planners to induce stakeholder collaboration and thereby aiming to maximize the emission reduction while ensuring social and economically livable cities.

Key Words

Urban planning, Urban governance, Sustainable Urban Neighborhood, Integrated Planning, Low Carbon Society, Smart Cities, Integrated Project Delivery

1. INTRODUCTION

To develop cities with a lower carbon footprint is a development goal all over the world. The building stock is thereby counting for one third of climate gas emission and 50% of energy consumption. In the last decades in Norway, a strong research evidence and building examples were achieved on the way to reach the ambition of Zero Emission Buildings (ZEB). ZEBs are compensating CO2 emissions with energy generation over their lifetime. Today, the

ZEN[1] concept moves this way of thinking beyond buildings. Successful planning for ZEN needs to consider not only energy and emissions, but also needs to incorporate the interests and ideas of a broad number of "new" stakeholders like e.g. utility companies from the early planning stage. Based on observation and interviews, this paper will present the main challenges identified when planning for Zero Emission Neighborhoods in the seven Norwegian cities and towns Oslo, Bergen, Trondheim, Bodø, Steinkjer, Evenstad and Elverum. Each of these cities is planning for or already developing a ZEN and all of them are partners within the Research Center for ZEN at the Norwegian University of Science and Technology (NTNU)[i].

2. BACKGROUND ABOUT ZEN AND SECS

Historically, ambitious neighborhoods were the art of the architects, building Functional Cities in line with the Athens Charter. Today, the planning of urban neighborhoods depend upon the facilitation of multi-stakeholder processes (Maggioni et al., 2012, Ouhajjou et al., 2017) and negotiation (Monstadt, 2007). Situations of give and take, where researchers, private developers, utility companies, transport administration, municipal planners and citizens have to contribute to make environmentally, socially and economically sustainable living areas.

The Smart Energy Community (SEC) concept was developed as a response to Bergen and Oslo wanting to become pilot cities for the purpose of developing and accessing better tools for the design of emission reducing communities. Two building projects, Zero Village Bergen and Furuset in Oslo, were starting points for this research and the following definition of a SEC was created within the PI-SEC project[2]: While Zero Emission Neighborhoods are still in the development of a concluding definition from NTNU,

'A Smart Energy Community (SEC) is an area of buildings; infrastructure and citizens sharing planned societal services, where environmental targets are reached through the integration of energy aspects into planning and implementation. The Smart Energy Community aims to lower dependency on fossil fuels by becoming highly energy efficient and increasingly powered by renewable and local energy sources. Its spatial planning and localization considers reduction of carbon emissions also through its relationship with the larger region, both through the design of energy systems and by including sustainable mobility aspects of the larger region. It further encourages sustainable behavior through its overall design from building and citizen scale to community scale. The application of open information flow, a large degree of communication between different stakeholders and smart technology are central means to meet these objectives' (Nielsen et al.). The concept of ZEN is widening the definition of SEC by taking not only emissions into consideration which are produced within the operation of the neighborhood, but as well emissions which are produced while planning and constructing the area, as well as embodied emissions (Wiik et al., 2018).

In earlier research, we have identified 10 challenges on the way to ZEN within the seven case areas in Norway (Andresen et al. 2017):

1. Stakeholder collaboration and project management
2. Lack of knowledge
3. Legislation
4. Goal conflicts

[1] The ZEN Research Centre is a research centre for environmentally friendly energy [forskningssenter for miljøvennlig energy]. It was established in 2017 by the Research Council of Norway. The ZEN Research Centre is hosted by the Norwegian University of Science and Technology and organized as a joint NTNU/SINTEF unit. More information in english available on https://fmezen.no/.

[2] The Planning Instruments for Smart Energy Communities (PI-SEC) is a research project funded by the Norwegian Research Council, spanning from 2016 to 2019. See https://www.ntnu.edu/smartcities/pi-sec

5. Time and cost pressure
6. New energy technologies
7. System boundaries
8. Risks and uncertainties
9. Flexibility
10. Transferability

There is a strong believe among stakeholders in the case areas that technological solutions will enable the development of ZEN. But the collaboration of multiple stakeholders within the development process is highlighted as the one of the main challenges as well as enablers for a successful development. Planning for energy and emission reduction and developing ZEN is a multi-stakeholder challenge with new stakeholders on the agenda and the need for new planning and design approaches.

2.3 Challenges related to stakeholder Collaboration

Stakeholders are defined as any individuals, groups or organizations from different disciplines and with different needs, responsibilities, and resources who affect the project, or are affected by it, or exhibit an interest in it.

Designing energy ambitious areas depend upon stakeholder collaboration where all stakeholders need to commit and contribute more than 'business as usual'. While the ambition level is increased by the high environmental commitments following the Paris agreement, (Agreement, 2015, Hulme, 2016), stakeholder collaboration and the relationship between private and public actors are old topics in urban planning(Huxham, 1996, Abdulgader and Aina, 1970). The liberalization of utilities revitalized the need to better governing of private and public stakeholders(Monstadt, 2007), and the emission reduction agenda increased the need for better practices and policies even further. The climate emission reduction depend on the success of integrating energy into urban planning, meaning that collaboration may be the 'win or lose' aspect of the entire vision. (McCormick et al., 2013) The initial reason for the frustration [about stakeholder collaboration] seems to be the separated design and construction, or disintegration of the construction project process in general(Lahdenperä, 2012)" Further, the "low bid syndrome can be recognized as a major determinant behind the customary adversarial behaviour [of stakeholders](Lahdenperä, 2012).

An important aspect is that governance and planning are identified as the key leverage points for transformative change(McCormick et al., 2013), yet neither are simple key points to address and change quickly in the right direction.

In this paper, we contribute to this discussion by looking for cross-sectoral stakeholder-collaboration related challenges in seven real neighborhood cases; finding the most pressing issues that need to be adressed in order to achieve the transformative change in governance and urban planning.

3. CASES

Seven Norwegian neighborhood developments are dedicated to be developed as a ZEN and are participating as pilot projects within the ZEN center at Norwegian University of Science and Technology (NTNU). The cities of Bergen and Oslo are similarly participating within the PI-SEC project. The pilot projects are innovation hubs for co-creation between researchers and building professionals, property developers, municipalities, energy companies, building owners, and users. As urban living labs they shall help to verify, document and optimize the real-life performance of the solutions developed. They will also be lighthouse projects to learn, inspire, and disseminate ZEN-related knowledge.

The seven neighborhood developments varies regarding size, functionalities, time frame and some are green- and brownfield development as others are existing neighborhoods. The most common project owner of the neighborhood developments are the municipalities and only the Zero Village Bergen (ZVB) project has a private developer as project owner. The neighborhood projects in Elverum, Bergen, Bodø, Trondheim and Steinkjer are transforming former brown- or greenfields or areas in use for other purpose as an airport or commercial area into a ZEN. The pilots are developed into multifunctional sub centers in Oslo and Trondheim and to a multifunctional area in Bodø. The pilots in Elverum, Bergen and Steinkjer will be developed as residential areas with public services as schools or kindergartens located within the neighborhood. Evenstad is a university campus and the only pilot which is already in the operational phase, meaning that no further construction is planned within the coming years. The focus in this project is the transformation of the energy system. Figure 1 gives a short overview of the seven case study neighborhoods.

	City population (1.1.16)	Project owner	Area size in m^2	Planned/ Current Function	Construction	Status/Phase
Elverum - Ydalir	14 794	Public (Municipality)	430 000	Residential area with school and kindergarten (planned)	New construction, 1 000 dwellings (ca. 100 000 m^2), a school and a kindergarten	Planning
Oslo - Furuset	652 940	Public (Municipality)	870 000	Multi-functional sub centre with 1 400 dwellings and 3 800 inhabitants, 213 100 m^2 (existing)	Retro-fitting/upgrading and new construction, 1 700 – 2300 dwellings and 2 000 – 3400 work places (up to 160000 m^2)	Planning and Construction
Bergen - ZVB	252 772	Private (Developer)	378 000	Residential area with a kindergarten and additional services (planned)	New construction, 720 dwellings (92 000 m^2), a kindergarten and additional service functions	Planning
Trondheim-Sluppen	177 617	Public (Municipality)	275 000	Multifunctional Neighbourhood (existing)	Retro-fitting and new construction	Planning and Construction
Steinkjer – NRK	12 466	Public (Municipality)	11 113	Kindergarten and dwellings (planned)	Re-use and new construction of 10-12 dwellings	Planning
Evenstad - Campus	2 623 (Municipality)	Public (University)	61 000	University Campus (existing)	Building stock in use: 10 000 m^2, no further construction planned	Operation
Bodø - NyBy	40 209	Public (Municipality)	3 400 000	Multifunctional city centre extension with residential and business areas (planned)	Re-use and new construction, 2 800 dwellings in the first construction stage	Planning

Figure 1: The seven pilot projects within the Zen research center at a glance

4. METHOD

39 interviews were undertaken with stakeholders involved in the neighborhood developments in 7 municipalities during 2016-2018. In addition, we conducted six workshops with a participatory design thinking – approach, with municipalities on certain topics. Participants were from municipal planning offices, climate section, regional governors, national road administration, utility companies, private developers, city architects, energy researchers from the case cities, and also international experts from review groups and two international conferences.

The interviews were transcribed and analyzed while the workshop outcome was photographed and discussed in separate reports and papers (Juhasz-Nagy et al., 2017, Nielsen et al., Nielsen et al., 2017). In the analysis for this study we were first looking for stories indicating challenges related to the stakeholder collaboration aspect of planning and implementation of integrated ZENs, and secondly we looked at the same material for strategies or best practice examples meeting these challenges.

4. FINDINGS

During the analysis, we identified four challenges relating to stakeholder collaboration:

1. Achieving multi-stakeholder concept design and commitment;
2. Private/public relationship and responsibilities;
3. System borders in regional and city planning
4. Balancing social and high environmental goals.

We will present each of the challenge with examples from the various pilot projects in the Norwegian cities. For each of the challenge we will also present Best Practice Examples for attempts to solve these challenges, for other projects to learn from.

(1) Achieving multi-stakeholder concepts and commitment

A significant challenge, seen from the municipal planning side, is to achieve a good process that allow for co-design with all relevant stakeholders. This most commonly includes municipality planners and climate section, private developers, real estate, utility companies, and architects. To aim for a climate gas reduction on a neighborhood level, the commitment and participation of multiple stakeholders – including citizens- within the process is crucial. For the construction industry ZEN requires to go beyond the ambitions of current building act requirements, and requires the collection and provision of data regarding emission in building materials and construction processes. Essential facilitators to gain for energy and climate gas reduction like the building industry or energy utilities are often reluctant to gain for more as asked from regulation and law framework.

The case of ZVB included high influence of one private stakeholder on the project development. After planning and designing the neighborhood the regional governor filed a protest with regard to the location of the planned neighborhood. The project is already on hold for 9 years and still waiting for approval. An integrated co-design or dialogue approach with more stakeholders from public and private sector represented, could have been one of the aspects avoiding this situation.

Best Practice Example 1 The dialogue platform 'Forum Sluppen' in Trondheim

In 2015, a dialogue platform was established between the stakeholders in the Sluppen project in Trondheim, called 'Forum Sluppen'. The Forum Sluppen was established as an experiment in the CityLab approach of Trondheim and has been partly funded by the Norwegian Ministry of Local Development and Modernization within the planning program for Norwegian cities above a certain scale. The goal was to test new forms for collaboration between public and private stakeholders in the area.

Trondheim municipality, Sør-Trøndelag county, the National Road Authority and the biggest private landowner R. Kjeldsberg participated in the Forum Sluppen. The project leader is Trondheim municipality. It was also tried to involve other stakeholders. Siemens as industry stakeholder in Sluppen and Koteng, another private landowner in Sluppen, participated only at an early stage.

In 2017, a feasibility study for Sluppen was conducted as a parallel assignment. The reason for doing this as a parallel assignment was that the participants in the Forum Sluppen wanted an open process with a broad academic discussion. NTNU has assisted the work with the feasibility study. The parallel assignment involved three invited interdisciplinary teams with architects and advisory engineers who were selected by the Forum Sluppen members after an open tender competition with 13 providers.

It was important for the participants of the Forum Sluppen to ensure that the selected teams could share experiences during the process and get input from the Forum Sluppen along the way. In the period from March to June 2017 a start-up seminar, a mid-term seminar and a closing presentation meeting was organized to ensure the possibility for discussion. The final presentation meeting in June was also open to the public and around 55 persons participated. The Forum Sluppen evaluated the three proposals. The results are presented within the evaluation report of the feasibility study (Trondheim Kommune et al., 2017).

Trøndelag County (Trøndelag Fylkeskommune, 2018) evaluates the dialogue within the Forum Sluppen as good and especially useful to find common agreements about the objectives and requirements for the feasibility study. The collaboration is described as an open dialogue, characterized by an understanding for the different positions and agendas of the involved stakeholders. The work with the feasibility study has pointed out the difficulties to find a solution in line with the different demands and requirements. The will for cooperation and compromises is described as crucial for an integrated and long-term solution for land-use in Sluppen, the implementation phase and financing. The cooperation in the Forum Sluppen enabled the participants to understand the demand for compromises and to set the development in Sluppen within a long-term perspective. It also helped to build up a better understanding for each other and the development of common goals.

(2) Private/public relationship and responsibilities

As utilities are privatized, municipalities more often than before play the role as negotiators rather than managers of urban planning. In highly ambitious emission reducing projects, we see a shift from public sector responsibility for social needs at the beginning of a project, and technically advanced dialogues between private stakeholders once the implementation start. This is perhaps nothing new, but the advanced technical innovation taking place is dependent on technical tools such as energy simulations and heat exchange and storage; being both expensive, sector dependent and with little relevance to the citizen involvement taking place at the beginning of the planning process. This makes it seem as if the citizen needs is an accountability issue for private sector, while private sector to a decreasing degree shares this responsibility. Also, public stakeholders see themselves as responsible for "pushing" the environment agenda while project developers in general stick to the minimum standard – which still is perceived as environmentally innovative (TEK 17[3]) by the industry. The private sector on their side believes public sector locally and nationally do not respond to the need for capacity building, both within the building sector and in the municipality.

An argument from several municipalities is that there is a need for a better coordination unit, facilitating innovation in the direction of environment, climate and energy, that can work across the municipal organization. In Furuset, the Futurebuilt programme was one such example,

[3] Regulations on technical requirements for construction works, for English translation: https://dibk.no/byggereglene/Building-Regulations-in-English/

created to develop environmentally ambitious architecture in the Oslo region, has been the coordinating body ensuring stakeholder collaboration particularly within the municipal organization. Despite a thorough citizen-involvement phase and strongly documented citizen needs, the timeline from citizen involvement to implementation has been lengthy. Also, the lack of investment interest in the area has been a significant barrier. The area is seen by public media as 'challenged' with a high immigrant population and low housing prices ((Rosten, 2012, Dyb et al., 2011)). As public sector is spending more than usual on low-emission buildings on municipal land, what the urban planners refer to as "the Core of the Community" (CofC) is difficult to finance. The CofC are in this case the spatial qualities combined with the citizen behavior aspects related to energy use and spatial planning in the Furuset neighborhood. The CofC is to include a public square, the upgrading of a shopping mall and community house, a park, a green axis, all centered around a public transport hub with metro access; also containing charging stations for electric vehicles. This core is seen as key to make sure the inhabitants use the neighborhood in a sustainable way and that they participate in the community; something that again affects the need for safety and security that was identified in the citizen participation at the beginning of the project.

Best Practice Example 2 Masterplan Development in Ydalir, Elverum

One measure approved in the Ydalir project in Elverum to facilitate an early dialogue between stakeholders was the development of a Masterplan for Ydalir in a collaboration between the project owner and the other involved stakeholders. The masterplan of Ydalir provides general goals and requirements for the neighbourhood development regarding design and technical solutions to aim for a ZEN (ETS 2017).

Five workshops over the period of 6 months were held on the key element for stakeholder collaboration in the development of the Masterplan. Each workshop was dedicated to different aspects of the project development. These included different topics such as aims and vision, energy, building and infrastructure, user and quality aspects, and transportation. These workshops were concluded with a summarizing workshop in April 2017 and the results of these workshops influenced the Masterplan for Ydalir, which was completed in 2018. The Masterplan development, including the workshops, were partly funded by Enova – a public owned company providing funding to develop and implement innovative solutions for energy and climate gas reduction in building or neighborhood developments and the energy system - and facilitated by the consultant agency Asplan Viak.

The project owner, the land development agency of Elverum (ETS), stated that they "deliberately invited a bit wide" to the 5 workshops to integrate as many stakeholders as possible in the masterplan development. The interview partners, who participated at the workshops, described the process as fruitful and important to develop a common understanding for the project and the ambitions related to ZEN. The workshops gave the arena to discuss challenges and integrated solutions for the development of ZEN. One challenge discussed at the workshop was e.g. the difficulties to integrate the energy system, the district heating system, into the design of the buildings and install the energy system correctly. As a result of that, a guideline for the implementation of the heating system will be developed under the guidance of the utility company Eidsiva and with the help of researchers from the ZEN center.

Another example of a new collaboration between stakeholders involved in the Ydalir project is the walk- and cycle pathway that will tie Ydalir to the center of Elverum. This will be built in cooperation between the municipality and the utility company Eidsiva, as Eidsiva must nevertheless dig up a channel to offer district heating to the district. The pathway was originally an idea from the local architectural office Plan1, and with the opportunity to gather stakeholders and their good ideas, the way could be realized. Creating an attractive walking and cycling network is part of the core of community concept within the Ydalir project. In this case parts of it were realized as a public-privatepartnership.

(3) System borders in regional and city planning and infrastructure planning

During planning and implementation of concepts that include an integration of mobility, behavior, energy in buildings and attractiveness, design is challenged by the misalignment of decisions on different system level. In the Bergen case, the regional governor stopped the project entirely due to conflict with urban sprawl regulations that came in place after the project had been politically approved by the previous government. In Furuset, the National Road Administration did not agree with the municipality's plan of adding space and attractiveness through a highway lid. The Regional Governor [Fylkesmann] has overturning authority regarding health and environment while the National Road Administration focuses on cost and safety. Large road infrastructure plans are made by the National Road Administration, working on different time schedule but with more authority than local municipalities. Further, national decision makers can make stricter decisions on things like urban sprawl or traffic limiting policies. While private developers mainly involve collaboration with local municipality, maximizing the emission reduction potential of neigbourhoods depend upon the ability to cross traditional system borders.

Best Practice Example 3: Cooperation contract on transport in Bodø

Regarding transportation planning, a cooperation contract 'smart transport' was signed for Bodø in February 2018 between stakeholders from national level (National Road Authority, Norwegian Railway Directorate, Coastal Administration and the aviation company Avinor AS), regional level (Nordland county) and Bodø municipality. This cooperation shall guarantee that national investments in transportation infrastructure in Bodø is aligned with goals for city development on a local level. This agreement will mostly account for the ZEN development of the "New City – New Airport" project, which is the biggest city development project for the coming 80 years and including the construction of a new airport. The alignment is important as the national investments for the airport and road system are made in an early phase of the neighbourhood development, while the urban development with residential and commercial buildings of the vacant land will follow at a later stage.

(4) Balancing social and high environmental goals

When conducting the interviews in the different pilot projects, stakeholders involved could be divided into two groups. One group, enthusiastic to reach for high environmental goals and seeing this as chance for innovation and better performance of their own organization and the other group being more reluctant and skeptical. Among stakeholders from this group, a ZEN development is often perceived as implementing an additional burden, by making the development more expensive and time consuming as well as being not congruent to social development goals. In this context interview partners often mention that first of all - and before ZEN - they want to develop "a good place to live" Steinkjer. The Steinkjer case has showed how resistant the future users of the ZEN development are against the concept of ZEN. ZEN was perceived as an additional burden to an already delayed and difficult project development. Future user resistance against the re-use of existing buildings – a main concept within ZEN – stopped the further development of the neighborhood as ZEN pilot project.

On the other hand, the "enthusiastic" group also pointed out this problem but emphasized the importance to develop the neighborhood in balance with environmental and social development goals. The idea "You have to give something while you take something" (give an take-concept) was mentioned from several interview partners, meaning to develop an understanding for where to cut down perceived comfort while improving services and usability at another part. The above-mentioned example of the cycle pathway in Ydalir as god example for that. While cutting down parking spaces within the Ydalir neighborhood, the cycle network and connectivity to surrounding areas will be improved.

Best Practice Example 4: Branding strategy in Ydalir

To develop a vision for the neighborhood based on future citizens demands and ideas, a branding strategy was developed at the beginning of the planning phase in Ydalir. A workshop was conducted with participants from ETS, local politicians, members of the administration of the municipality, and participants of the focused inhabitant groups of Ydalir.

The aim was to identify needs and values of the potential inhabitants regarding the neighborhood development. Representatives from different potential user groups participated at the workshop: citizens who have just moved to Elverum, former citizens of Elverum, which are living abroad and considering moving back as well as older residents living in Elverum. Three values are especially important for the potential inhabitants: close, constant and real. Each of these values was filled with a bundle of ideas how the everyday life shall be in Ydalir.

The values and ideas developed at the workshop were used to develop Ydalir as a brand with an own logo and a marketing strategy. The aim is to promote Ydalir as a sustainable neighborhood which incorporates the future way of living. While creating a positive image and pictures of the future, citizens shall have an affirmative attitude to Ydalir and its ZEN ambitions. They shall get an idea "what they get", instead of focusing on what they could lose. Figure 2 shows example pictures from the branding strategy. People displayed at the marketing pictures are residents from Elverum.

Figure 2. Examples of the logo and marketing visualisations for the Ydalir project, Source: ETS

5. DISCUSSION AND RESULTING TOOL

The previous chapter presented the challenges in the field of stakeholder collaboration within sustainable neighborhood projects. We pointed out- that in the worst case – processes stopped due to objections from individual stakeholder groups as in the Steinkjer and Bergen case. Most of the challenges could be addressed by creating stakeholder collaboration platforms – meeting places - where different stakeholders meet and get the chance to develop a common understanding, goals and solutions for the fulfillment of the high environmental goals of the neighborhood development.

On the other hand, we see that in thematic areas, the integration of social sustainability and spatial planning is the threatened aspects in neighborhoods with high environmental and energy ambitions. This is perceived as a 'goal conflict' among interview partners and thereby not only creates tension between citizens, urban planners, politicians and private developers but most significantly may lead to not intended results as poor living conditions and gentrification . The concept of "give and take" and the 'Core of Community' as a holistic and citizen-centered development concept are responses to this challenge.

But how to deal with these challenges and the good examples we can learn from?

Within several workshops, participants from the Bergen and Oslo case designed a new solution to this imbalance between spatial quality and social sustainability and smart energy communities. They proposed a more stakeholder led version of the planning process, very similar to the integrated project delivery contracts (Lahdenperä, 2012). The Smart Energy Community Planning Wheel (SEC Planning Wheel) was designed through collaborative efforts matched with needs identified in the interviews; and is presented in figure 3.

Figure 3. SEC Planning Wheel, Nielsen et al. 2017

The Smart Energy Community Planning Wheel describes a process in which stakeholder collaboration and citizen inclusion run as parallel priorities from the first step (Step 1 SEC Agreement). This is before a collective agreement is made for the public and private stakeholders to commit to finance the Core of Community as early as possible (Step 2 Core of

Community fund). The idea is that obligation to finance the central elements of the neighborhood development will prevent delays in the implementation. It will lower risk and avoid the situation where "everyone waits for everyone" as happened in Furuset, and overarchingly to increase the sustainability of the neighborhood or community. Ideally, the involved stakeholders suggested that contributing to this fund should lead to a set of incentives (Step 3). Further, participants explained that this would only work when the municipalities would not let other private developers or projects to compete directly with the planned neighborhood development (No Go policy), but prioritize the ones contributing to the CofC. Finally, the learning element particularly needed in the municipal organization, is represented through the need for an evaluation (Step 5).

6. CONCLUSION

Development of neighborhoods with high environmental goals do face a lot of challenges. Some of them are common challenges and could be found in nearly every neighborhood project, as some are distinctive for ZEN and SEC developments. Stakeholder collaboration is one important challenge but meanwhile an enabler for solving challenges in other thematic fields as solving the perceived "goal conflict" by aligning the neighborhood projects with both environmental and social goals.

As these challenges are influential in keeping the silos that we need to think outside to achieve sustainable behavior coupled with technological optimization, we have proposed with the SEC planning wheel a solution in terms of an integrated delivery (Ghassemi and Becerik-Gerber, 2011) orientation. In the planning wheel combining the core of spatial quality and sustainable behavior design with the conceptual development of low-carbon neighborhoods, we place accountability not only for the delivery of buildings, but also for the "Core of Community" – the very aspects that the citizens believe are key to keep the attractiveness of the area.

The SEC wheel is providing an understanding for the planning of neighborhoods with high environmental goals in 5 phases. The presented examples for stakeholder collaboration from the various pilots will be helpful as best practice examples and tools to integrate in the SEC planning wheel. Our future work will therefore focus on the evaluation of the stakeholder collaboration in the pilot projects with special focus on the individual and local context of each pilot project. We do not only need good examples to learn from, but as well an understanding under which circumstances and which context these examples are replicable and a frame to set these best practice cases and tools in a context to each other - the SEC planning wheel.

Windows of Opportunity for Smart City Solutions in the Urban Fabric

Judith Borsboom-van Beurden, NTNU, Norway

Abstract

This paper focuses on the development of a methodology for identifying the windows of opportunity for smart city solutions within the current urban fabric. Advanced ICT and the wealth of urban data offer unprecedented opportunities nowadays for smart urban (re)design, smart operations of urban infrastructures as energy and transport, and for smart interaction with citizens. However, most successful examples of application of smart city solutions come from greenfield developments or comparable situations such as redevelopment locations of substantial size, where the legacy of the past in the form of building characteristics and specific choices for supply of mobility and energy, do not hinder full-scale application of smart city solutions. It is not common practice yet for cities to identify systemically where smart city solutions could be applied within the current urban fabric while planning its management and maintenance. This is a missed opportunity, as the financial flows in management and maintenance programs in the built environment are far larger than investments available for use of innovative solutions in experimental situations of limited size, such as pilots and living labs. Therefore a methodology is needed which identifies local windows of opportunity from spatial and economical perspective. Prospected outcomes of this methodology are citywide hotspot maps and generic business cases at district level. This paper outlines the proposed methodology and describes the next steps in its development.

1 Dynamics in the urban fabric

Each city has to address its current and future challenges being equipped with an urban morphology and with infrastructures designed for the past. In Europe, most cities are defined by a core from medieval or industrialisation time. They have developed subsequently in rings or sectors around this core, depending upon specific physical constraints to construction, transport options, culture, housing and business preferences, social requirements and planning principles. Wegener et al. (1986) describe the temporal characteristics of dominant urban change processes in terms of a stimulus-response scheme, shown in Table 1.

It demonstrates that changes affecting the physical stock of the city have the longest response time and the most long lasting impacts, with small, almost irreversible changes, usually in the range of 1-2% replacements of the existing stock per year (Wegener et al. 1986). What is more, an increasing demand is often fulfilled by adaptation of existing buildings instead of demolition and rebuilding (Grover and Grover, 2013).

Frequently the building stock and urban infrastructures even outlive their economic value for a variety of reasons, such as aesthetical, social or operational motives, which reduce the perceived need for development and substitution, see for instance Zhu and Bostic (2009). Altogether, even in areas with demographic and economic growth where urban change and expansion are significant, overall the pace of change in the urban fabric is often surprisingly low.

Because low or zero energy neighbourhoods and advanced ICT are essential elements in many smart city plans of European origin, critical infrastructures for energy supply, production and distribution, and for ICT should be added to the overview composed by Wegener et al. (1986). Key features to be included in Table 1 describe change process, stock affected, response time, response duration, response level and reversibility of these infrastructures. Most of these infrastructures are characterised by the same slow level of dynamics as buildings and the transport system. For instance, the average lifespan of electricity grids is approximately 45 years, distribution networks for natural gas are used for more than 50 years, heating and cooling networks for 40 to 80 years, and ICT networks 10-25 years.

Level	Change Process	Stock Affected	Response Time (years)	Response Duration (years)	Response Level	Reversibility
1 Slow	industrial construction	industrial buildings	3-5	50-100	low	very low
	residential construction	residential buildings	2-3	60-80	low	low
	transport construction	transport system	5-10	>100	low	nearly irreversible
2 Medium Speed	economic change	employment/ unemployment	2-5	10-20	medium	reversible
	demographic change	population/ households	0-70	0-70	low/high	partly reversible
	technological change	transport equipment	3-5	10-15	medium	very low
3 Fast	labour mobility	workplace occupancy	<1	5-10	high	reversible
	residential mobility	housing occupancy	<1	5-10	high	reversible
	daily mobility	traffic	<1	2-5	high	reversible

Table 1: Urban change processes. Source: Wegener et al. (1986), p. 4

This means that the larger part of the urban building stock, utilities and infrastructures have not been designed for current contexts, lifestyles and technologies, are more often than not, unable to meet current performance standards, for instance in the field of energy savings and production of clean energy.

Therefore, cities are ill equipped to respond to current or future challenges, such as adaptation to and mitigation of climate change, the ever-increasing demand for transportation and the on-going digitisation of our society. While building stock, energy and transport infrastructures, play a dominant role in emission of greenhouse gasses (GHG), the abundance of legacy systems in urban morphology and infrastructures may hamper the transition towards smart and sustainable cities. Thus, in order to meet the Europe wide objectives of at least 20% respectively 40% GHG reduction, a share of more than 20”% respectively 27% of renewable energy sources in energy consumption, and of 20% respectively 27% energy savings compared to 1990 by 2020 and 2030, both building stock and physical infrastructures need to be deeply renovated, adjusted or operated in a fundamentally different way.

Given the slow pace of urban dynamics discussed above, this is not an easy task. For instance, Hajer (2016) describes how, despite the vital role of urban infrastructures in improving resource efficiency, governance of their alteration is highly complex because long periods of cumulative investments have made them static and make changes very costly, not to mention the consequences of interrupted daily use during refurbishment. For that reason, he expects more from using urban infrastructures in a more sustainable way through smart technologies. In the light of the EU's energy roadmap's eventual aim of an 80 to 95% reduction of GHG emissions by 2050, it can be said that the desired transition to a low-carbon economy with low-carbon cities, will take an enormous effort.

This research will focus predominantly on those physical entities in the built environment, which are relevant to implementation of smart city solutions and subject to low levels of change, as shown in the first row in Table 1. For that reason, this table will be complemented with additional information on these objects, for instance energy and ICT infrastructures.

2 Focus on energy efficiency and renewable energy in cities

This paper departs from the EU's perspective on smart cities, where the reduction of GHG emissions in the built environment by application of smart, in particular ICT-based, technologies, plays a dominant role (see section 3). For that reason, it will not go into the wide range of other application domains of smart city technologies, for instance health, environmental quality, inclusiveness and parity of access, and economic competitiveness. While their importance from a societal perspective is clear, this research wants to stay closely aligned to the EU interpretation of the smart cities concept.

Many authors have demonstrated that investments in energy savings and renewable energy systems (RES) can very well have viable business cases, especially when they offer substantial co-benefits; see for instance Gouldson et al. (2018). However, the slow pace of change in the built environment and the lack of a widespread transition to smart sustainable cities (EC Directorate-general for Internal Policies 2014, Loorbach et al. 2016), indicate that the business cases might not yet attractive enough compared to regular investments. This in spite of the prospected size of this market (Gouldson et al., 2015, McKinsey Global Institute, 2018) and the significant potential to reduce GHG emissions. For instance, Hoornweg and Freire (2013) calculated that wide scale deployment of smart city technologies could reduce CO_2 emission by 7.8 gigatonnes, nearly 20% of global emission in that year.

It is clear the local governments can at best only partially bear the full costs of investments of a transition to smart and sustainable cities. This means that for the realisation of their aims, local governments have to rely on strategic allies and co-initiators of plans for smart sustainable cities, such as housing associations, energy suppliers and energy network operators, transport providers, local businesses, tenants and owner-occupiers in housing. Besides, a different governance philosophy is needed where civil society and private parties actively contribute to the realisation of public goods as sustainability (Hajer 2011). So far, urban stakeholders are often insufficiently involved in decision-making, while implementation cannot be forced upon them, and knowledge and creativity of non- governmental parties is insufficiently used. Only by exploiting the potential of an «energetic society» of articulate, creative citizens and by acknowledgement of society's learning abilities, can governments realise public objectives as sustainability (Hajer, 2011).

3 Definition of the Smart Cities concept

There is a wide range of different definitions of smart cities, and thoughts about what constitutes them and makes them smart, see for instance excellent overviews of definitions and concepts by Albino et al. (2015) and Mora et al. (2018). Generally spoken, the smart city concept assumes the emergence of a new layer of urban data and advanced, interoperable, ICT's on top of the traditional physical elements in the built environment, opening up new possibilities for (re)design, operation and use of the built environment, and for interaction

between citizens, or between government and citizens, what can lead to new or better services and new business opportunities.
However, despite increasing popularity of the term smart cities in science and practice, there is no agreement yet on a common accepted definition. Albino et al. (2015) attribute this to the fact that the term smart cities has been applied to both the “hard” domain of urban morphology and its infrastructures, where ICT fundamentally influences the functions of systems, and the “soft” domain of education, social inclusion, culture, innovation and administration, where ICT application is less decisive. Nevertheless, common features of smart cities can be defined, such as a citywide, networked infrastructure enabling political efficiency and social and cultural development, room for business and creativity-led urban development, attention for social aspects of urban development, and the natural environment as key strategic component (Albino et al., 2015).

In their bibliometric analysis of the smart city research field, Mora et al. (2018) found specific thematic clusters, each related to a specific understanding and conceptualisation of smart cities, which is reflected in a particular strategic perspective for smart city development. They observe a distinct European path, where ICT’s are seen as a key factor in improving energy efficiency in the built environment. Thus, smart cities are defined as cities that create the conditions for market acceleration and widespread uptake of energy-efficiency technologies in cities, eventually leading to a transformation of the currently unsustainable energy system (EC, 2009). Contrary to the Ubiquitous, Experimental, Corporate, and Holistic Paths, the European Path does not embrace as many domains as possible, but focuses on the deployment of low-carbon technologies in transport, buildings and energy distribution networks (Mora et al., 2018).

4 Smart cities in Europe

In EC policy, smart city policies are anchored in a number of directives and agreements. At first the Strategic Energy Technology (SET) plan (EC, 2017) and the climate and energy policy objectives for 2020, 2030 and 2050 (EC, 2010a, 2012, 2016b). At second, smart city policies are linked to the Digital Agenda for Europe (EC, 2010b). Lastly, ambitions for low emission mobility and logistics as laid down (EC, 2016a).

Experiences from successful earlier programs, such as CONCERTO and CIVITAS, have been very important for further articulation of EU smart city policies. CONCERTO has proved in 53 pilots that a district-based approach to deep refurbishment and clean energy can deliver more than 50% reduction in energy consumption and GHG emission with a viable business case (EC, 2014). CIVITAS has amply demonstrated the feasibility of sustainable transport solutions. Subsequently, more integrated, cross-domain smart city projects have been part of Framework Program (FP) 9 and Horizon2020 SCC-01. The first generations of these lighthouse projects as Triangulum, SmarterTogether and REMOURBAN, have now successfully implemented plans integrating smart transport, smart buildings and smart infrastructures, usually in a specific district. Common ingredients of most Horizon2020 SCC-01 plans are installation of smart meters, smart thermal and/or power grids, and RES in combination with thermal insulation and deep retrofitting, smart lighting, introduction or extension of car sharing systems, promotion of private and public electric vehicles, Intelligent Transport Systems (ITS) and instalment of urban platforms. The urban platforms connect the different domain subsystems through interoperable ICT and provide new services to both citizen and government, or support co-design and co-creation of solutions to urban challenges (Borsboom-van Beurden et al., *forthcoming*, 2018).

A host of excellent projects, programmes, initiatives and networks has worked on low energy districts and smart cities in the EU, not only the aforementioned CONCERTO, CIVITAS, FP9 and Horizon 2020 projects and programmes, but also networks as C40, ICLEI, Covenant of

Mayors, 100 Resilient Cities, and European Innovation Partnership on Smart Cities and Communities. A learning environment has been created, where knowledge, best practices, and lessons learnt are shared and jointly brought to the next level. Nevertheless, the pace of adoption of new methods and technologies is still too slow to achieve EU goals on energy savings, renewable energy and emission of GHG's for 2030 and particularly for 2050 (EEA, 2015). Not only should new policies be implemented earlier, also should the supply of energy, food, transport and housing be restructured, substantial investments made in RES, smart meters and energy saving appliances be used more widely, high standards set for energy performance of buildings, and alternative fuel vehicles, public and slow modes of transport promoted (EEA, 2015).

While many European cities are embracing the smart city concept, developing smart city strategies and implementing smart city projects, a widespread breakthrough seems not yet to be taking place ((EC Directorate-general for Internal Policies, 2014, McKinsey Global Institute, 2018). A couple of persistent barriers and obstacles result in lengthy planning and implementation phases, or sometimes even in cancellation of smart city and low energy district projects. These barriers and obstacles have been analysed, for instance for CONCERTO programme by Mosannenzadeh et al. (2017), and for smart city projects by consultants as PWC et al. (2016) and McKinsey (2018), and by the Action Cluster Integrated Planning/Policy and Regulations of the European Innovation Partnership on Smart Cities and Communities (Borsboom-van Beurden et al., *forthcoming,* 2018).

The most common barriers are 1) high initial and operational costs of smart city solutions, 2) lack of financing and appropriate business models, 3) siloed governments, 4) lack of technical skills in staff, 5) risk aversion by financial organisations, 6) split incentives, 7) inconsistent government policies, 8) prohibitive legislative frameworks, for instance for pre-commercial procurement, 9) lack of proven solutions and validated examples, and 10) difficulties with engagement of local stakeholders. The latter can be in particular a problem in highly privatised European countries. The multitude of interdependencies existing between urban actors makes it even more complicated to align interests and create a common operational picture, especially when concessions are granted to best-value-for money without sustainability criteria.

What is more, the direct impact of implemented smart city projects can be limited due to their usual "pilot-like" character: more or less singular, tailored to a specific context and situation, with a limited scope, subsidy-dependent, quite small and sometimes lacking a truly holistic perspective. While these complex projects provide invaluable information and lessons learned, and are quintessential for building a learning community, market acceleration of successful technologies, products and methods is lagging behind. A pattern of "islands of smartness" seems to prevail, as Snøhetta director Kjetil Trædal Thorsen labelled it during a panel discussion at Nordic Edge 2017 conference.

5 The need for a systemic citywide scan of windows of opportunities

A couple of reasons have inspired this research to focus on upcoming changes and adjustments in the urban fabric and the investments involved. At first, local governments have insufficient resources to finance full-scale transformation of the built environment and its infrastructures to a smart and sustainable state. At second, the volume of investments by local governments, owners and operators into maintenance and management of buildings and infrastructures, is a multitude of the volume of so-called innovation pilots, and they will happen anyway, so why not make maintenance and management measure vehicles for smart and low energy solutions? At third, lengthy preparation phases can be shortened and success rates of implementation improved if possibilities for smart city solutions are included earlier in policy and decision making processes, for instance because relevant stakeholder are identified and engaged earlier. At fourth, by making pilots part of a larger systematic approach to smart cities and low energy districts, the potential for replication within a municipality's jurisdiction increases. Currently, pilot projects are often more or less incidentally chosen, often more on political than on strategic grounds. By selecting those areas that are highly representative for the city's building stock and urban infrastructures, most in need of adjustment and having the largest potential for improvement, future replication can be fostered.

However, more mundane reasons for transitions to smart and low-carbon cities not taking off could also be in play. Current policy and decision-making processes by key stakeholders in the city might simply overlook possibilities for such investments, especially in very early phases of policy and decision making processes, because they are recognised too late. As these phases contain the seeds of future change, the question is whether smart city solutions would be implemented more widely, if rudimentary information on the potential of smart city solutions would be available during these very early phases. These considerations have led this research to focus explicitly on the pre-phase of actual planning and decision-making, and on the role of information on viable business cases and models for smart city solutions in this pre-phase. It aims to identify which dynamics and changes can be expected in the urban fabric, which stakeholders are involved, and how the opportunities that urban dynamics and changes offer for useful application of smart sustainable city solutions, can be seized by identifying them at a very early stage. In that way, such investments can be made part of novel practices in planning, real estate development and exploitation, and lastly maintenance and management of building stock and urban infrastructures during its lifecycle.

The following sections discuss the different building blocks that could compose a systemic citywide scan of the windows-of-opportunities for introduction of smart city solutions.

6 Potential windows of opportunity made explicit

The term «window of opportunity» is stemming from political sciences, as part of the Multiple Streams Framework (MSF), or Multiple Streams Analysis (MSA), which explains policy changes under multi-actor and multi-level conditions (Kingdon, 1995; Zahariadis, 1999). Three more or less independent streams, that is, a problem stream identifying problems, a policy stream containing ideas about possible solutions, and a politics stream reflecting the "national mood", produce these policy changes together. When there is simultaneously high attention for the problem, a viable solution available and a policymaker motivated and able to select it, a window of opportunity is open for major policy change (Zahariadis, 1999; Cairney and Zahariadis, 2016).

The MSF has been applied at many different scale levels and in other situations than national government agenda-setting studies, with varying degrees of success (see Cairney and Zahriadis, 2016). It is obvious that the multi-actor, multi-sectorial and often multi-level policy and decision-making required to create a smart and sustainable built environment, is endlessly more complicated, and maybe even too complicated, to apply the MSF. Nevertheless, the concept "window of opportunity" offers a powerful metaphor for the unique opportunities, both in space and in time, now and in the future, where policy and decision-making in cities can bent towards more effective sustainable and smart options. Exactly for its metaphorical power, the MSF concept of a "window of opportunity" has been chosen here as point of departure for a systemic, citywide analysis of spatial and temporal possibilities to incorporate smart and sustainable methods and technologies in joint policy and decision-making processes.

As follows from the MSF, one of the conditions for a window of opportunity is the existence of a viable solution, which is known to the initiator of the policy change. One of the reasons for not being on track for the 2030 and 2050 GHG emissions, energy savings and share of renewable energy, might be that strategic windows of opportunities for the introduction of sustainable and smart city solutions are missed, and that business as usual prevails often in practice. Given the incredible slow pace of change regarding vital urban objects as buildings and infrastructures, this is a missed chance. For that reason, it is of paramount importance that viable solutions are known at the very moment that a window of opportunity arises, and preferably even before.

A comprehensive overview of expected dynamics and adjustments at object level in building stock and urban infrastructures reflecting stakeholder’s agenda’s, combined with an overview of relevant smart and sustainable solutions, and a generic business case and exploitation model, will provide policy and decision makers with an evidence base when windows of opportunity are popping up in future.

7 Main changes in the urban fabric identified

Altogether changes in demography, lifestyles, and economy, translate into continuous development and adjustment of urban morphology and urban structures, often quite gradually. Spatial planning puts preconditions to these developments and channels it. It can be expected that the dynamics in cities as described in section 1, will offer many possibilities for implementation of smart low-carbon technologies in cities, by local governments, and strategic allies such as citizens, energy suppliers and transport network operators, and for enablers such as investors. Policy processes might be for instance the implementation of the mandatory Sustainable Urban Mobility Plans (SUMP’s) or the Strategic Energy (and Climate) Action Plans, where local governments commit themselves to in the Covenant of Mayors.

Section 8 summarises the usual actors in integrated planning and management of smart city projects. In order to be able to define the windows of opportunity now and in the future more precisely, this paper distinguishes the main processes of change in the urban morphology and urban infrastructures, and in their operation, which might open up new possibilities for introduction of smart city solutions. Table 2 is a first attempt to make an overview of typical smart city solutions applied in Europe. Table 3 summarises the main processes of change from a holistic perspective, and relates these to specific objects in the built environment and potential windows of opportunity. These tables will be validated and completed later.

Objects	Typical smart city solutions
Residential, buildings; Commercial, social, educational, medical buildings; Industry buildings and installations	Low-, zero- and positive energy construction and refurbishment technologies, installations and appliances, e.g. thermal insulation, passive houses, heat recovery from ventilation; Integration with renewable energy production; Making buildings more intelligent through sensors, actuators and interoperable ICT, smart meters; Creating uni- or bi-directional charging infrastructures for electric vehicles as cars and bikes; Providing collective solutions for energy supply, such as solar plants, geothermal or district heating; Make operation and use of the building smarter, e.g. through sensorised smart lighting; Using clean mobility and logistics solutions to provide transport, e.g. electric vehicles, smart parking, clean “lastymile”yinylogistics,y Applying principles or smart (re)design, integrated planning and implementation at district level, e.g. based on holistic energy and transport designs which have been co-designed with stakeholders; Smart process technology in industry, e.g. allowing re-use of excess heat and by-products as hydro
Infrastructures	Enable smart operation and use of the infrastructures with sensors and actuators, other urban data and ICT, i.e. intelligent transport systems; Make thermal and electric grids smart(er) so they can respond real-time; Enable exchanges, conversion and co-production of energy, e.g. with data centres, or using combined heat power (CHP); Adding sensors and actuators to the physical infrastructures; Organise interoperability between physical infrastructures and buildings through protocols, standards, e.g. Internet of Things, Internet of Everything; Organise smart operations, smart (re)design and improved/novel services to citizens through urban platforms

Table 2: Typical smart city solutions applied to urban morphology and urban infrastructures

At this stage of the research, specific windows of opportunity are not yet linked to specific smart city solutions, appropriate for that situation. These linkages will be made explicit later.

Change processes	**Objects**	**Potential windows of opportunity** if decisions are taken on:
Construction: large scale development *of* new objects on greenfields or comparable tabula rasa, e.g. obsolete harbour areas, or large scale demolition and substitution by similar object(s) with similar function at district level		
Development or substitution of housing and social, educational and medical facilities Development or substitution of offices and business parks Development or substitution of industrial buildings	Residential buildings; Commercial, social, educational, medical buildings; Industry buildings including installations	Densities, land use, form, mobility and logistics; Design of buildings (i.e. building envelope, use of materials, construction technologies, design of installations and choice for appliances, energy performance of the building, (re-)use of resources and circularity) Design of energy supply for electricity, heating and cooling to buildings and district (individual and/or collective systems, central or decentral solutions, exchange of energy between buildings and electric vehicles, use of excess heat and cold, recovery of heat and electricity) Design of provision of other utilities to buildings and districts ((hot)water, sewage and waste treatment and collection, ICT connectivity), process technology Business cases; use and operation, contracting future maintenance and management, facilities and asset management
Construction of new roads; new (light)rail; new utilities such as sewage; new energy networks and distributions grids; ICT connectivity	Infrastructures for transport, energy supply and distribution, utilities, ICT	Selection of design and construction technologies; Standards regarding (re-)use and circularity of resources, e.g. waste treatment; Desired level of energy performance, i.e. of lighting, of equipment and installations Operation of the infrastructures and business cases Desired level of intelligence in infrastructure Integration of infrastructures through ICT
Upgrading, updating and periodical maintenance: original objects adjusted and upgraded to meet new needs and standards		
Refurbishment, upgrading and adjustment of existing buildings and their installations (thermal insulation, , different degrees: can be minor or major adjustments	Residential, commercial, social, educational, medical buildings	25-30 year deep refurbishment cycles and updating to current living standards Proposed changes to building envelope, i.e. thermal insulation Renovation, replacement and upgrading of installations and appliances to up-to-date technical and legal standards, i.e. energy saving solar boilers or smart meters and sensors, or new EPBD Improvement of energy efficiency of building and district, e.g. through recovery or exchange of heat Extensions of the building Transformation into other, more profitable or useful functions, e.g. redundant office space to housing
Renovation, upgrading and adjustment of networks and utilities; also major and minor adjustments	Infrastructures for transport, energy supply and distribution, utilities, ICT	Improvement and rationalisation of management by adding sensors and actuators to the infrastructure; Improving the performance and robustness of infrastructures, e.g. upgrading district heating networks to multi-commodity grids Development of new services and business opportunities on urban platforms connecting and integrating information on infrastructures and buildings;
Demolition, out phasing and possibly replacement of redundant buildings and infrastructures after the end of their life-cycle, often substitution by newly constructed object(s), probably with another function,		
Stepwise, small-scale replacement and redevelopment of buildings in the urban fabric	Residential, commercial, social, educational, medical buildings	Legal requirements and fulfilment of policy obligations, aiming to improve liveability, sustainability, health, comfort, or affordability for residents Problems in use and operation of the building due to outdated installations and appliances, e.g. sick building syndrome Building(s) no longer in demand, changed preferences or needs of customers Economic and financial reasons, profitability of substitution and redevelopment
Phasing out and replacement of existing infrastructures,	Infrastructures for transport, energy supply and distribution, utilities, ICT	Legal changes, e.g. motivated by sustainability, safety or affordability reasons, which induce exploration of alternatives, e.g. for instance substitution of natural gas networks by all-electric or going off-grid by decentral energy supply Economic and financial reasons, profitability of substitution and redevelopment Changes in procurement and licenses to operate Infrastructures no longer in demand, e.g. due to new technologies or lifestyles, e.g. promotion of walking and cycling, or public car sharing replacing own car

Table 3: Overview of main changes in urban fabric in relation to windows-of-opportunity

8 Relevant actors

Nearly all smart city projects are founded upon collaboration in the triple or quadruple helix of local administrations, knowledge institutes, industry and citizens. This means involvement of relevant stakeholders and governance play a dominant role in the successful implementation of any smart city project. The complexity of most smart city projects means that many stakeholders need to be involved, and the fact that many interdependencies exist between these stakeholders, implies that a large variety of interests have to be aligned (Nijman, 2014). Figure 1 depicts a non-exhaustive overview of common stakeholders.

9 Contours of a methodology

The key objective of this research is to develop a methodology for identifying the windows of opportunity in districts and cities for the most common smart city solutions on a systemic and long-term basis, inclusive financial aspects, which deliver best value for money and can be easily coupled to investments that are planned anyway. Such a systemic scan during very early, explorative phases of policy and decision-making, will enable local governments, their strategic allies and their enablers, to better exploit specific dynamics and developments as vehicles for bringing about an urban transition towards smart and sustainable cities. The proposed methodology combines elements derived from four methods:

- *Geo-ICT and geodesign*: central to the proposed methodology are spatial data representing the building stock and urban infrastructures. With geo-ICT possible windows of opportunity in future are made spatially explicit, for instance by creating maps of hotspots. In addition, current representation, collaboration and visualization features of Geo-ICT can support transition management by providing detailed information on buildings and infrastructures, by showing interests and positions of different actors and owners, and by showing the possible impact of specific solutions. Geodesign, "*an iterative design and planning method whereby an emerging solution is influenced by (scientific) geospatial knowledge*,… *integrates the exploration of ideas with direct evaluation in the same moment, generating an advanced design solution"* (Lee et al., 2014), will be used as a method during stakeholder workshops.

- *Transition management:* this governance approach is increasingly applied in cities and aims at "*1) Bringing together frontrunners from policy, science, business, and society to develop shared understandings of complex transition challenges; 2) developing collective transition visions and strategies; and 3) experimentally implementing strategic social innovations"* (Wittmayer and Loorbach, 2016). Elements from the transition framework will be borrowed and used in an adjusted form to create a joint appreciation and understanding of urban challenges, and to develop a joint strategy how to address these challenges.
- *Impact assessment:* standard methods and protocols for impact assessment, for example from Societal Cost-Benefit-Analysis, will be applied to analyse not only the spatial impact of expected dynamics on building stock and infrastructures, but also the impact of smart city solutions at GHG emission, share of renewable energy, energy savings, reduced use of fossil fuels and potential co-benefits.
- *Value chains*: standards methods for value capturing will be applied for drafting business cases and value propositions at district level for technically feasible smart city solutions. See for instance Brouwer (2017) for methods to assess the financial aspects of future-resilient and sustainable urban development.

The methodology will eventually support the following stages:

Snapshot	• Define area (street, neighbourhood, district, village or city) • Collect spatial data on objects in the urban fabric (land, buildings, infrastructures for energy, transport, utilities and ICT, other relevant physical objects) • Collect attribute data on ownership, operational and legal responsibilities, and use per object
Dynamics & investments	• Draft list of transport and urban planning interventions by local/regional authorities • Draft list of regular and foreseen refurbishments and adjustments by owners and operators of physical objects as buildings and urban infrastructures • Make timeline of interventions, and expected refurbishments and adjustments • Chart spatial impact of this on physical objects and map corresponding stakeholders (owners, operators, users) • Estimate the value of planned and expected investments per object • Visualise dynamics and investments in GIS «Dynamics» and «Investments» layers • Draft timeline for urban dynamics and investments • Identify hotspots where robust opportunities occur in future, rank these • Validate hotspots and ranking with experts and strategic allies, which most-promising?
Windows of opportunity	• Draft list of applicable smart city solutions given foreseen dynamics and ajustments • Assess suitability, technical and economic feasibility and potential impact of smart city solutions for objects, select most-promising options with owners, operators, users • Visualise high-feasibility, high-impact solutions in GIS in «Feasibility» and «Impact» layers • Create combination map by overlaying «Dynamics», «Investments», «Feasibility» and «Impact» layers, flag objects with high scores • Map these «spatialised» upcoming windows of opportunity on the timeline
Negotiations and financing	• Share outcomes with strategic allies and key enablers, select most-promising solutions • Develop roadmap for integrated planning and implementation • Engage stakeholders, analyse appropriate financial schemes, PPP's, start negotiations

Figure 2: Proposed methodology for a systemic, city-wide scan of windows of opportunities for smart city solutions

Not all stakeholders included in Figure 1 will be end-users of the envisaged systemic, citywide scan. Nevertheless, it is possible to identify some key actors as potential end-users:

- Those who have specific responsibilities in the built environment as *municipalities and regional authorities, r*esponsible for public goods as accessibility, and environmental and spatial quality. They give permission for changes to buildings and infrastructures. Municipality-owned housing associations also belong to this category;
- Stakeholders that are responsible for *operation, management and maintenance of urban buildings and infrastructures*, such as local energy producers, transport operators, non-municipal road authorities, and utility providers. These stakeholders might be public or private, as provision of basic needs as water and electricity to inhabitants and local businesses is organised very differently per country;
- *Owners of land, buildings and urban infrastructures*. Not only can they initiate planning and implementation of smart city solutions themselves, they have to agree on the plans when proposed by others, and possibly share the financial burden of implementation. This category is very heterogeneous, depending upon planning system and culture, and can range from pension funds owning rental housing to housing cooperatives and farmers still owning plots of land in the city. Residential owner-occupiers can be a difficult category to convince if the plan does not fit their own interests and ambitions, or just does not suit their timeline.
- *Users of the built environment*, who come in many forms, making the “citizens” a difficult group to define: tenants, who often are required by law to approve of plans, local businesses and their staff, commuters, visitors and tourists.
- Those who have ensured *financing*, such as investors, banks who gave loans, private equity, and want to secure the profitability of their current and future investments.

10 Conclusions and next steps

Transitions to low-carbon cities are hampered and delayed by costs, uncertainties and risks, sunken costs, path dependencies and legacies, and non-aligned stakeholders. The possibilities to smartify cities by making investments in a different way through alignment with planned and upcoming adjustments and interventions is enormous. This paper proposes a geodesign based methodology, which scans the possibilities for deployment of smart city solutions at a very early stage. This helps to take better decisions far in advance. Further development of the methodology will take place with the following steps:

1. Desk research on expected dynamics and adjustments to the urban fabric during the lifecycle of its physical objects in the case study areas;
2. Interviews with the aim of collecting more information on how are decision making is prepared in different change processes by local governments and their strategic allies, in particular during very early phases. In addition, interviewees will be asked to reflect on the design of the methodology and potential end-users. This input will be used to extend Wegener’s table with buildings and infrastructures relevant for smart city solutions and to adjust the proposed methodology;
3. Selection of three to four cases across Europe, representing different geographies, planning cultures, city sizes, governance models, and local challenges;
4. Working out the methodology as depicted in Figure 2 for every case;
5. Testing of the methodology in workshops with stakeholders in the case study areas;
6. Evaluation of the outcomes together with local governments and key stakeholders and refinement of the methodology.

Planning issues of wind farms siting in Russian Federation

Dmitry BOYKO, GeoClever, Russia
Valeriya PATUEVA, GeoClever, Russia

1. Introduction

Russia as a country with the largest territory in the world and one of the longest coastlines has enough suitable locations for siting onshore, nearshore and off-shore wind farms. Wind power potential of Russia is estimated at 16'500 TW.h/year [1]. Although these opportunities do exist, the Russian Federation is strongly bound to fossil fuels both in the internal economic development and in import-export balances.
Despite huge wind resources and governmental support, national plans for wind energy are modest. Based on the National Energy Strategy of Russia till 2035 and current trends, the International Renewable Energy Agency (IRENA) [2] predicts up to 5% of total energy demand to be covered by renewable sources, the installed capacity of solar power plants by 2030 – to be only 2.7 GW, and wind power stations – 5 GW. For comparison, US government reports estimate wind power to contribute up to 20% of national electricity supply by 2030 [3]. WindEurope's Central Scenario assumes to get a 30% share of EU's power demand from wind power [4].
At the same time, the Russian Federation is considered to be one of the world's leaders in carbon dioxide emission with 5% share in 2014 [5]. Even so, Paris agreements, calling for 25% to 30% emission reductions below 1990 levels by 2030, were not ratified by Russia [6].
This article discusses the constraints on the way to provide better conditions for wind farms' construction, looking for necessary improvements in Russian national policy, planning system and land use operational mechanism.

2. National context

2.1 Wind resources

Starkov et al. (2000) developed Russian Wind Atlas, where wind energy resources are studied.

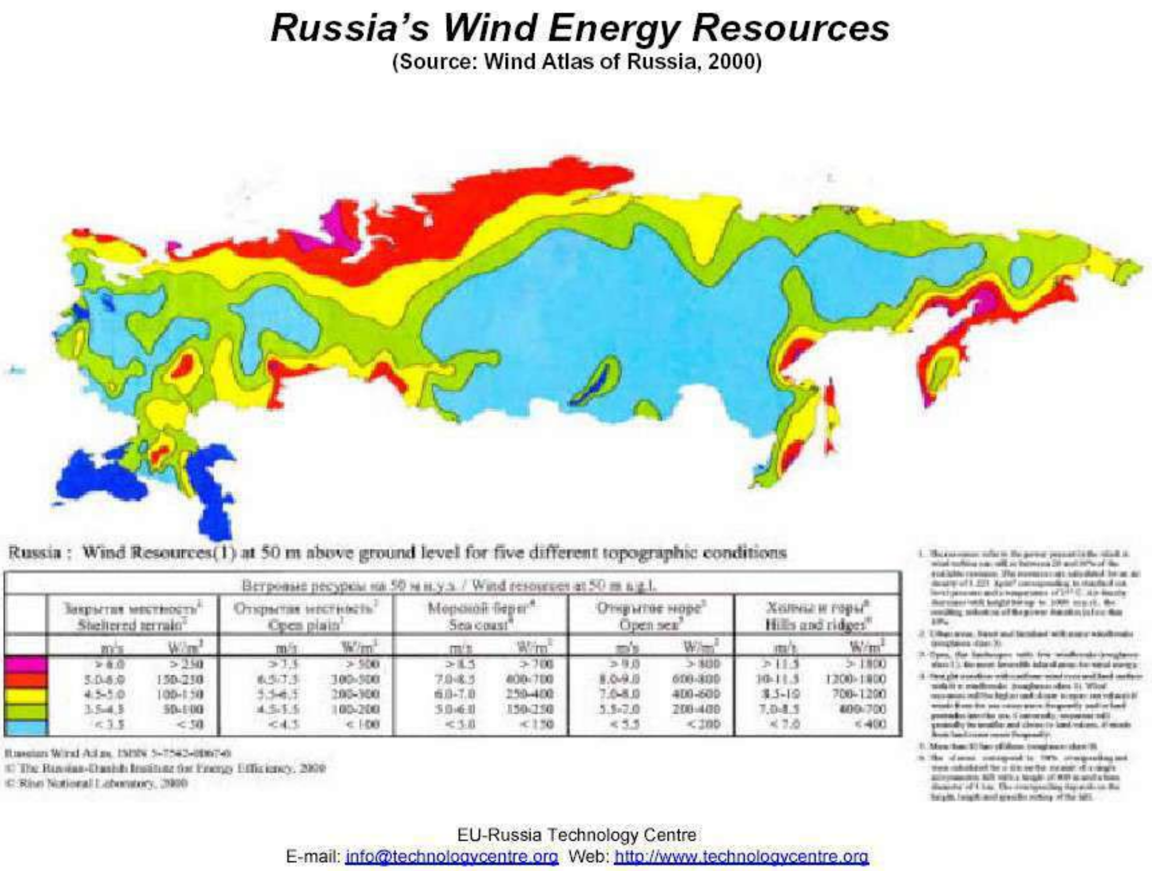

Figure 1 : Russia's wind resource map (source: Russian Wind Atlas)

The areas of greatest wind resource are the regions where the population density is less than 1 person per km2 [7] The coastal areas of the Pacific and Arctic Oceans, the vast steppes and the mountains are the areas of highest potential. Recent estimates suggest that the European part of Russia has a gross wind energy resource of 29 600 TWh/yr (37%) and the Siberian and Far East part, 50 400 TWh/yr (63%). The technical resource for each is reported to be 2'308 and 3'910 TWh/yr, respectively.

It has been suggested that large-scale wind energy systems might be applied in areas where the resource is particularly favourable and there is an existing power infrastructure and major industrial consumers. These would include various locations in Siberia and the Far East (east of Sakhalin Island, the extreme south of Kamchatka, the Chukotka Peninsula in the Magadan region, Vladivostok), the steppes along the Volga river, the northern Caucasus steppes and mountains and the Kola Peninsula. Additionally, offshore wind parks could be considered in some of these areas, especially in the Magadan region and in the Kola Peninsula where existing hydropower stations could be used to compensate for the intermittent wind power.

The Russian Association of Wind Industry (RAWI) has stated that as at March 2010, 4'134 MW of wind capacity sites had been identified.

Breyer et al. [8] created a computer model, which considers the energy costs of various types of renewable sources, and marked the optimal kind of renewable source according to its regional potential. This strategic choice was offered for a long-term path to a completely renewable energy power supply.

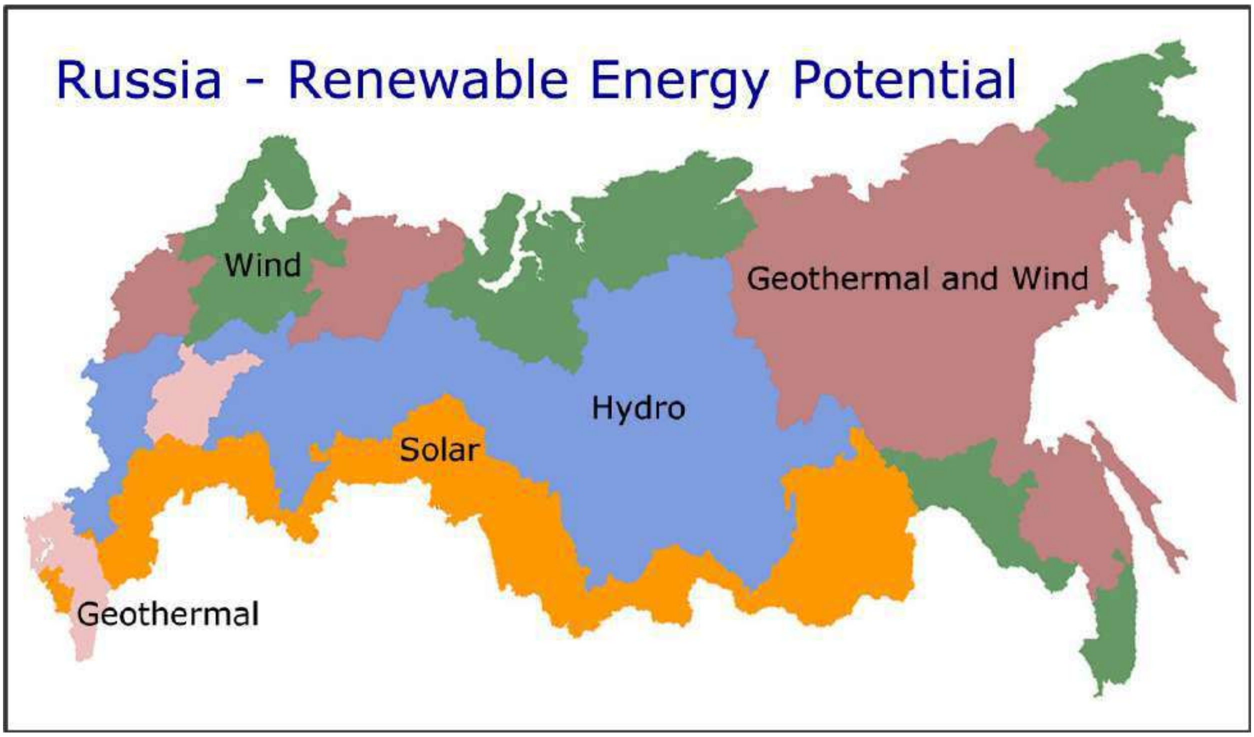

Figure 2 : Russian renewable energy potential (source: Bogdanov, D., Breyer, C. [9])

2.2 Current power production

The total power capacity in Russia currently equals 239.8 GW, while wind power annually produces 96.71 MW, which is less than 0.05%. The Unified Energy System of Russia includes 748 power plants with a capacity of over 5 MW and generates about one trillion kWh of electricity per annum.

Table 1 : Power output and consumption in Russia (2017) (source: System operator of the Unified energy system http://so-ups.ru/)

№	Parameter	millions kW h	%
1	Output	1053861,5	100,00%
a	- thermal power plants	611341,5	58,01%
b	- hydroelectric power stations	178901,6	16,98%
c	- nuclear power plants	202642,4	19,23%
d	- others	60976	5,79%
2	Consumption	1039879,9	98,67%

Energy deficit regions are mostly located in the southern part of Russia (deep in the Eurasia continent), what makes land-based wind farm more relevant (see Fig. 3).

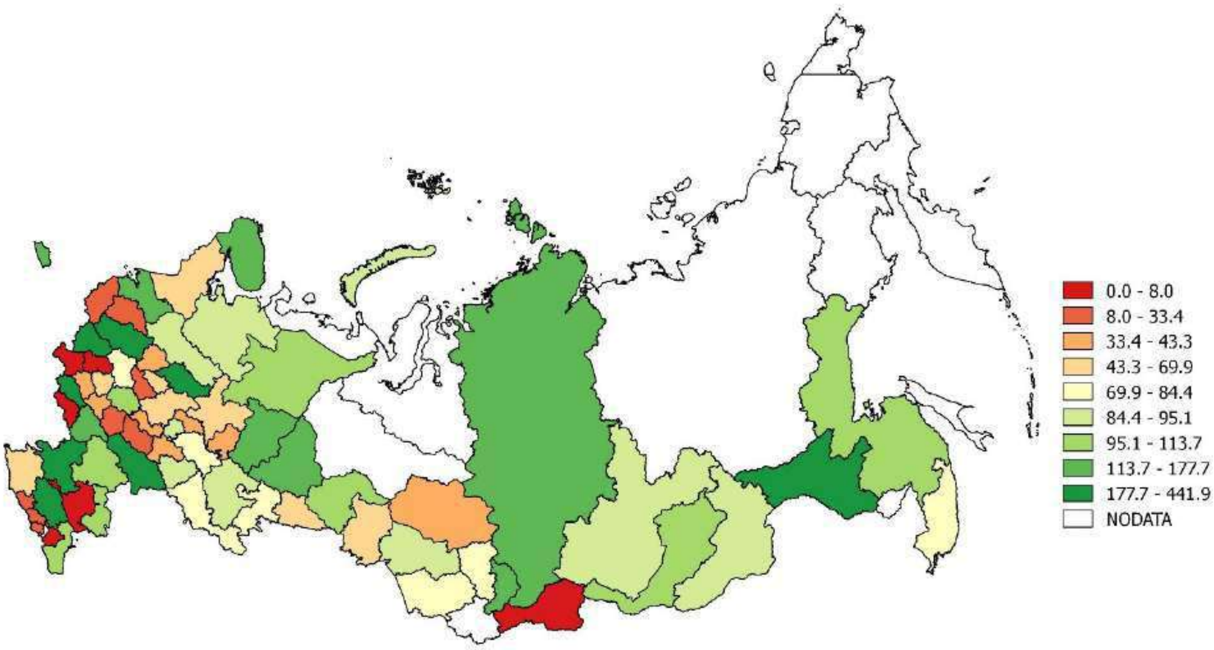

Figure 3 : Map of power production divided by power consumption (per cent) for each region in Russia (2017). Green regions are «power donors», red regions are «power recipients». (source: made by author)

Wind power stations and projects of planned wind farm construction are distributed unevenly (see Fig. 4).

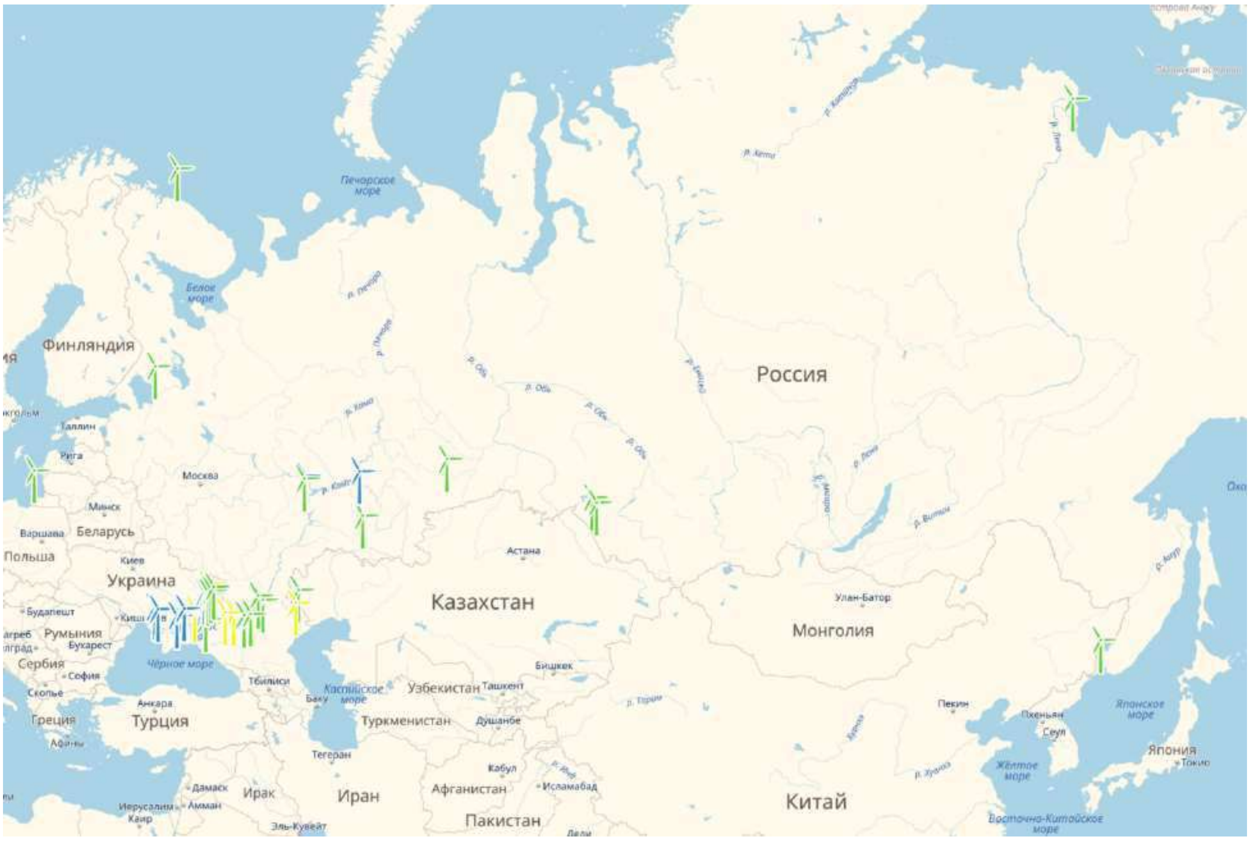

Figure 4 : Map of wind energy projects in Russia. Yellow – wind monitoring stage, Green – design stage, Blue – exploitation stage. (source: Russian Association of Wind Industry, RAWI https://rawi.ru/ru/map18/)

According to the RAWI data, there are 8 existing wind farms in Russia.

Table 2 : Wind power stations in Russia (source: Russian Association of Wind Industry, RAWI)

№	Name of the wind farm	Region	Installed capacity, MW	Year of completion
1	Ulyanovsk wind farm	Ulyanovsk region	35	2018
2	Tyupkildy wind farm	Republic of Bashkiria	1,65	2001
3	Presnovodnenskaya wind farm	Republic of Crimea	7,39	2006
4	East Crimean wind farm	Republic of Crimea	2,81	2009
5	Sudak wind farm	Republic of Crimea	3,76	2001
6	Sakskaya wind farm	Republic of Crimea	20,82	1998
7	Donuzlav wind farm	Republic of Crimea	6,78	1992
8	Tarkhankut wind farm	Republic of Crimea	18,5	2001

Total installed capacity of wind farms in the Republic of Crimea is about 64 MW, but all of them were commissioned before 2014, when the Russian Federation began to consider Crimea to be a part of its territory.
The energy infrastructure of isolated regions is based on a stand-alone power supply ("off-grid") mainly consisting of diesel power plants with one or more diesel generators. The number of diesel generators in these isolated areas is about 900; diesel power plants produce about 2.5 billion kWh, which equals the consumption of approximately 1 million tons of diesel fuel per year (to substitute diesel power completely with wind power would require a wind capacity of 1000-2000 MW plus storage, depending on the specific sites.) There are cross-subsidization in these regions and procedures how to cover the difference between the real generation costs (up to 2.5 $/kWh) and the actual rate for the customers (3-4 cent/kWh) have not been worked out yet [Elistratov et al., 7].

Table 3 : List of stand-alone wind-diesel hybrid energy systems in Russia (source: Elistratov et al.)

Location	Wind	Diesel
The Bering Island (Kamchatka)	550 kW (2 Vergnet GEV-C with unit capacity of 275 kW)	1168 kW
The Ust-Kamchatsk village (Kamchatka)	first stage: 1 Vergnet GEV-C (capacity of 275 kW in the version for cold climates); second stage: 3 wind turbines Komai KWT 300 (unit capacity of 300 kW)	8 MW
The Novikovo village (Sakhalin region)	450 kW (2 turbine with unit capacity of 225 kW)	N/a
The Republic of Tatarstan	Ghrepower FD 12-30/11 (30 kW)	N/a

The Amderma village (Nenets Autonomous Okrug)	200 kW (4 arctic version turbines Ghrepower-50 with unit capacity of 50 kW)	800 kW

2.3 Legislation

Russian government made first steps to support the development of wind and renewable energy, codified in the amendments of 4.11.2007 in the Federal Law of 26.03.2003 № 35-FZ “On Electric Power Industry”1 . Based on that Law, the Non-profit Partnership “Council for Organizing Efficient System of Trading at Wholesale and Retail Electricity and Capacity Market” (“NP Market Council”) was established. This organization, on a membership basis, brings together electricity sellers and buyers that are wholesale market entities (including renewable energy and wind power) taking part in the circulation of electric power on the wholesale market. It also pairs up companies operating the commercial as well as technological infrastructure of the wholesale market and other companies of the electric power industry.
The Government Decree of 28.05.2013 Nr. 449 “On the mechanism of promoting the use of renewable energies in the wholesale electricity market and power” was approved as another important step: A requirement for mechanisms was introduced to work with renewable energy projects in the wholesale electricity market, including regulations to develop renewable energy until 2020.
The development of renewable energy in the retail market of Russia is carried out in accordance with the programs of the energy efficiency in these regions, and the local authorities are taking over the role of the “NP Market Council”, e.g. by organizing tenders. The main documents in the retail market are the Government Resolution of 04.05.2012 Nr. 442 (ed. on 10.11.2016) “The rules of functioning of retail electricity markets” and the Federal Law of 23.11.2009 Nr. 261 “The improvements on energy saving and energy efficiency in the retail market” (energy service contracts). In addition, there are local energy efficiency laws in some isolated regions.

2.4 Support from the government

Wind energy like other renewable energy sources is legislatively supported in Russia since the May of 2013. The goal of support is not a replacement of traditional generation (based on natural gas, oil, coal, etc.) with renewable sources, but the development of new power generation technologies. The support is provided both in the wholesale and retail energy markets.
Legislative support of renewable energy sources includes following privileges:
- power produced by wind farms over 25 MW is totally purchased during 15 years at a fixed price plus 12% profit for investor;
- the fixed price takes into account fluctuations in the exchange rate, the actual value of the project's capital expenditures, other parameters.

According to the Government Decree №449, 3.35 GW of installed capacity will be installed by 2024 – 4.5 GW in 2030.

Table 4 : Installed capacity of the wind farms to be supported according to the current program for each year (source: the Government Decree №449)

Year	2017	2018	2019	2020	2021	2022	2023	2024
Capacity, MW	200	400	500	500	500	500	500	150

Main conditions for obtaining the support are:

- the maximum of capital expenditures (CAPEX) for wind power projects is determined (for example, in 2016 it was 152'000 roubles for 1 kW);
- localization principle - wind farms built in Russia should use equipment and services, produced in Russia. If a wind farm is commissioned after 2019, then localization rate has to be 65% or more.

Energy projects based on renewable energy sources are being held for a contract for the supply of capacity (CSC) as a legal form of the support mechanism. The selection of wind farm projects is held every year for the upcoming 4 years. The CAPEX is the main criterion: the smaller the CAPEX is, the more likely to win.

Table 5 : Wind power projects selected for the wind energy supply since 2013 till 2016 (source: https://www.atsenergo.ru/vie/proresults)

№	Year of the selection	Name of the wind farm	Region	Installed capacity, MW	Date of completion (plan)	Date of completion (fact)
1	2013	Aksaray wind farm, Funtovo wind farm,	Astrakhan Region	15 + 15 =30	2016, 2017	uncompleted
2	2013	Airport wind farm, Novosergievskaya wind farm	Orenburg region	15 + 15 = 30	2017	uncompleted
3	2013	Karsun, Isheevka, Novaya Maina wind farms	Ulyanovsk region	15 x 3 = 45	2017	uncompleted
4	2014	Priyutnenskaya wind farm, 1 stage	Republic of Kalmykia	51	01.12.2015	uncompleted
5	2015	Ulyanovsk wind farm	Ulyanovsk region	35	01.12.2016	01.2018
6	2016	Pilot wind farms	Krasnodar region	20 MW x 23 = 460	10 in 12.2019 13 in 12.2020	is being implemented
7	2016	Shovgenovskaya wind farm	Republic of Adygea	48 + 70 + 32 = 150	01.12.2018	is being implemented

Thus, only one of the 9 wind farms, which should have been completed by today, is really built. But even it was built 2 years later.

Speaking about projects, the implementation period of which is known, but has not yet come, in 2017, projects with a total capacity of 1.65 GW were selected, including 924 MW in the southern regions. And in 2018, projects with a total capacity of 853 MW were selected, including 588 MW in the southern regions. This distribution follows the energetic deficit in southern part of Russia, which was described earlier.

2.5 National planning

At the same time, Scheme of territorial planning of the Russian Federation at the field of power engineering, STP RF PE (national level planning document) plans 15 wind power plants to be sited in different regions till 2030 with total installed capacity over 4500 MW.

Table 6 : Wind farms planned for construction until 2030 (source: STP RF PE)

№	Region	Installed capacity, MW
1	Kaliningrad region	200
2	Leningrad region	300
3	Murmansk region	300
4	Murmansk region	100
5	Nizhny Novgorod region	350
6	Orenburg region	150
7	Saratov region	1000
8	Astrakhan region	100
9	Republic of Kalmykiya	150
10	Krasnodar region	1000
11	Republic of Adygeiya	195
12	Republic of Adygeiya	102
13	Republic of Adygeiya	144
14	Karachay-Cherkess Republic	300
15	Omsk region	110
	Total	4501

The most ambitious wind power projects (1 GW each) are planned in Saratov region and in Krasnodar region. As it was shown earlier, Krasnodar is the second most energy deficit region in Russia after Moscow, so the decision seems reasonable. But Saratov is the biggest energy donor in the country, which generates three times more then uses for internal needs. It makes the distribution of future wind farms questionable.

3. Challenges and constraints of wind power development

Most common constraints of wind power projects discussed by researchers in different countries are:
- environmental impact;
- territorial requirements:
- amount of land;
- configuration of parcels;
- landscape conditions;
- temporary and permanent land uses;
- distance to residential zones;
- complications for agriculture;
- volatile power supply by wind farms and the necessity of storage infrastructure;
- social acceptance;
- lack of properly adjusted law.

Based on stakeholders' interviews Gsänger and Denisov [10] outline main barriers for the Russian wind power industry:
- a general lack of investments and investors which is primarily related to an insufficient and intransparent remuneration scheme and the small market volume but also to the macroeconomic situation in the country.

- a significant number of weaknesses in the regulatory framework, including land use issues, standards etc.
- challenges with grid connection.

In a sense, all of the above constraints can be connected to the planning process, that's why we will study them more.

3.1 Environmental impact

Although wind power is considered to be one of the cheapest renewable energy sources (by levelized cost of energy – LCOE [11]), it doesn't mean that energy production became completely harmless for the natural environment. To avoid these risks a relevant site-specific research should be conducted before siting a wind farm.
Often this impact is shown through the bird migration processes [12, 13]. Wind turbines' sweep of the blades can reach up to 200 meters, what can potentially be catastrophic for birds' population.
Wind turbines are also criticised for its noise. Latest studies show that noise level of modern wind power plants is usually 35-40 dB(A) [14], what people still find annoying. Prescribed minimum sanitation distances from a wind turbine to residential zones and houses can make a certain difference for planning practice and controls over the urban sprawl.

3.2 Territorial requirements

As wind turbines are most effective in a certain distance one from another, wind farms in total need many hectares of land. Land (on average 34 ha/MW of total project area - according to Denholm et al., 2009) is needed for permanent and temporary use and the required area depends mostly on the number of turbines, their installed power and their configuration in space.
Configuration of wind plant for land use planning purposes was divided by National Renewable Energy Laboratory (NREL) [15] into four general categories: Single String, Multiple Strings, Parallel Strings, and Clusters. Taking configuration into account NREL estimates for US wind farms that 70% of the permanent area is being used for roads. So there is a big reserve for the land use optimization while siting wind power turbines, electric grid and roads at the local level.
Wind farm should be sited in a place, where the land cover is as smooth as possible, because any roughness brings to decrease of wind speed. That is why strongest winds blow over the sea, what usually allows off-shore wind power plants produce more energy from each turbine. As land for wind farm is almost always can't be provided inside the inhabitable locality, most of appropriate places are related to agricultural land category. Wind farms also bring more energy when they are located far enough from wind breaking forests and mountains and use natural advantages of the landscape and wind microclimate.
When a wind farm is constructed it takes not much territory to use. But it's necessary to have roads to do technical maintenance several times a year. Wind turbines one with another are connected with power lines that can be put under the ground, but there is still a protection zone for each line. These two types of lines create a net of restrictions, which are seen to be barriers for use of the agricultural land around the towers. Though some part of the land is still free from these restrictions, the effective use of agricultural machines requires open ways forward and back to cover all the land. So taking agricultural farm land for wind farms is often necessary, but the matter of balance is to organize complementary use of land.

3.3 Social acceptance

Matter of social acceptance of wind farms sometimes falls out of planner's sight. People protesting aspect [16, 17] is often being seen as NIMBYism. However, when meeting the resistance of the local community in the construction of wind farms, one should look back

and consider whose interests are given the highest priority in the implemented policy. Is this the private sector or certain community groups?
Therefore, it is important to try, on the one hand, to engage the community to the development of renewable energy, overcoming the widespread misconceptions and spreading knowledge, and on the other hand, to critically evaluate concrete projects to find out the root causes of social contradictions.

3.4 Lack of properly adjusted law

Based on our analysis of Federal laws in the Russian Federation, two main features ignoring wind power specificity were found.
When there is still no design decision where each turbine should be built, wind farms need big plots of land, is almost always can't be provided inside the inhabitable locality, most of appropriate places are related to agricultural land category and forest land category, where any construction is forbidden (Land Use Code). General plan is the necessary step to change the category of land, usually to industrial land category. The procedure of change empowers regional administrations for agricultural land category and federal government for forest land category.
Construction of wind measuring towers according to the federal law (Urban Planning Code) because of their height is considered to be a kind of structure that needs a permit to build. Also Rules of land use and building (so called "PZZ", zoning) should envisage that this permit will be asked to allow it. And general plan needs to be a basis for zoning (PZZ) to work together or PZZ can be cancelled by court. That is why general plan should reflect future wind measuring towers or the building permit can't be legally provided.
In this sense technical algorithm to be realized in legislative aspect needs to implement into general plan not just the wind power plant, but also wind measuring towers. As it's impossible to design the wind farm without data about wind resources, general plan needs to be changed two times: first to get a proper category of land and a building permit for wind measuring tower, and second to get the same for the wind power plant itself.
Based on the particular qualities of wind power projects, these two points (land use category and urban planning decision making) need to be changed at the national level. These legal issues can increase the project duration by one year at least, even if there is no controversy in local community.
As it was shown in this chapter most of wind energy challenges can be responded by planning system as a part of national legislation and by certain planning technics at the local level.

4. Method

The method used for further analysis is to assess the decision making process in parallel with formal planning documents' preparation using data on the first functioning wind farm in Russia, located in Ulyanovsk. We use contradictions identified earlier in this paper as a framework for this study.

5. Case study: Ulyanovsk Wind Farm

In Krasny Yar village in Ulyanovsk region in January 2018 the first wind farm in Russia was put into operation [18]. The 35 MW power plant was built by Finnish company Fortum and has 14 Dong Fang wind turbines [19].
Now we apply the assessment framework considered above to analyze this case against all the contradictions.

5.1 Environmental impact

According to official statements of the Fortum company, the necessary work towards reducing the negative impact on the environment was done.
First, the closest wind turbine to houses is located 900 meters far from them. Besides, new models with no mechanical transmission are installed, what makes the vibration and noise indistinguishable at a distance of 300 meters.
Second, the project of the wind farm construction contains sections on the environment protection and passed the state expertise and received a positive conclusion.
Third, since the wind farm is located next to Volga river, where bird migration routes pass by, dangerous events for birds can take place. For this reason, each wind turbine is equipped with ultrasonic bird repeller to keep them at a distance.
As wind farm has less then a year of operation, it's difficult to make a certain conclusion about its environmental impact, but certain necessary measures have been definitely undertaken.

5.2 Territorial requirements

First part of the Ulyanovsk wind farm, which is in operation now, was planned by the General plan of Krasny Yar municipality (located next to Ulyanovsk) (see Fig. 2). According to the State register of the real estate, current land area is 59,4 hectares.

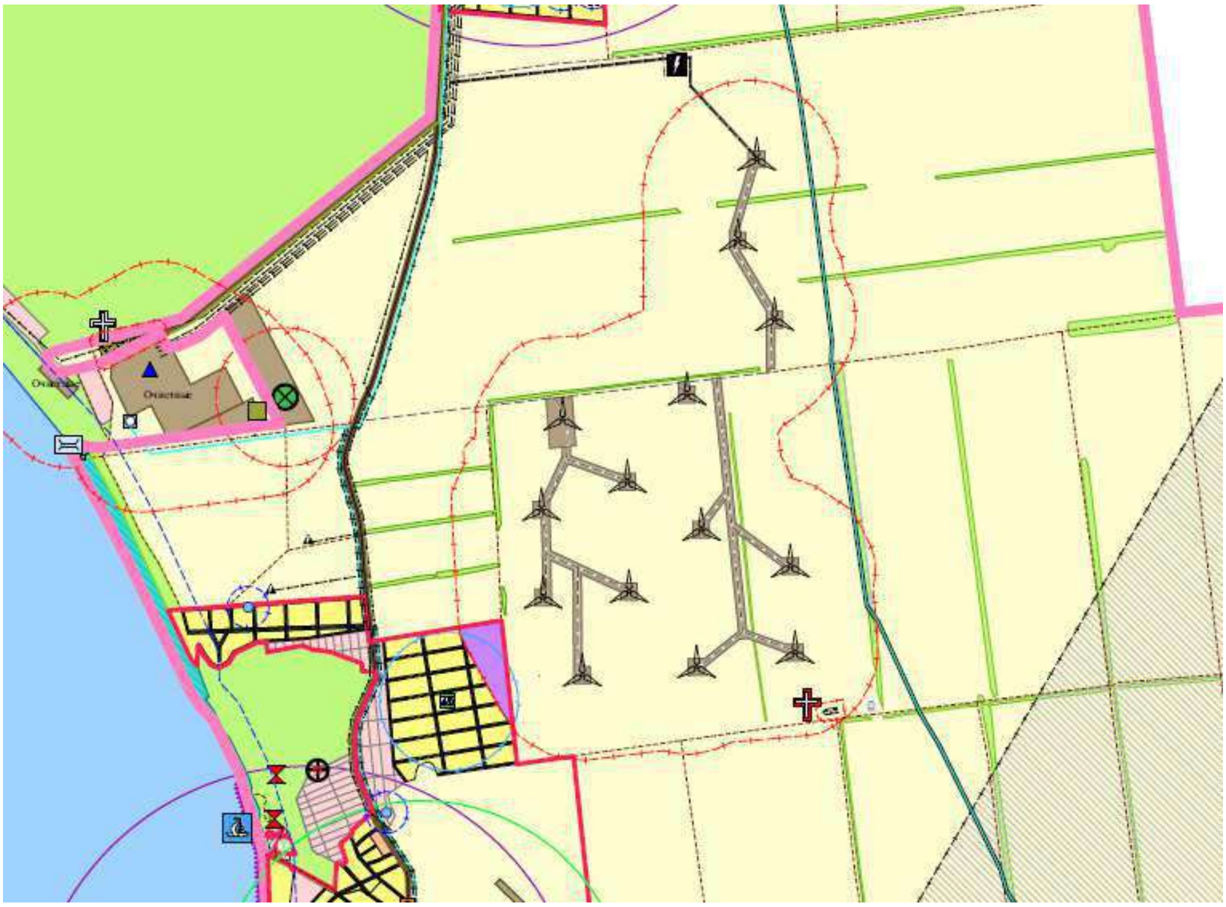

Figure 5 : Fragment of the general plan showing wind turbines and power lines (source: Federal state information system of territorial planning, https://fgistp.economy.gov.ru/)

Second part of the wind farm is announced to be built with installed capacity 50MW. Future development of the wind farm hasn't been reflected in the General plan yet, but a couple of land parcels, intended for this purpose, can be found in the same source – of 16,5 hectares in the northwest, and of 21,5 hectares in the north (see Fig. 3). Wind turbines can be recognized as small squares, connected with each other with roads and power lines.

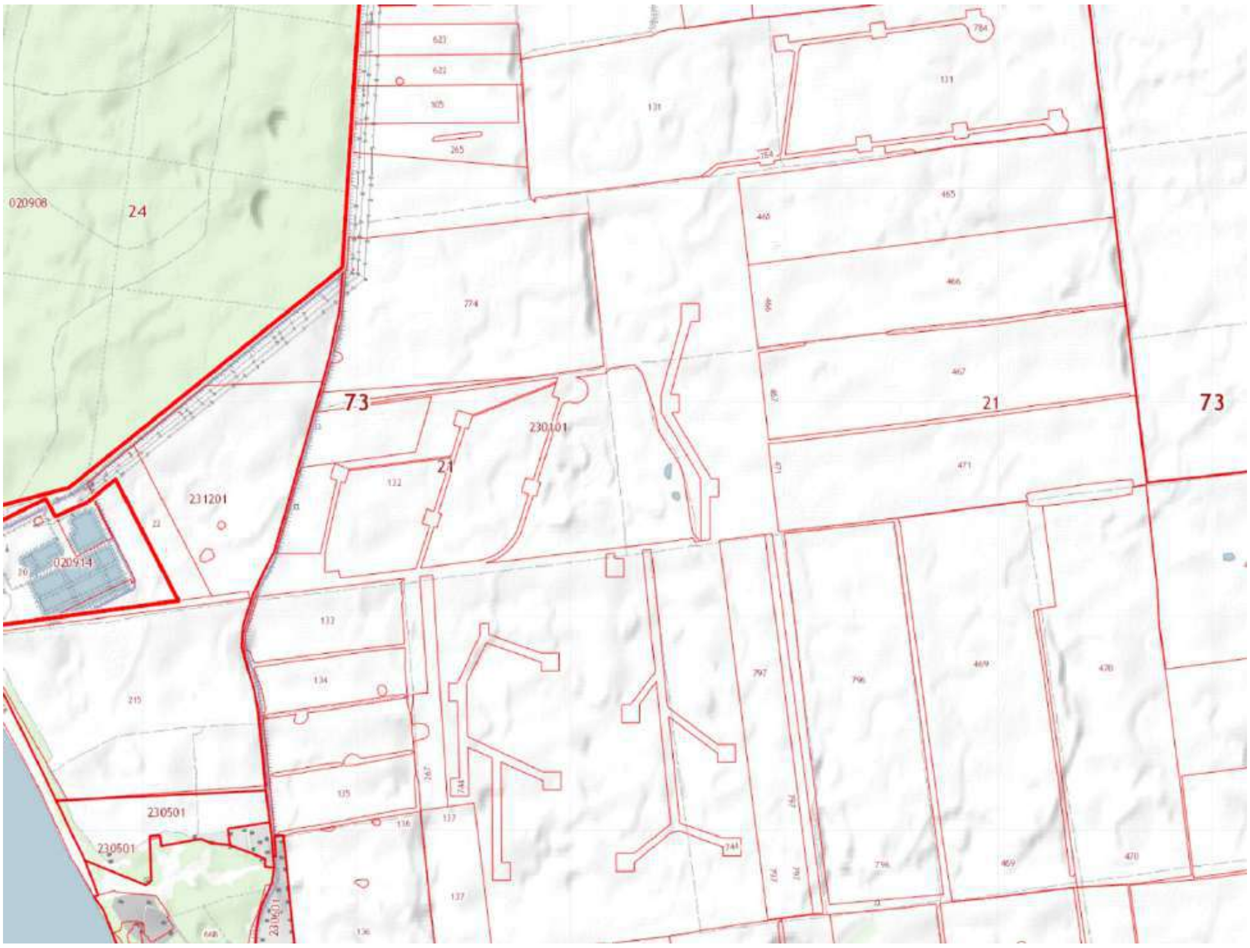

Figure 6 – Fragment of the public cadastral map (source: http://pkk5.rosreestr.ru)

As shown in the figures 2 and 3, the wind turbines are placed along the cluster scheme, which uses compact land plots. However, the use of surrounding agricultural land, especially soil tillage by machines, becomes impossible due to the presence of wind towers and their security zones. It means the actual area taken by wind farm is around 860 hectares in the central part and around 480 hectares in the north part. As each wind turbine has installed capacity of 2.5 MW, and 26 locations for wind turbines that can be distinguished now, the area for production of 1 MW equals 20,6 hectares. In comparison with NREL study and US average area of 34 ha/MW, Ulyanovsk wind farm uses land effectively.

5.3 Social acceptance

Analysis of the materials of Ulyanovsk media did not provide an opportunity to assert about the existence of a social conflict over the construction of the wind farm. However, there have been several publications of ornithologists concerned about the possible death of birds and journalists on corruption and violations during construction.
However, it seems that private sector and regional administration interests were drivers for this investment project while community interests are not formulated.

5.4 Lack of properly adjusted law

It was a long journey from the national tender for wind power company won in June 2015 (and the early preparations made to participate) to the end of the construction phase it took 2,5 years.
To force the realization of the Ulyanovsk wind project several administrative steps were taken.
1) Wind farm is being developed as a part of the long term strategy to create a technological valley to create conditions for increasing the investment attractiveness of the region. So wind power production becomes an answer for the needs of new consumers and especially for residents of Zavolzhye industrial park of 706 ha. Industrial zones development program in Ulyanovsk region started in 2007. It received financial support from the national government from 2008. In the industrial park over 30 investment projects are realized, and the number of residents is growing.
2) From the strategic perspective Ulyanovsk region and the regional capital have mentions of the technological valley, industrial park, wind power and other connected objects in their socio-economic strategies. But strategies are more declarative and reflect decisions that already were made. The effect of this on the development is limited.
3) To coordinate the future development of industrial park its territory was included to the Ulyanovsk municipality. It was done to have more taxes for Ulyanovsk and to have a single center for coordination. The regional decision on changing borders of municipalities was approved at the end of 2014. As the Ulyanovsk wind farm is located outside the new borders after the extension, wind power producing company pays prescribed taxes to Krasnoyarskoe rural settlement. And the future technological valley will develop in several neighbor municipalities.
4) To have the necessary information on wind resources of the site, proper measurement were made. It is an internationally accepted practice to build high structures with the equipment on top to collect data for a year. There is no detailed information about building permits for the construction of wind measuring towers. But the land parcel for the first part of the Ulyanovsk wind farm was formed for the exact configuration of the wind turbines before the General plan of Krasny Yar was changed to show where the wind farm is to be built. It means that wind measurements and wind farm design were ready earlier.
5) General plans of municipalities reflect comprehensive plans for energy and industrial development now. General plan of Krasny Yar was changed to adjust to the new requirements when decisions on the place and the configuration of the wind farm were already known. Technical parameters, which were accepted in general plans, earlier were detailed in territorial design projects. New version of Ulyanovsk general plan was presented in 2017. That is why the general plan for Krasny Yar shows the exact parcel for each wind tower.
6) German company (Assmann Beraten + Planen) developed a territorial design project for the Zavolzhye industrial park in 2011, and the territorial design project for the Ulyanovsk wind farm was developed by local specialists according to the data of Fortum.
7) Land readjustment for the wind farm territory was done to change the configuration of parcels and the allowed land uses according to general plan and zoning. Then with proper building permits and construction project developed, wind turbines were raised and power lines constructed.

6. Discussion of results

New wind farm in Ulyanovsk became a breakthrough and opened most of systematic and administrative inconveniences connected to national planning system and technological features of wind farms themselves.
Siting of wind farms on the national and regional level should be determined based on an analysis of energy needs and available wind resources. We assume that these sites can be detailed more. But the exact parameters for the power station shouldn’t be designed at this stage.

The wind industry functions as a market, despite state regulation and the participation of state-owned companies. In such circumstances, decisions on the location of wind parks, including their comprehensive justification, are taken within the framework of the strategies and business plans of the companies. Public territorial planning, linked to such procedures as the transfer of land from one category to another, the provision of land plots from state and municipal property for construction, participation in federal and regional programs of investment development, becomes the mapping of the planned, not always required by the business entity.
The uncertainty about necessity of building permits for wind measurement towers we propose to clear by establishing a special order of getting permits for this type of structures. This order shouldn't include changing planning documents of strategic level such as general plans.
Land ownership played a visible role on siting the Ulyanovsk wind farm. Based on the configuration, it is likely that the land parcels for the wind farm were provided from the state and municipal property. As it's easier to provide land this way, it can be seen as a plus. But it restricts from making a wind farm from perspective of optimal siting to get more power in given natural conditions. To overcome ownership constraints, legislation needs to be completed by mechanisms of public private partnership in land ownership aspect.
Landscape has been out of sight during all the Ulyanovsk wind farm siting and design. We propose to take surrounding agricultural land into consideration when making a structure of power lines and siting each turbine. Changing the optimal siting scheme of turbines' allocation can help important qualities of agricultural land use to be kept.

7. Conclusions

The main findings of this paper include common international features and specific Russian planning issues, that should be taken in account.
Planning issues of the international importance include:
- wind farm siting as a specific aspect of providing building permits, designing power network, land use management, taken in account in planning system;
- transmission technology of strategic decisions for network development to land use planning while siting wind farms; interaction of public and private plans;
- standards and rules for environmental studies in wind farm projects;
- support mechanism of bottom up initiatives for community driven wind farm projects;
- partnership framework for land owners and farmers to optimize land use patterns and to make wind farms work within the existing agricultural landscape.

Russian planning issues of wind farm siting represent a simplified version of common world issues. To eliminate existing barriers and stimulate the renewable power production in Russia, the planning process for wind farm siting needs to be improved. It is more likely that these changes lie in the legislative field. Experience of planning and construction of the Ulyanovsk wind farm can already become a basis for simplification of existing procedures and strengthening of the planning expertise in Russia.

CLIMATE ADAPTATION: TRANSIT ORIENTED DEVELOPMENT AS A STRATEGY FOR ASIAN CITIES

Olga CHEPELIANSKAIA, UNICITI, France

Synopsis

Increasing climate vulnerability has made adaptation a critical matter for Asian cities. Several urban adaptation strategies, such as engineering solutions or climate resilient planning and land use regulations, have been largely tested. Climate adaptation contribution of a Transit Oriented Development (TOD) has however hardly been assessed, highlighted and tapped into. Yet, the advantage of a TOD approach lies in its capacity to come as a co-benefit to other major urban improvements: containing urban sprawl, reducing air pollution, GHG emissions and the urban heat island effect, mainstreaming mixed land use and generating public spaces, boosting the economy and improving the overall quality of life. With the same investments, TOD significantly contributes to climate adaptation in terms of both managing and preventing disaster risks.

This paper builds the case of TOD as a climate adaptation strategy for Asian cities. It outlines major features of TOD and demonstrates how these are relevant to strengthening climate adaptation. Learnings from successful TOD implementation models such as Hong Kong, Seoul Copenhagen and Singapore are examined.

Compact development model facilitates Asian cities' climate adaptation

Asia has been rapidly urbanising from 0,3 billion urban dwellers in late 1950s, the region moved to 2,1 billion in 2015, which is projected to reach 3,3 billion by 2050 (Worldometers, 2018). Over 60% of world megacities are likely to be located in the region by 2025 (UN, 2018). The rapid infrastructure development accompanying this trend came **at the cost of significant vulnerabilities**. Over 40% of South Asian urban population lives in slums (UN Habitat). Basic infrastructure and housing needs are tremendous: ADB estimates that between 2010 and 2020 over USD 8 trillion need to be invested into infrastructure in Asia (ADB, 2009).

Climate change and increasingly intense and frequent extreme weather events exacerbate the already high urban vulnerabilities and create a major threat in the region: 6 out of 10 most climate change affected nations are located in Asia-Pacific; 410 million urban dwellers in Asia will be at risk of coastal floods by 2025 and South Asia alone is projected to annually lose 1.8% of GDP by 2050 due to natural disasters. Climate change adaptation is hence a critical and urgent matter for Asian cities.

The urban sprawl urban development model, largely dominating in Asia, is however not up to the challenge. Urban sprawl is commonly defined as a dispersed, segregated land use and automobile-oriented urban-fringe development (NCE Cities, 2015, p. 10). Urban dwellers in sprawling cities depend on motorised vehicles for most activities: work, education, health, grocery, access to recreation areas, etc. Increasing purchasing capacity in Asian cities, more affordable car ownership and fuel subsidies in some countries further nourish the model. Between 2000 and 2010, Manila's urban area grew from 1,800 km2 to 2,300 km2. Most of the expansions occurred in neighbouring provinces rather than Manila itself. The core municipality attracted only 10-20% of the urban growth between 1950 and 1980 and virtually 2% of the growth from 1980-2010. As per the 2010 data (Cox, 2011), over 50% of Manila's urban population lives in the inner suburbs and 40% in the outer suburbs. The satellite imagery below shows how this development pattern reflected upon green and blue spaces. After 50% of the city was flooded in 2012, experts referred to an unplanned city expansion, extreme pressure on existing resources and mismanagement of natural resources as reasons for the disaster to occur (de Leon, 2012).

2: Manila 1988 and 2014. Source: (NASA, 2015)

In addition to a well-known harmful pollution, GHG emissions, congestion, economic and overall liveability impact, **urban sprawl hence significantly compromises urban climate adaptation.** Indeed, car oriented cities require vast spaces for parking and roads, which encroach upon valuable natural urban ecosystems such as agricultural lands, wetlands, parks and forests. For example, in the Los Angeles central business district, parking areas (including large multi-storey parking garages) equal to 81% of the total land area (Zhao, et al., 2016, p. 5). Sprawl typically increases per capita land consumption by 60-80% and motor vehicle travel by 20-60% (NCE Cities, 2015). Resulting encroachments upon lakes, rivers, streams, wetlands and coastal areas severely **damage urban areas' flood and heat control capacities and reduce ground water tables**. The scale, intensity and duration of floods have increased in Asian cities while these face severe water scarcity. Bangalore, India, once a city of 2,500 lakes, has tripled its size over the last 4 decades, with only 80 lakes remaining in 1993 (Murali, 2016) (Seth, 2012). As a consequence, 78% of the city surface is impervious to water (Nagar, 2018) and the city faces severe floods regularly since 2000 (IISC, 2017), while it is expected to run out of ground water by 2020 (NITI Aayog, 2018). Similarly, urban sprawl is associated with **increased surface temperatures** in cities and intensity of heat waves. Bangalore's average temperature has risen by 2° to 2.5°C between 1995 and today (Vidal, 2017).

3: Los Angeles 1964 from the Griffith Observatory. Source: (Murphy, 2017)

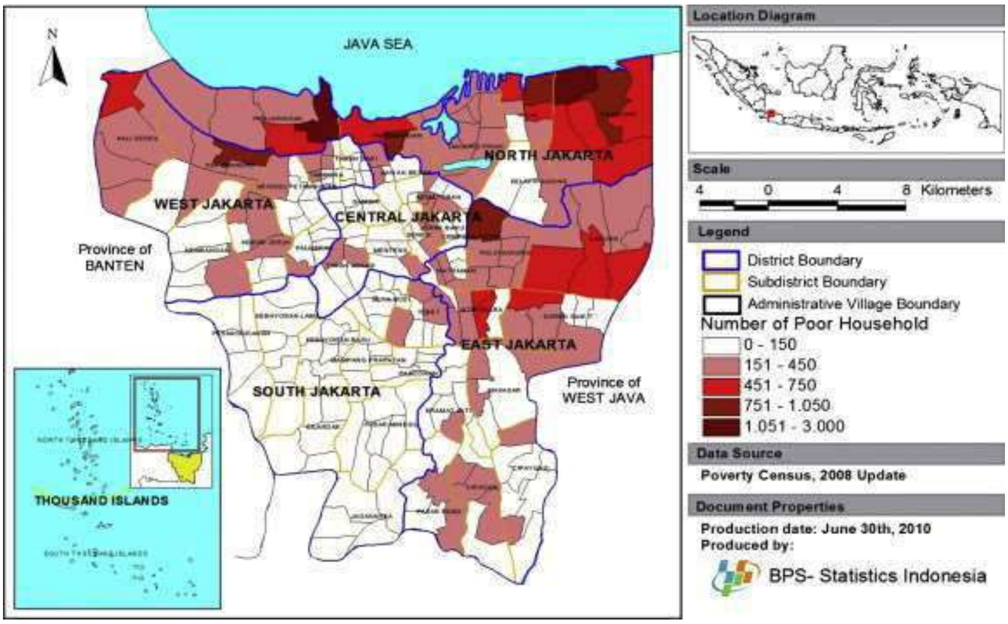
Largely criticised and gradually abandoned in the West starting from the 1960s, the model prevails in the Asian region (Zhao, et al., 2016). Night lights data analysis shows that South Asia's urban areas have annually expanded by 5% between 1999 and 2010. This despite the population only grew by 2.5% a year. Therefore, cities' territories grew twice as fast as their population, which is a clear indicator of urban sprawl (Ellis & Roberts, 2016, p. 3).

Urban policies have largely contributed to urban sprawl development and automobile dependency directly or indirectly. Examples of such policies include master plans that favoured urban expansion over increasing core densities, restrictions on building density and heights, minimum parking space and setback requirements, transport planning that favoured automobile commute, utility pricing and tax rates that failed to reflect higher costs of providing public services in sprawled locations (NCE Cities, 2015). For example, Thailand used tax rebates on car purchase, which has encouraged settlements in the outskirts of Bangkok and increased road congestion (Saengpassa , 2013). As a result, Bangkok grew by 30% between 2000 and 2010 and its suburban provinces grew by 66%. Much of this new development has been townhouses and detached housing in areas accessible only by cars, typical of the sprawl model (Cox, 2012).

Such policies reduced housing and transport options in the core city while they increased economic and environmental costs. Urban sprawl costs the American economy over USD 1 trillion annually: greater spending on basic services such as water supply and sewage pipelines, solid waste management facilities or roads. Americans living in sprawled communities hence directly bear an astonishing USD 625 billion extra costs (NCE Cities, 2015).

Finally, urban sprawl poses a major social equity concern:

- The **urban poor are at a loss in car dependent cities** because a significant share of public investments goes to automobile-related facilities while these are used by a small share of the population (NCE Cities, 2015), taking resources away from activities that could benefit the majority of citizens.
- **Informal settlements tend to crop up in environmentally vulnerable areas**: river or lake banks, steep slopes or low lying coastal zones as in Jakarta (map below).
- Disaster related costs for the urban poor are tremendous because these citizens **lack health and property insurance.** The quality of their housing is the poorest and least resistant to extreme weather events (Feiden, 2011)**.**



4: Potential climate-change related vulnerabilities in Jakarta: Challenges and current status. Source: (Firman, T. et al. 2011)

Climate resilience and climate adaptation advantages of the compact urban development model over the urban sprawl model have largely been demonstrated. A compact urban development model is commonly defined as a dense development pattern, well linked by mass transit systems and maintaining an easy accessibility to local services and jobs. Compact development usually reduces the impact of development on the environment by limiting urban expansion (OECD, 2012). Compact cities are viewed as resource-efficient and less dependent on the use of private cars (UN-HABITAT, 2013). **Transit Oriented Development (TOD)** is a form of a compact development model built around existing or planned transit stops, hubs and corridors supporting light rail, train, or bus ridership. Hong Kong has supported compact transit oriented development since 1960s, which allowed the city to host a population of over 7 million by building on only 24% of its total land area, reaching an average population density of 7,000 people per sq.km and yet maintaining an overall high quality of life (LEGCO, 2016).

Compact city policies promote investments in mass transit and integrate active mobility (such as walking and biking) to make the transport system comprehensive. Such policies hence provide the urban poor with a better access to job opportunities and services promoting equity and inclusiveness. In parallel, such policies reduce the share of required impervious land in urban and peri-urban areas which, combined with adequate land use regulations, helps preserve natural ecosystems to divert and absorb flood water, replenish ground water tables and reduce heat. Through compact development, Hong Kong has been able to maintain 76% of its land as natural ecosystems, comprising of grasslands, woodlands, farmlands, wetlands and water bodies (LEGCO, 2016).

All major internationally adopted guidelines highlight climate advantages of the compact development model versus the sprawl model. The *New Urban Agenda* highlights the benefits of integrated planning and compact development in paragraphs 51, 52, 69 and 98, making an emphasis on transit oriented development (TOD) and integrated mobility in paragraphs 114 (b) and 118. Sustainable Development Goal 11 highlights that by 2020 countries must substantially increase the number of cities that adopt and implement integrated policies towards climate change adaptation in line with the Sendai Framework for Disaster Risk reduction 2015-2030. "The role of transit in sustainable urban development is increasingly being recognized and promoted as a way to moderate climate change and increase the mobility of the poor" (Suzuki, et al., 2013, p. 25).

Let us compare an example of an urban sprawl versus a compact city model. With a similar population of about 5 million, Barcelona has a significantly lower spatial coverage and carbon footprint than Atlanta: 7,692 versus 648 km2 and 1,2 versus 6,9 tonnes per capita respectively. Over 20% of trips made by Barcelona citizens are walked (UN-HABITAT, 2013). This is a result of a longstanding commitment to planning and designing transit oriented compact, mixed-use walkable neighbourhoods.

Transit Oriented Development as a strategy for urban climate adaptation

Based on considerations above, identified while the author assisted a number of Asian cities with strengthening climate adaptation, the present paper initiated exploring direct and indirect linkages between TOD and climate adaptation. The objective of this exploration is to help vulnerable Asian cities obtain significant socio-economic, environmental and climate co-benefits through optimising their scarce territorial, natural, economic, human and financial resources. The topic revealed hardly explored by academic and policy literature, which is both the value and the limitation of the present paper, in particular when it comes to quantifying climate adaptation benefits of adopted TOD strategies. While direct author's experience of working with cities feeds considerations and conclusions of the research, specific city related data often cannot be publicly disclosed. The paper hence presents results of an on-going research, which will lead to further data collection and analysis.

Transit-oriented development (TOD) is commonly defined as an urban planning model that promotes compact, high-density, mixed use development within a walking distance (one kilometre) to transit stations and high quality public transit services (BRT systems, trams, underground trains). A TOD block consists of a mixture of housing, offices, retail and/or other amenities organized in a **compact walkable neighbourhood** (Suzuki, et al., 2013). Key components include:

- Mixed use neighbourhoods minimize the necessity to use motorized transportation by placing all key daily activities within a walking/cycling distance: housing, office spaces, schools, shops, green and recreational spaces. Major components of mixed land use neighbourhood development are mixed functions buildings, vibrant ground floors, open public spaces, dedicated pedestrian and cycling paths, limited car speed, limited roads and parking spaces.
- The neighbourhood is dotted with pedestrianized public spaces, designed in a way to create a public realm and provide ample interaction opportunities. The overall quality of life is uplifted by increasing free usage spaces. These make individual residential spaces' size somehow less critical and help creating compact areas.
- While walking and cycling is encouraged at the neighbourhood scale, rapid inter-neighbourhood transit is provided between neighbourhoods. This transit consists of rapid efficient public transportation and transit nodes located at a walking distance in all major points, which encourages citizens to shift from cars to public transport. Often, private car usage is additionally discouraged at policy and infrastructure levels: reduced parking lots and increased parking cost, city entrance fee, congestion charges/ taxes. This combination favours a gradual **shift to non-motorized and public transport mobility.**

A number of the above-listed TOD features directly contribute to climate adaptation, although not often viewed as such. While reducing traffic loads, creating recreational green areas and public spaces, they seamlessly adapt the city to climate change and extreme weather events. These features preserve and strengthen natural urban and peri-urban ecosystems, which is a key element of climate adaptation in the long run; enhance urban food security; locate densely populated areas in safest zones of the city; improve accessibility and evacuation networks; and de facto often benefit to the urban poor and vulnerable populations. These components can be examined on the example of a few successful Asian cities' cases (Hong Kong, Singapore, Seoul) and selected Western cities' models (Copenhagen, Stockholm, Houston).

- ***TOD preserves and strengthens natural urban and peri-urban ecosystems.***

Containing urban sprawl and reducing road space through TOD frees up urban and peri-urban land areas for green and blue spaces (parks, forest, agricultural land, water bodies, etc.) that act as buffers during extreme weather events (floods, heat waves, climate change resulting potable water stresses). Compact development can indeed save up to 1/3 of land development and infrastructure costs (Gar-on Yeh, 2002).

Hong Kong opted for a highly compact development and prioritized regeneration and reclamation of existing urbanized territories while developing TOD rather than expanding into green-field areas. Over 45% of Hong Kong's land is legally protected as a country-park since the 1970s, (the Mass Transit Railway Corporation ordinance leading to TOD planning was passed in 1975) while another 30% remain undeveloped and subject to various degrees of protection under a hierarchy of preserved areas (Salat & Ollivier, 2017). Interestingly, such a development mode did not affect but rather, on the contrary, enhanced real estate development opportunities. Through its R+P (Rail plus Property) TOD model: developers have been allotted suitable land and FAR rights that have been demarcated in the overall land use planning by the MTR and other planning bodies. For example, revenues from R+P developments around stations along the MTR's Tseung Kwan O line financed the extension of that line to serve a new town, which has since grown to a population of 380,000 (Yifan, 2017). MTR makes sure that all new developments adhere to guidelines for urban design, pedestrian circulation and public amenities. Today, **the city's resilience and quality of life index rank amongst the top 5 in Asia**. Hong Kong promotes knowledge and experiences across government departments as well as private sector to maximise opportunities that create sustainable urban ecosystems and make Hong Kong more climate-ready.

Urban green and blue spaces cool the air and provide shade limiting the urban heat island and heat waves effects. This is of a particular importance to low income communities, which can hardly afford artificial cooling. TOD principles includes providing green areas next to high density major transportation nodes, which make important natural buffers in high density zones. Learning from Singapore, cities with large footprint buildings can adopt block policies to provide well landscaped and ventilated pedestrian and bike routes, permeable pavements and green intermediary spaces that mitigate UHI (Urban Heat Island). Studies in Singapore have demonstrated that green areas reduced the average air temperature by 1.3°C (Aflaki, et al., 2016).

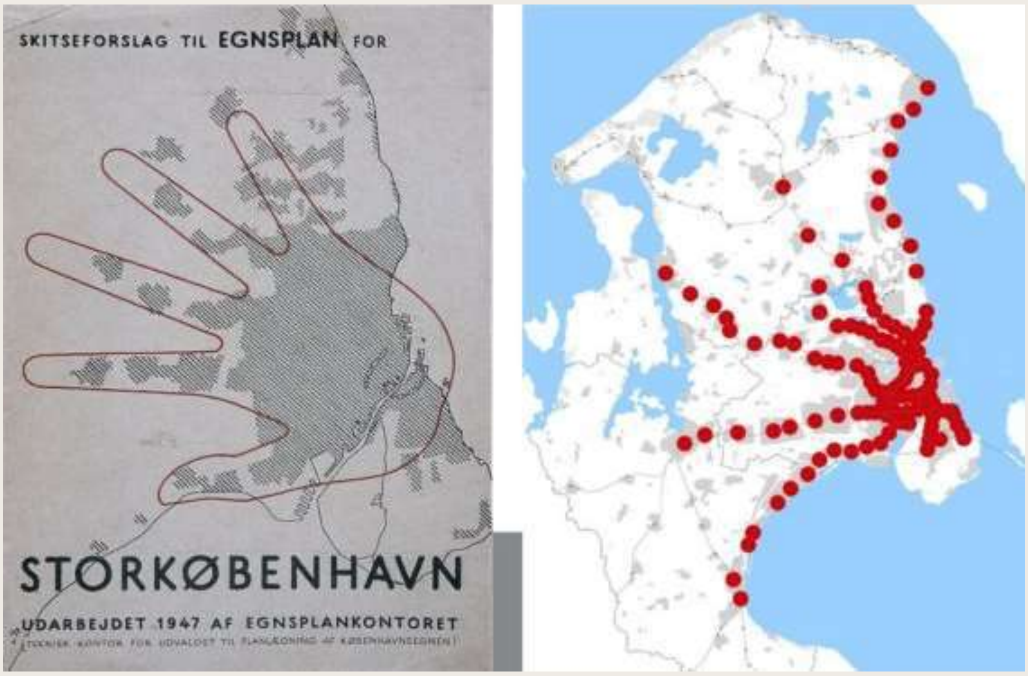
Natural ecosystems also play an important role in reducing flood risks by retaining flood waters and allowing water absorption thereby recharging ground water tables and increasing the fresh water quantity, quality, and reliability (Erwin, 2018). At Singapore's Bishan Park, a 2,7 km straight concrete drainage channel was restored into a sinuous, 3,2 km long natural river in 2012, which meanders through the park. After redevelopment, the naturalised river's carrying capacity increased by 40%. The river system now accommodates fluctuating water levels and protects surrounding built up areas from flooding during heavy precipitations (Zheng, 2017). As part of its Sponge Cities program, China increasingly focuses on revitalising natural ecosystems to collect and manage storm water: restored wetlands, rain gardens or bio swales, permeable pavements and subsurface detention systems all facilitate the natural movement of water, and help runoff and infiltration into the ground (Gallego-Lizón, 2017).

Pioneering TOD interventions in Europe, the celebrated 'Finger Plan' of Copenhagen and the 'Planetary Cluster Plan' of Stockholm, both defined corridors for channelling overspill growth

Copenhagen TOD policies for long term sustainable urban development

An example of **long-range planning visions shaping TOD**, which in turn shaped urban growth, comes from Copenhagen, with its celebrated "finger plan" that was proposed as early as 1947. Planners identified corridors for channelling overspill growth from the urban centres. Rail infrastructure was built, often in advance of demand, to steer growth along desired growth axes. Copenhagen has adopted a **3/3 mobility policy**: at least 1/3 of trips are to be made by public transport, at least 1/3 by bike, and at most 1/3 by car (Als, n.d.).

More importantly, **designated greenbelt lands were set aside** as agricultural preserves, open spaces, and natural habitats and accordingly major infrastructure was directed away from these districts (Curtis, et al., 2009). Copenhagen takes full advantage of its forests, farmlands and open green spaces by limiting development along transit corridors, thereby maintaining a favourable ecological urban environment and mitigating urban sprawl. Integrating transit and land use and discouraging private car use has been an important step in land-constrained, low-lying Denmark that is vulnerable to the rising sea levels because of climate change (Suzuki, et al., 2013, p. 189). After the 2011 '100 year cloudburst' that caused damage totalling more than DKK 6 billion, **a long term Cloudburst Management Plan 2012 has been devised to be fully adaptive with the TOD and other infrastructure initiatives** such as new roads, bridges, or public spaces as well as green and blue climate initiatives, to ensure a common plan can be implemented (Climate-Adapt EEA, 2016).



6: Finger Plan 1947-2007. Source: (Als, n.d.)

from the urban centres early in the planning process, and rail infrastructure was built in advance of the demand to steer growth along desired growth axes.

Natural ecosystems preserved through TOD planning - Singapore

In Singapore, the **Concept Plan** is a strategic, long-term integrated land use and transportation plan that guides the city development for 40 to 50 years, reviewed every 10 years. The Concept Plan holistically maps out Singapore's urban development: it determines locations for major infrastructure projects (e.g. the MRT Network, reservoirs), future housing, commercial and industrial clusters. Green and blue spaces (e.g. nature reserves, parks and open spaces) are safeguarded as part of the Concept Plan (Bin, 2013). The first Concept Plan was prepared in 1971 and the MRT network opened in 1987. Subsequently, the task of revising the Concept Plan and taking up further TOD development was placed under a single authority founded in 1989: the Urban Redevelopment Authority.

TOD allowed Singapore to preserve its natural ecosystems while directing development to low risk zones. Green cover increased by 1/3 between 1986 and 2007 (NParks , 2016). This approach helped Singapore reduce its flood prone area from 3,178 ha in 1970s to only 34 ha in 2013 (IWRM, 2014). The ND Gain index, which ranks countries on their ability to leverage investments and convert them to climate adaptation actions, places Singapore on the top of the list (ND-GAIN, 2018).

- ***TOD ensures better food security***

Compact development measures contribute to preserving urban agriculture. In the Chinese Pearl River Delta, massive agricultural land was consumed by urban development in the early 1990s. For example, 'paddy production in Dongguan in the Pearl River Delta in Southern China dropped by 63% in 1979-94'. Nearly 25% of the total area of Dongguan had undergone changes in 1988-93. In contrast, only 3.2% land use change occurred in transit oriented compact development Hong Kong between 1987-95 (Gar-on Yeh, 2002). Hong Kong used 10% of its total area to produce 45% of fresh vegetables, 15% of pigs, and 68% of chicken consumed by its population in the 1990s. Singapore grew 25% of the vegetables consumed by its population, in the same period (Yeung, 1988). As a co-benefit, urban agriculture contributes to disaster risk reduction and climate adaptation by reducing water runoff, keeping flood plains free from impervious built surfaces, reducing urban temperatures, capturing dust and CO2. This comes along with a major mitigation benefit: growing fresh food close to consumers reduces energy spent on freight, cooling, processing and packaging, whilst potentially reusing urban organic waste and wastewater productively (RUAF Foundation, 2018).

- ***TOD helps locate major transportation nodes, high density areas and critical infrastructure in less vulnerable areas***

A TOD design requires a thorough holistic assessment of the city: not only densities, mobility patterns, activity hubs but also topography, hydrology, climate and related potential vulnerabilities. Since TOD calls for major investments, present and future vulnerabilities are thoroughly taken into consideration when laying out transportation nodes and roads. This approach leads a number of climate adaptation benefits: high population densities can divert to less hazard exposed areas and these can provide refuge to more exposed citizens or, if required, people located in highly connected zones can, on the contrary, shift to a safer location faster (Salat & Ollivier, 2017).

- ***TOD improves accessibility and evacuation networks***

Accessibility may prove critical when a disaster hits the city. As demonstrated above, **major transit routes are usually located in safer city areas** and are efficiently linked to more remote neighbourhoods. This structural set up can be very effectively complemented with non-structural components. For example, transit control rooms for metro networks or bus traffic monitoring systems can be linked to emergency operations centres so that they circulate real-time information on the movements of both passenger vehicles and buses, and identify chokepoints during disasters.

Houston’s transportation authority, METRO, has set up an agreement with the neighbouring island town of Galveston stating that in the event of a hurricane, METRO will help evacuate Galveston residents located in vulnerable storm surge zones. During hurricane Rita (2005), METRO evacuated individuals from Galveston and Houston, arranged for supplementary rail services using other regional passenger rail agencies Amtrak and Trinity’s (Dallas commuter rail) railroad facilities for evacuations, provided support to stranded motorists on freeways, and offered shelter and basic amenities to METRO’s affected employees and their families. METRO used 500 buses and 500 other vehicles to transport 20,000 individuals to safe areas in 4,500 trips. (TRB, 2008, p. 85).

To take an Asian example, residents of R+P developments in Hong Kong value the fact that they can commute without getting wet during typhoons and storms (Leong, 2016). Given high typhoon vulnerability of several coastal cities in Asia, TOD developments that address evacuation processes and emergency relief can notably minimise damages for its vulnerable populations.

- ***TOD investments are de facto pro-poor and pro-vulnerable populations’ investments***.

Housing infrastructure through TOD investments mitigates climate vulnerability of poor urban dwellers who often choose to be located in vulnerable areas in order to remain within an easy access to job opportunities. Indeed, high land value does not allow poor and informal settlers to rent accommodation in well protected areas, however often these areas are surrounded with low land value vulnerable areas. The matter is worsened by the use of cheap and non-adapted to climate hazards construction materials. In Bangkok’s Khlong Toei slum, 100,000 poor urban dwellers live in makeshift tin shack houses just minutes away from luxurious malls, expat bars, high-end hotels, parks and its Stock Exchange that provide them livelihood opportunities. Khlong Toei is extremely susceptible to floods due to its location in a low lying port area, inadequate storm water drainage and substandard living conditions (Sapsuwan, 2014). As a result, the poor pay the highest part of the burden related to extreme weather event damages. In the Philippines, poor urban households suffered 90% of the USD 4.3 billion damages caused by Typhoon Ketsana in 2009. Similarly, during the 2011 floods, a third of Bangkok’s population was directly affected, but this included two-thirds of the city’s poor (UN-HABITAT, 2014).

TOD connects low income populations to jobs by providing an efficient, rapid and affordable transportation on one side and through **creating more equitable socially mixed neighbourhoods** on the other side. The Housing and Development Board (HDB) website reports that over 80% of Singapore’s population reside in publicly governed and developed housing. These residential complexes are part of planned transit oriented districts (IBI Group, 2014). In addition, developers are provided incentives such as density bonus, parking space reduction or higher FARs to include mixed income housing.

- ***Climate adaptation through TOD carries a large number of co-benefits***

Climate adaptation through **TOD comes with valuable co-benefits**, such as optimisation of local spendings, climate mitigation, reduction of air pollution and congestion, improved health, placemaking and wellbeing.

Creating networks of dense, walkable communities greatly **reduces the energy consumption** in cities. A family moving from a drivable suburban house to a walkable urban place can reduce its energy usage and GHG emissions by 50-80% (Leinberger, 2012).

TOD helps local governments **optimise scarce municipal funds** by saving on building roads, flyovers and parking spaces, and even helps generate additional revenues. For example, land value capture in Hong Kong brought in about HKD140 billion revenues between 1980 and 2005, and unlocked land for 600,000 public housing units (Salat & Ollivier, 2017). Cities that introduced TOD tend to increase and concentrate real estate values in the best-connected areas and are more competitive than other cities, as a result of agglomeration effects. At the city level, transit investment can have twice the economic benefit than a highway investment. A double-track light rail system occupies 50 times **less urban space** than highways and parking needs for cars. (Newman & Kenworthy, 1996). At the household level, **disposable incomes saved** on buying a car can be channelized towards household level adaptation and mitigation measures such as rain water harvesting systems or solar panels. This approach works even better when incentivised by government support, such as subsidies or tax incentives.

Mixed land use coupled with a continuous passenger flow near transit stations allow for a range of daytime and night-time amenities, creating **active streets** throughout the day. This means ‘more eyes’ on the street, making cities safer for women and children. Community amenities such as shops, cafes, groceries and open spaces on the ground floor of residential buildings mean greater convenience for those living around, along with more opportunities for neighbours to meet and interact with one another adding to the urban social fabric. These are only some co-benefits that TOD brings to urban environments. As a result, planners and urbanists have been worldwide recognised TOD as a viable development model for cities in developing cities.

Conclusion

As demonstrated above, TOD interventions have a number of features that directly contribute to strengthening climate adaptation. Investments made into TOD are investments made into an overall socio-economic environmentally sustainable development, which is an essential priority for developing Asian cities. These are hence synergized investments, which makes it easier to address the funding challenge. Looking at TOD as a climate adaptation strategy may therefore be considered as a pragmatic and achievable model.

Successful TOD implementation requires strong management and governance, co-ordination between stakeholders and significant financial investments over time. These pose political, fiscal and operational challenges in low and middle income Asian nations that may face difficulties with the above due to complex inter-governmental structures, political economy, weak leadership and a narrow access to funding. These challenges and potential solutions are examined in more details in the up-coming related paper. Meanwhile, learning and strategizing based on successful TOD business and operating models while targeting climate adaptation can be adopted in association with private investors and international development institutions.

Do High-Speed Trains improve the urban economy? Evidence from the Yangtze River Delta

Yi FENG, Nanjing University, China

Abstract:

High-Speed Trains vastly improve traffic connections among cities and have significant impact on the regional spatial structure. On the one hand, high-speed trains bring new opportunity for urban economic development; on the other, for cities less competitive, high-speed rail may exacerbate the resources flow and become a new challenge for municipal development.
China pays attention to high-speed railway construction since the 21st century and soon plays a leading role in the world. In this essay, the Yangtze river delta is chosen as the research object to examine whether high-speed trains improve the urban economy or not.
The quantitative model is modified from CD production function. The dependent variable is GDP in every city in each year. Three basic variables are: fixed asset investment, labor, and the proportion of tertiary industry. This study includes two observation variables: railway passenger flow and whether there is HST this year (dumb variable). Based on data from 24 cities from 2009 to 2016, I use a regression model to analyze the economic impact of HST in YRD. As a result, the overall construction of HST has a positive impact on urban economic development, but this effect is not significant for non-first-tier cities.

1. Introduction

High-Speed Trains (in short, HSTs) vastly improve traffic connections among cities and have significant impact on the regional spatial structure. It has become a hot topic in the field of economic geography for a long time that whether the high-speed trains improve urban economy or not. In China, the first HST line, Beijing-Tianjing HST line was open to traffic in 2008, which signals a revolution in the regional transit system.
Passed by HST line means that the city has been incorporated into a more efficient economic network, and thus it has become an important strategic resource in the competition among major cities. But on the other hand, many scholars mention that the construction of HST has adverse effects, that aggravates the outflow of resources for some cities. The effect of high-speed trains on the economic growth of cities along the lines becomes a heated topic. I will examine this effect by observing the Yangtze River Delta area and base on panel data from 2006 to 2016.

2. Literature review

2.1 high speed trains construction in China

"High speed" is a relative concept compared to the speed of ordinary railways. The definition of high speed railways varies in different countries. The State Railway Administration of China defines the High-Speed Train as: trains designed to 250km/h (including the upgraded ones) and more EMU trains, and the initial operation speed is not less than 200 km/h.
The construction of HST in the world started in Japan. In 1964, Tokyo-Osaka's Shinkansen was the first HST line with a speed of 210km/h, making a day trip possible between Tokyo and Osaka. In 1981, the first TGV high-speed train line opened in France, connecting Paris with Lyon and running at 270km/h. Subsequently, the HST lines in Germany, Spain and other countries have been opened, including not only the newly built HST lines, but also the

upgraded lines based on the original railways. The HST has become the core issue attracting global attention in the second half of the twentieth Century, bringing the second railway age.
In twenty-first Century, China began to focus on high-speed and large volume railway construction and put it into practice quickly. The State Council of China depicted "four vertical and four horizontal" passenger HST lines in the Medium and Long Term Railway Network Plan, released in 2004. In 2009, Wuhan-Guangzhou HST marked the High-Speed Train Era in China with the speed of 394km/h. A global report by the world bank compared the construction of HST all over the world, as showed in the figure 1 and 2. HST construction of China quickly surpassing the developed countries in Europe and the United States. China becomes the country with the longest mileage of HST in the world.

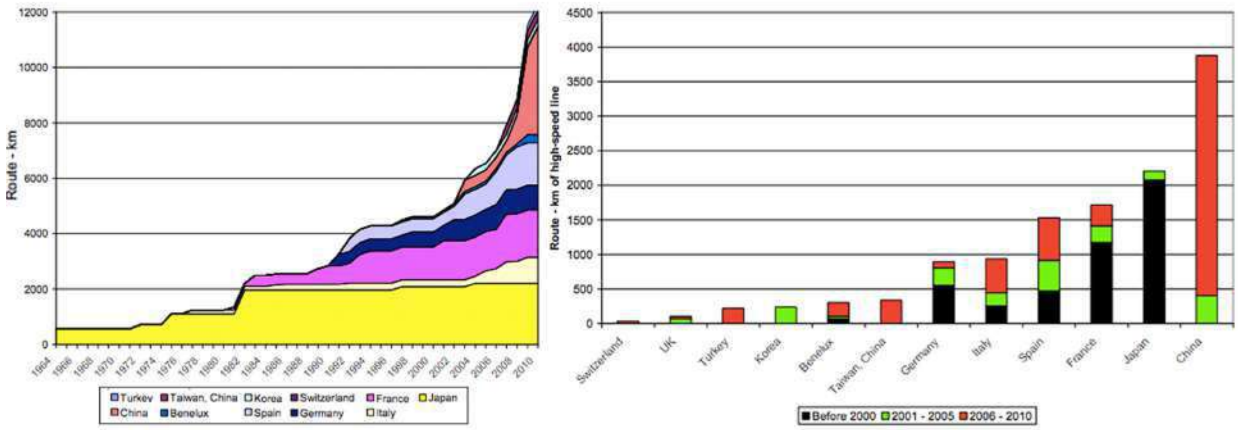

Figure 1-2: The world's HST mileage 1964-2010; HST mileage increasement 2001-2010 (source: the World Bank report)

However, after ten years of rapid development, the regional disparity of HST construction of China is noteworthy. As Myrdal(1957) said, the more developed regions are, the more attractive they are to attract new investments. In 2012, scholars applied accessibility analysis on national HST lines and found that HST network can improve the accessibility of the whole country, but the promotion of accessibility is not balanced nationwide. They expected that with the expansion of HST construction to the west, it may be more balanced. Based on National High-Speed Rail data and GDP data in 2014 compared with data in 2006, Liu conducted a spatial analysis by GIS and found "corridor effect" along Beijing-Shanghai, Beijing-Guangzhou, Shanghai-Wuhan and Shanghai-Xuzhou-Xi'an. Places with high accessibility gathered near larger cities and HST corridors. Wen (2017) analyzed the influence of HST on the accessibility of Chinese cities on a scale of urban agglomeration. It is proved that the HST construction has the largest impact on the Yangtze River Delta area, and influence on Beijing-Tianjin and the Pearl River Delta followed. In this essay, I will examine the influence on the Yangtze River Delta.

2.2 debates on influence of HST on urban economy

Scholars who believe that the construction of HST promotes local economy explain that the HST lines can enhance the economic ties among cities, and then promote the integration and overall development of the regional economy. The main logic of this conjecture is that the HST strengthens city accessibility, thereby enhancing the regional production factors and ultimately bringing about economic growth. Scholars first proved that with the construction of high-speed rail network, the accessibility of cities has been significantly enhanced. There is an obvious correlation between accessibility and production factors in the region. From the perspective of time and space compression, faster speed redefines the boundary of the interconnected regions, facilitates cooperation in a larger regional market, and expands the scope of the flow

of production factors. Accordingly, some scholars with positive attitudes point out that "there will be an integrated development trend between cities or regions" and may form a "high-speed rail economic belt".
Along with the HST construction nationwide, more and more scholars remind the negative effects of HST construction on the development of cities along the line. For example, Wang Jie(2015) think that "siphon effect" is a major challenge for cities along the high speed rail line, that the lost resources exceed resources being attracted to invest in the target city. The development of regional transport network is a double-edged sword. The convenience brought by HST speeds up the resource flow, and also promote the accumulation of capital, talents and information to the regions with more competence. That is, the HST construction can greatly improve the accessibility of the city and promote the formation of a larger scale of the division of labor, but for some cities, the loss of the elements will also be accelerated.
Since the 70s of the last century, the impact of the construction of high speed rail on the urban economy and the regional economic pattern has attracted wide attention from scholars in Japan, Britain and France. For example, Bonnafous (1987), when studying the impact of French high speed rail (TGV) on the development of Lyon City, pointed out that high speed rail transit provides a new economic vitality for the economic development of Lyon. Pol (2003) also put forward a similar view by a case study in Lille, but at the same time, he believed that only cities with exceedingly economic potential can use the accessibility of large external traffic to improve their own economy. If not, the increase of external traffic accessibility will even bring the backwash effects. Puga (2008) also indicated that the high-speed railway benefited the core cities at the expense of minor cities, exacerbating the regional imbalance.
In China, scholars are still arguing about the effect of China's HST development on the urban economy. Some scholars believe that HST has brought opportunities for some cities, but they never indicate cities gaining profits while others losing fortunes on a scale of urban agglomeration. Some scholars point out that the siphon effect of HST construction has existed but fail to scale the influence, because the duration after HST construction is too short. This study tries to analyze the effect in YRD area, hoping to show the impact of the HST on the economic development of the cities.

3. Research design

3.1 research area

As cited above, the construction of China's HST started from east to west, and the urban agglomeration in the Yangtze River Delta is one of the first agglomerations equipped with HST and the speed of construction is astonishing and the passenger volume is remarkable. Considering the following three reasons, this study chose the Yangtze River Delta as the research object. Firstly, as a world-class urban agglomeration, the YRD is in the forefront of the country with an active market and strong capital flow, thence it is easier to observe the economic adjustment. Secondly, HST construction started relatively early in YRD, which can provide data for this study for a relatively long time. Besides, information and development data of the Yangtze River Delta urban agglomeration are relatively open. According to the development plan of the Yangtze River Delta urban agglomeration in 2016, this area includes Shanghai, 9 cities of Jiangsu province (Nanjing, Wuxi, Changzhou, Suzhou, Nantong, Yancheng, Yangzhou, Zhenjiang, Taizhou), and 8 cities of Zhejiang Province, 8 cities (Hefei, Wuhu, Ma'anshan, Tongling, Anqing, Chuzhou, Chizhou, Xuancheng), as a total of 26 cities. By 2016, 24 cities(except Yancheng, Zhoushan) had been included in the national HST network. In order to compare the relationship between economic development and high-speed rail transport, the panel data in this study ranged from 2006-2016. Finally, 166 objects were obtained, including Shanghai, Nanjing, Hangzhou, Hefei, Ningbo, Taizhou, Jiaxing, Shaoxing, Jinhua, Suzhou, Shanghai, Nanjing, Hangzhou, Hefei, Ningbo, Taizhou, Jinhua, Suzhou, Wuxi, Wuxi, Ningbo, Ningbo, Hangzhou, Hangzhou, Taizhou, Jiaxing, Jinhua, Suzhou.
In the context of China's high-speed rail, I consulted the difference between D line and G line.

High speed railways generally refer to "railway lines" while D line refers to a type of marshalling trains. According to some scholars' textual research, EMU trains run on high-speed railways in Russia, which means that the two concepts are not antagonistic. In China, the difference of high speed rail and motor train is in speed, that the D train runs at 200-300km/h speed while the G high speed rail reaches above 300km/h. According to China Railway Administration, trains running at more than 200km/h are HSTs, so cities with D trains passing through are also calculated in this study. The construction sequence of the Yangtze River Delta high-speed railway is shown in the following table.

Time	Line	Cities (in YRD)
2008	Hefei-Nanjing line	Hefei, Nanjing
2009	Yong-Wen line	Ningbo, Taizhou
2010	Shanghai-Nanjing line	Shanghai, Suzhou, Wuxi, Changzhou, Zhenjiang, Nanjing
2010	Shanghai-Hangzhou line	Shanghai, Jiaxing, Hangzhou
2011	Beijing-Shanghai line	Chuzhou, Nanjing, Zhenjiang, Changzhou, Wuxi, Suzhou,
2013	Hangzhou-Ningbo line	Hangzhou, Shaoxing, Ningbo
2013	Ningbo-Hangzhou line	Nanjing, Changzhou, Huzhou and Hangzhou
2014	Hangzhou-Changsha	Hangzhou, Shaoxing, Jinhua
2015	Hefei-Fuzhou line	Hefei, Tongling, Xuancheng
2015	Jinhua-Wenzhou line	Jinhua
2015	Nanjing-Anqing line	Nanjing, Ma'anshan, Wuhu, Tongling, Chizhou, Anqing
2016	Nanjing-Nantong line	Nanjing, Yangzhou, Taizhou, Nantong

Table1: construction sequence of HST in Yangtze River Delta area

3.2 model and variables

Taking the construction of HST as one of the independent variables, this study uses an econometric model to simulate the development of the urban economy. In the traditional econometric research, CD function is widely used to estimate the development of the urban economy. That is, economic progress is determined by technology, capital and labor force. In the study of economic development in the YRD area, some important conclusions have been obtained by simulation and correction of models. For example, Zhang Xiaodi and Li Xiaozhong (2005) compared the TFP and the growth rate of Jiangsu, Zhejiang and Shanghai in the YRD area, finding that the marketization and internationalization were the main ways to improve the regional efficiency. Zhou Xiaoyan (2009) analyzed the economic growth of the YRD by a stochastic production frontier model. It is believed that the improvement of the urbanization rate, the structure of the second industry, the level of infrastructure and the level of human resources in the second industry will increase the efficiency of production. Zhang Xueliang and Sun Haiming (2009) divided the economic growth of the Yangtze River Delta into four parts: capital accumulation, efficiency improvement, technological progress and human capital input through DEA analysis. It is considered that the dominant economic growth is still the accumulation of material capital, and the second is the accumulation of human capital. At the same time, they found evidence of TFP's leading role in economic growth in Shanghai.

Based on previous studies, this essay modifies CD function. First of all, the economic development of the YRD area mainly depends on the accumulation of capital and labor force. Other factors, such as technological progress, industrial structure and policy advantages, have different degrees of contribution. The first-tier cities, such as Shanghai, are more affected by technological progress. Considering the availability of data, this essay selects three main variables including fixed assets investment, labor quantity and three production proportion. According to the purpose of this study, the statistics of railway passenger flow and whether HST lines passes by are also included. To eliminate heteroscedasticity, I take the logarithm of both sides and the model in this study as follows:

$$lnY_{it} = c + \alpha_1 lnL_{it} + \alpha_2 lnK_{it} + \alpha_3 S_{it} + \alpha_4 lnQ_{it} + \alpha_5 P_{it} + \alpha_t + \beta_i + \varepsilon_{it} \quad (1)$$

The dependent variable Y is the annual gross domestic production (GDP) of each city.
The five independent variables are:
1) Variable L stands for the labor force. The value is the total number of employed persons in various cities at the end of each year.
2) Variable K stands for capital and the value is the total investment in fixed assets of different cities at the end of each year.
3) Variable S stands for the industrial structure and value is the proportion of third industries to the annual gross domestic production.
4) Variable Q stands for the railway passenger flow and the value is the railway passenger volume each city in a year.
5) P is a dumb variable indicating whether HST line passes through this city or not. The value is 1 since the year when HST line passed, which is 0 before this year.

The key variables of observation are: Q_{it} and P_{it}.
If significant positive effects of the dumb variable on economic growth are observed, it proves that HST promote urban economy. Besides, I will further study non-first-tier cities in the YRD area. If significant negative effects of economic growth were observed, it demonstrates significant siphon effect of HST on the non-front-line cities.

4. Results

Firstly, 166 objects are analyzed by a panel regression model. The results are obtained by using the fixed effect and the random effect, and the result of Hausman test is 0.1053. Therefore, the fixed effect estimation is selected (Table 2). According to the results, there is a significant positive effect (95% confidence interval) in labor force, capital input and industrial structure. In addition, within the 95% confidence interval, the railway passenger flow has a significant positive effect on the urban economic development in the YRD area. The dumb variable P has a significant positive effect on the urban economic development in the 90% confidence interval. Therefore, generally speaking, HST construction has positive effects on urban development.

Variable	estimated coefficients	standard deviation	P value
L	0.948	0.111	0.000
K	0.346	0.035	0.000
Q	0.110	0.035	0.002
S	1.894	0.351	0.000
P	0.053	0.032	0.100

Table2: Results of economic development and HST construction in Yangtze River Delta

Then the panel data of non-first-tier cities is analyzed. 12 cities, including Hefei, Ningbo, Taizhou, Jiaxing, Shaoxing, Jinhua, Wuxi, Changzhou, Zhenjiang, Wuhu, Ma'anshan and Nantong, are selected for further regression. The amount of objects is 111. Through Hausman test, p value is 0.0215, and thence this part chooses fixed effect regression model, and the estimated results are shown in Table 3.

Variable	estimated coefficients	standard deviation	P value
L	1.354	0.149	0.000
K	0.261	0.043	0.000
Q	0.070	0.043	0.104
S	2.953	0.494	0.000
P	0.018	0.042	0.668

Table3: Results of economic development and HST construction effect of non-first-tier cities in YRD

According to panel regression analysis, labor force, fixed capital and industrial structure have significant positive effects on the economic development of non-first-tier cities. In the 90% confidence interval, railway passenger flow has positive effects on the urban economic development. However, the dumb variable doesn't show a significant economic contribution. That is, for non-first-tier cities, the effect of HST on urban economic development is not significant.

5. Conclusion and discussion

This essay first analyzes the impact of HST construction on the economic development of cities theoretically. Due to the significant spatial compression effect, HST construction is conducive to the economic cooperation and development of cities along the line, but the risk of resources outflow of non-first-tier cities is also increasing. Further, I conduct an empirical test based on panel data of Yangtze River Delta area for 11 years. The results show that the overall construction of HST has a positive effect on urban economic development, but this effect is not significant for non-first-tier cities.

The results of this empirical analysis reflect the complex effects of HST construction on urban economic development. For cities with superior economic development and strong resource competitiveness, they can easily benefit from high-speed railway stations. For non-first-tier cities, the construction of HST does not have a significant positive effect on urban economy, perhaps because of the "siphon effect", but the negative effect on economic development has not been found in the empirical analysis either. Perhaps for the YRD urban agglomeration, HST construction can promote the restructuring of the urban agglomeration economic structure, but the specific effects need to be further observed.

However, there are still many deficiencies in data analysis, which include three aspects: sample selection, variables and time effect.

Firstly, the total amount of data selected in this paper is small. Although the Yangtze River Delta's HST construction is at the forefront of the country, many cities only have high-speed rail after 2010. In order to expand the number of samples and form a contrast, this paper extends the time of panel data to 2006-2016 years, but the time of high speed rail in some cities is too short, which is unfavorable to the analysis of panel data. In addition, the difficulty of obtaining urban statistical data leads to the lack of many samples, resulting in a smaller data range.

Secondly, the selection of variables is limited by data availability. For the economic development of the urban agglomeration in the YRD, labor, capital and land are important factors, but the influence of policy, innovation and technological revolution is also significant. In the previous study, some scholars pointed out that only Shanghai has found the significant influence of policy and technological innovation on the economic development. Therefore, in this research, the model is simplified, and these kind of variables are not included.

Thirdly, in the result of the quantitative analysis, the construction of HST has no significant effect on non-first-tier cities. This conclusion also needs further observation. For some cities, after the high-speed rail operation in 2014, there is not sufficient data in this study, which needs further observation and analysis.

Urban Mobility in Transition: Perspectives and Challenges on Urban Living and Public Spaces in China

Moderator: GOETHALS, Sebastian (Vice President ISOCARP)

Speakers: PAN, Haixiao (Tongji University); WANG, Hongyang (Nanjing University, China)

ABSTRACT:

Automated and shared vehicles and mobility services – combined with electrification and connectivity – are about to transform our daily commuting habits and energy consumption modes in the urban and rural landscapes.

The traditional competition between private and public transport in cities is now challenged by the rapid emergence of “Mobility as a Service” (MaaS), including the sharing and hailing of not only cars and bikes but also buses, shuttles and parking spaces.

Since digital connectivity has opened new windows of opportunities for communities and commuters through the sharing economy, the way we use together and individually our streets and public spaces might be less segmented and informal, as a result of real-time and collective decision-making.

An optimized scenario of mobility revolution, integrating automation, sharing and electrification by 2050, presents a reduction from 4,600 to 700 megatons of CO_2 and from 2,1 to 0,5 billion vehicles worldwide.

A few cities are now starting to test smart mobility systems, but most of them dramatically lack of urban planning strategies in terms of integration of public transport and new mobility services, public spaces and parking management.

Chinese cities have recently become vast laboratories of mobility innovation and digitization. While large projects of urban mass transit networks have flourished across the country, multiple forms of car/bike sharing and hailing have appeared. In July 2016, the Chinese Ministry of Transport published the 13th Five-Year Plan on developing a smart urban mobility infrastructure, with the wish to integrate mass transit, electrification of vehicles and mobility services, especially the last-mile transport services, such as community shuttles, bike-sharing and smart parking and streets for all modes.

The session proposes to identify the major coming trends and challenges of the urban mobility revolution in Chinese mega-cities, approaching this complex transition from the experience of daily commuters and local planners involved in the session.

The first part of the session includes the introduction of the research topic and the presentation of five Chinese case studies of urban transport policies. Five Chinese urban planners will then witness their professional and commuter’s experience of the transforming urban mobility landscape in Beijing, Jinan, Ningbo, Nanjing and Guangzhou.

The third and last part of the session will be dedicated to a rapid visioning by the session participants of integrated solutions for healthy and smart mobility, public spaces and streets in Chinese cities, putting in perspective the role of city planners in the technological transition of cities.

How to develop a new public service

Moderator and Speaker: GUSCHL, Larissa (Urban planner based at participatory planning and design office WeloveTheCity, Rotterdam, The Netherlands)

ABSTRACT:

Citizens have plenty of ideas for the neighbourhood in which they live, work and play. Unfortunately, they don't always have access to the right information to develop their ideas into a concrete proposal. That's why Freie und Hansestadt Hamburg, Roma Capitale and The Royal Borough of Kensington and Chelsea want to share a combination of open data and expert knowledge. The smarticipate platform allows citizens, entrepreneurs, NGOs and city officials to submit their proposal for a sustainable neighbourhood and to receive immediate feedback. This means everyone can get involved, even those who have never interacted with local government before.

Smarticipate is based on a co-creation strategy which consists of three complementary concepts: Urban story, Smartathon and Smart Implementer Summit. This strategy resulted in three prototypes (Plant a Tree App, Urban Transformation App, 3D Planning App) which where tested by more than 350 participants in the pilot cities. During these testing sessions, or Smartathons, several citizens and entrepreneurs demanded to have access to the technological core of the digital platform. These so-called 'smart implementers' want to plug in their own topic like:

New Public Service
Improving cycle infrastructure
The German cyclist's association (ADFC) comprises 165.000 members. They are triggered by smarticipate's immediate feedback function and want to plug in their own topic: a better cycle infrastructure in the Hamburg Metropolitan Region. This brand new application should mobilize their members to come up with realistic proposals for infrastructural improvements like more 30 km roads, handy short-cuts and car free school zones.

New Public Service
Locating water pumps
The Dutch development aid organization (Cordaid) works in more than 50 urban slum areas in Africa and Asia. They also see the potential of smarticipate's immediate feedback function, especially in combination with its location-based feature. Their topic: finding the best locations for water pumps. This application, which will be based on an existing prototype / Plant a Tree App, should mobilize slum dwellers to point out the right spots for this essential piece of urban infrastructure.

We will invite all conference participants in Bodø to test the smarticipate prototypes. Besides that, we will challenge them to think about which kind of New Public Service they would like to introduce and how the smarticipate platform could help them in achieving that goal.

The smarticipate project is funded under the Horizon 2020 research and innovation programme under grant agreement No 693729. It runs from February 2016 to January 2019. For more information, check www.smarticipate.eu

Land Suitability Evaluation for Resilient Urban Planning: a Planning Practice of Pingdingshan City, China

Xin KAI, Shanghai Tongji Urban Planning & Design Institute, China

1. Introduction

1.1 Resilient urban planning

Cities are increasingly becoming complex systems of social, economic and ecological factors. However, they are very vulnerable when any of their subsystems are destroyed or fail to adapt to new challenges (Xiaoling Zhang, 2018). From 2005 to 2010, the world's urban population increased at a rate of 1.9%. Rapid urbanization and growing mega-cities point to a need for more resilient cities that have the capacity to withstand the shocks of population growth, rapid demographic shifts in population, and environmental catastrophes (Kevin C., 2013). Thus, fostering resilience gradually becomes an important goal for urban planning.

The concept of resilience has traditionally been used in physics and psychology to respectively indicate the ability of an object to return to its original position after receiving a hit and the ability to successfully survive a shock or trauma. It was first introduced into ecology in 1973 by Holling who described it as a measure of the ability of systems to absorb change and disturbance without losing the pre-disturbance relationships between their constituent elements (Ayyoob Sharifia, 2014). Resilience in terms of cities generally refers to the capacity of a city to rebound from destruction (ARUP, 2016), the ability to absorb, adapt and respond to changes in an urban system (Kevin C., 2013).

Urban resilience is divided into several main aspects that cover ecological, infrastructural, economic and social dimensions. The *Rockefeller Foundation* carried out a research about *city resilience index* in 2016, the result shows that the resilience of a city relates to 4 key dimensions, including people, organisation, place and knowledge. Underpinning these four dimensions, 12 goals are defined to represent the city's immune system (Tab.1). This paper is mainly concerned with the place dimension, the quality of infrastructure and ecosystems that protects, provide and connect people.

Table 1: The dimension and goals of city resilience

Dimension	**Goals**
People: health & wellbeing	Minimal human vulnerability, Diverse livelihoods & employment, Effective safeguards to human health & life
Organisation: economy & society	Collective identity & community support, Comprehensive security & rule of law, Sustainable economy
Place: Infrastructure & ecosystems	Reduced exposure & fragility, Effective provision of critical services, reliable mobility & communications
Knowledge: Leadership & strategy	Effective leadership & management, Empowered stakeholders; Integrated development planning

1.2 Land suitability evaluation

Land suitability evaluation processes, the bases to guide the urban planning, are essential for assessing and reacting to land conditions, opportunities, and threats for urban planning. The reasonable and orderly land suitability evaluation is of great significance for ordering spatial development, guiding population resource environments and ensuring socio-economic resilient development.

The *Urbanization work conference of CPC Central Committee* in 2013 paid high attention to the improvement of ecological-living-industrial space, which means reducing industrial land, appropriate increasing living land, and delineating ecological protection red lines for agricultural space such as cultivated land, garden land, vegetable fields. Wu Yanjuan (2016) built a land suitability evaluation framework from the perspective of the ecological-living-industrial function of land resources.

Table 2: Ecological-living-industrial land classification system

Classification		**Details**
Ecological land	Important land	Conservation land for water, soil, wind and sand fixation, flood regulation, riparian protection and biodiversity, including forest land, shrub land, woodlands, grasslands, pond water, beach coating, inland tidal flats, ditches, glaciers and permanent snow land
	General land	Saline-alkali land, swamps, sand and bare land
Industrial land	Agricultural land	Paddy fields, dry land, gardens, agricultural facilities land
	Industrial land	Mining land
Living land	Urban land	Cities, towns, scenic spots, railways, highways, airports, port terminals, pipeline transportation, reservoir water and hydraulic construction land
	Rural land	Village, rural road land

Source: WU Yanjuan, YANG Yanzhao, YANG Ling, ZHANG Chao, YOU Zhen（2016）"Land spatial development and suitability for city construction based on ecological-living-industrial space——take Ningbo City as an example", Resources Science, Vol.38: 2072-2081

1.3 Research purposes and methodology

The aim of this research is to propose a land suitability evaluation for resilient urban planning and applied it to the planning practice of Pingdingshan City, China. The methodological approaches of the Multi-Criteria Decision Analysis, Analytical Hierarchy Process and Delphi Process were used for the research. And the evaluation process is supported by a geographical information system (GIS) within the framework of ArcGIS software, combined with the Remote Sensing Image processed by ENVI (The Environment for Visualizing Images) software.

1.4 Research framework

The land suitability evaluation involves natural, agricultural and urban ecosystem resilience. From the aspect of natural ecosystem resilience, the evaluation involves three factors, including forest vegetation factor (vegetation coverage index, vegetation type index), river & reservoir factor (water level index, water quality grade index) and animal factor (biodiversity index). In the dimension of agricultural ecosystem resilience, two factors are considered, including crop factor (agricultural output value index) and farmland factor (Prime cropland area index). As for the urban ecosystem resilience, urban construction factor (elevation index, slope index, land-use situation index) and urban disaster factor (geological subside disaster index, flood disaster index) are selected. Finally, put forward resilient urban planning based on the result of land suitability evaluation (Fig.1).

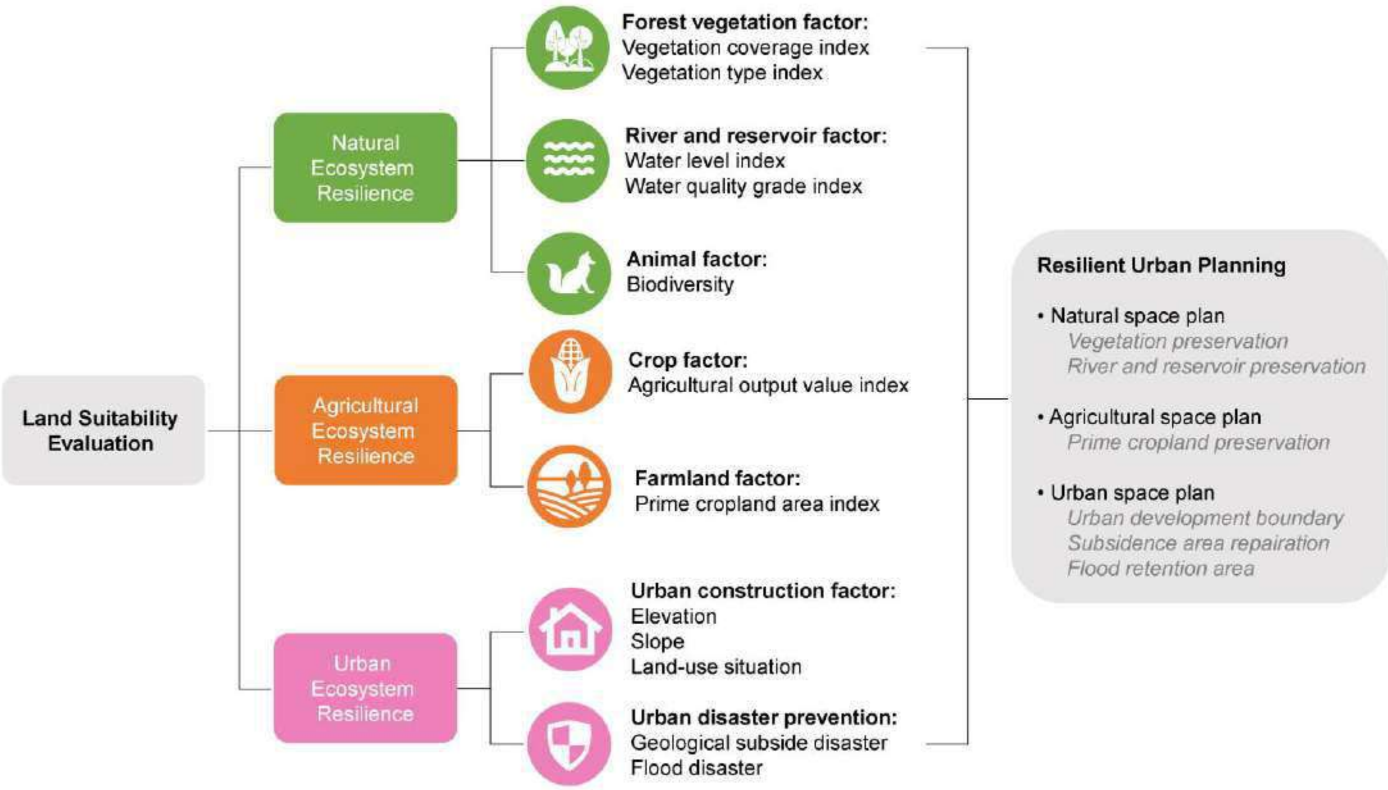

Figure 1: Research structure of land suitability evaluation

2. Land Suitability Evaluation for Pingdingshan City, China

2.1 Study area

Pingdingshan is a prefecture-level city covered 7,882 square kilometers in central Henan province, China. The city had 4,048 thousand inhabitants in 2016, 52.5% of whom lived in the urban area. Compared to similar inland cities, Pindingshan is very rich in water and ecological resources, and 42% area of the city are mountains and hills. But the urban economy has mostly relied on coal mineral exploitation for four decades, causing irreversible damage to the environment. Therefore, the planning of Pindingshan urgently needs a resilient and holistic approach of urban development and land use.

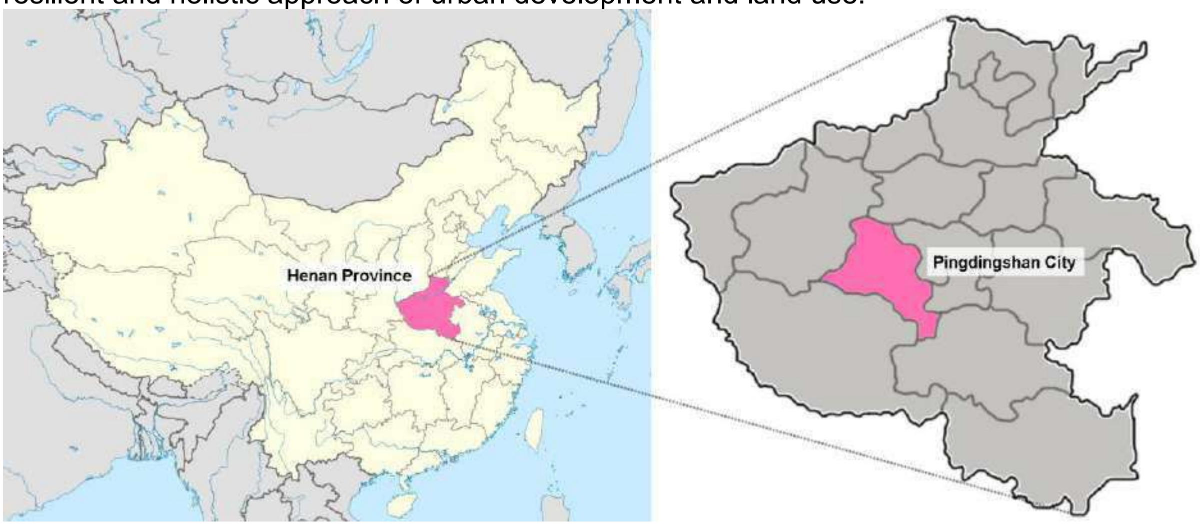

Figure 2: Location of Pingdingshan

2.2 Natural Ecosystem Resilience

For the forest vegetation factor, the area with important vegetation and high forest coverage need protecting. Normalized difference vegetation index (NDVI) was used to assess whether the area being observed contains live green vegetation or not. The formula is NDVI=(NIR-R)/(NIR+R), NIR means near infrared reflectance, and R means red reflectance. And based on the remote sensing image processed by ENVI (The Environment for Visualizing Images) software, the different area of coverage level was identified (Fig.3). Combination with the analysis of different vegetation type layout (Fig.4), the result shows that the western area of Pingdingshan has precious high coverage vegetation, which need strictly protecting. The northern and southern area of Pingdingshan has precious vegetation too, but the coverage rate is low, therefore these areas urgently need to be planed into the protection zone.

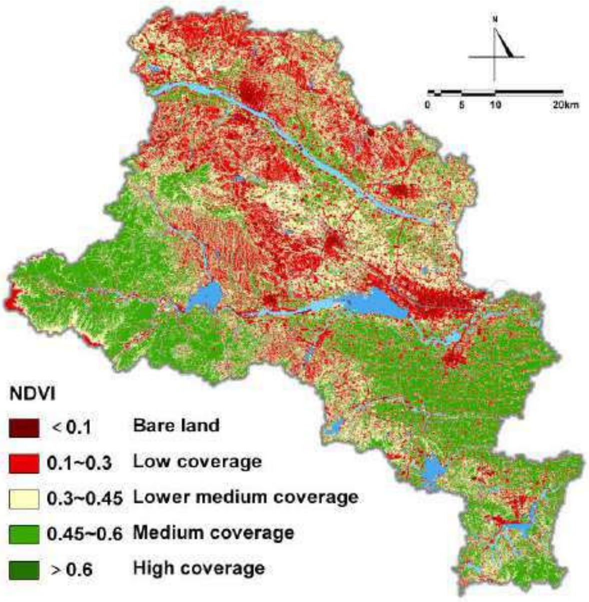

Figure 3: Vegetation coverage

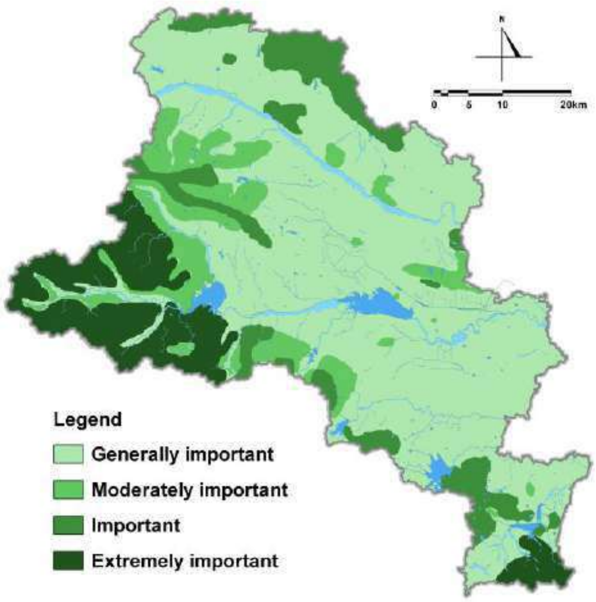

Figure 4: Layout of different vegetation type

Table 3: Importance of vegetation type

Grading standards	**Importance**
farmland, waters, wetlands	generally important
sparse shrubbery, subtropical economic forest, subtropical bamboo forest, low-to-medium coverage grassland, evergreen orchard	moderately important
subtropical broad-leaved or deciduous shrubs, high-coverage grasslands	important
natural or natural secondary subtropical evergreen broad-leaved forest, deciduous broad-leaved mixed forest, subtropical coniferous forests, evergreen deciduous coniferous broad-leaved mixed forest	extremely important

Source: Chang Bin et. al, 2014

For the river and reservoir factor, the quality, volume and grade of water are considered. And the water surrounding urban built-up area faced with serious pollution (Fig.5). One canal, five reservoirs and eight rivers are key protected objectives (Fig.6), which need strictly protection measures.

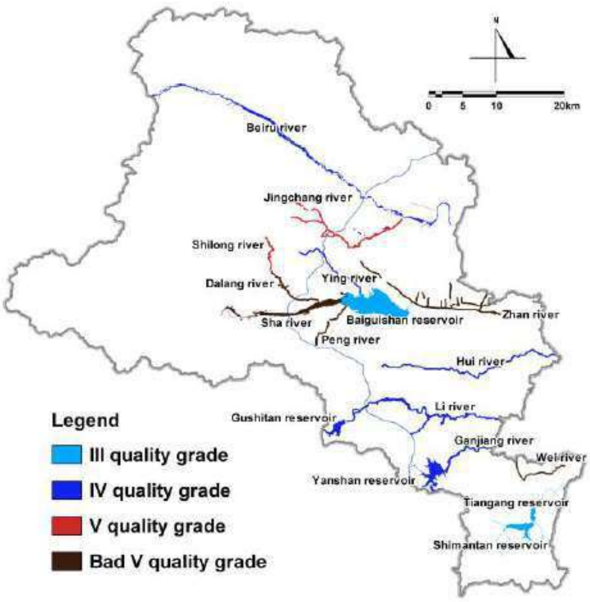

Figure 5: Water quality of river and reservoir

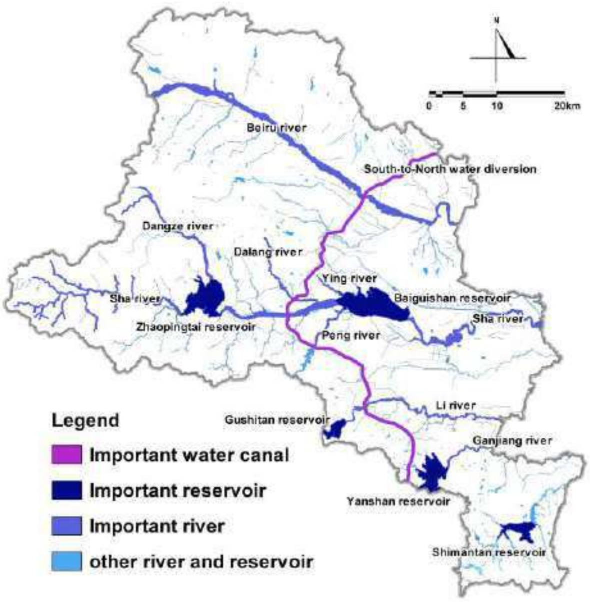

Figure 6: Important river and reservoir

Table 4: Water quality of river and reservoir

Water quality grade	**The water and reservoir in Pingdingshan**
III quality grade	Baiguishan reservoir, Tiangang reservoir, Shimantan reservoir
IV quality grade	Beiru river, Ying river, Hui river, Li river, Ganjiang river, Gushitan reservoir, Yanshan reservoir
V quality grade	Shilong river, Jingchagn river
Bad V quality grade	Dalang river, Sha river, Peng river, Zhan river, Wei river

Table 5: The protection area for important water resource

Water resource	**Protection area**	**The water and reservoir in Pingdingshan**
water canal	200m land area on both sides of canal	south-to-north water diversion
reservoir	200m land area surround reservoir	Baiguishan, Zhaopingtai, Gushitan, Shimantan, Yanshan
river	100m land area on both sides of river	Ganjiang, Li, Sha, Beiru, Dangze, Peng, Ying, Dalang

Source: Pingdingshan Municipal Water Conservancy Bureau (2015) The "13th Five-Year" plan for the development of water conservancy in Pingdingshan

For the animal factor, based on biodiversity survey data, identifying the priority species living areas, assess the conservation of ecological diversity. The western and northern areas of Pingdingshan with diversity ecosystem types and species, require strict protection (Fig.7).

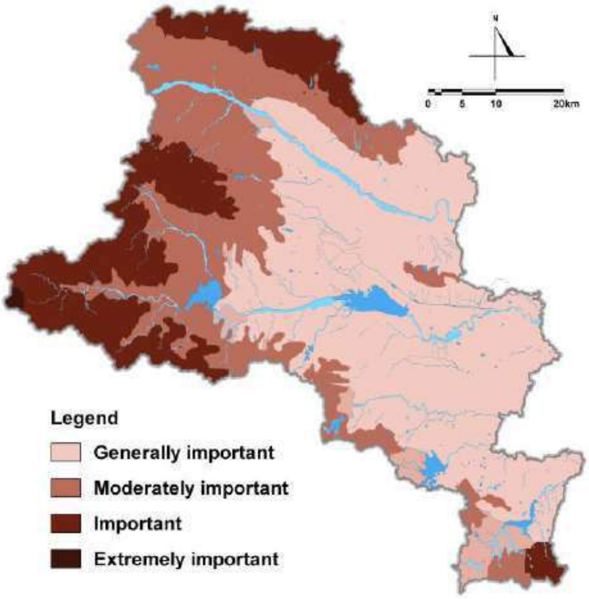

Figure 7: Importance of biodiversity

Table 6: Importance of biodiversity

The ratio of biological species to the total number of species in the city	**Importance**
Species ratio < 5%	generally important
5% < Species ratio < 15%	moderately important
15% < Species ratio < 30%	important
Species ratio > 30%	extremely important

Source: Chang Bin et. al, 2014

2.3 Agricultural Ecosystem Resilience

For the agricultural factors, the output value of agriculture, forestry, animal husbandry and fishery per unit area represents the capacity of agricultural production. The higher output of agriculture area has higher agricultural value, where is not suitable for large-scale construction (Fig.8).

Figure 8: Importance of agricultural output

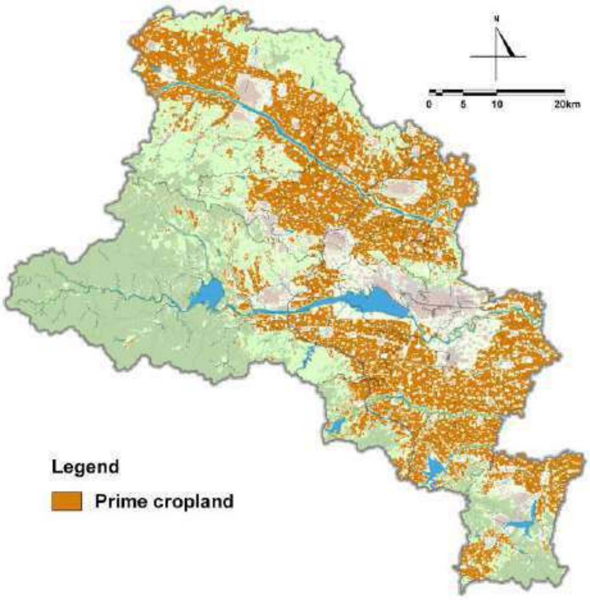

Figure 9: Layout of prime cropland

Table 7: Importance of vegetation type

Production value of agriculture, forestry, animal husbandry and fishery per unit area (10,000 yuan/km2)	**Importance**
production value per unit area＜100	generally important
100＜production value per unit area＜200	moderately important
200＜production value per unit area＜300	important
300＜production value per unit area	extremely important

Source: Chang Bin et. al, 2014

2.4 Urban Ecosystem Resilience

For the urban construction, the areas where elevation is higher than 120 meters (Fig.10), the slope more than 15° (Fig.11), are high ecological sensitive for construction. The highly ecological sensitive areas of elevation and slope are concentrated in the west, north, south of the city. And the urban built areas are low ecological sensitivity.

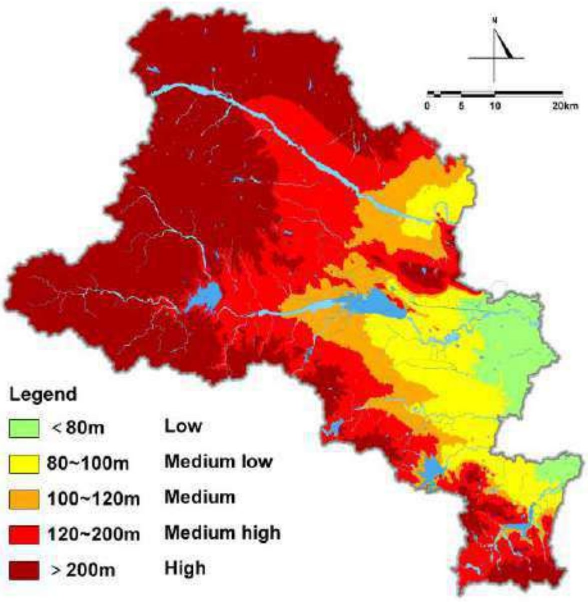

Figure 10: Elevation of Pingdingshan

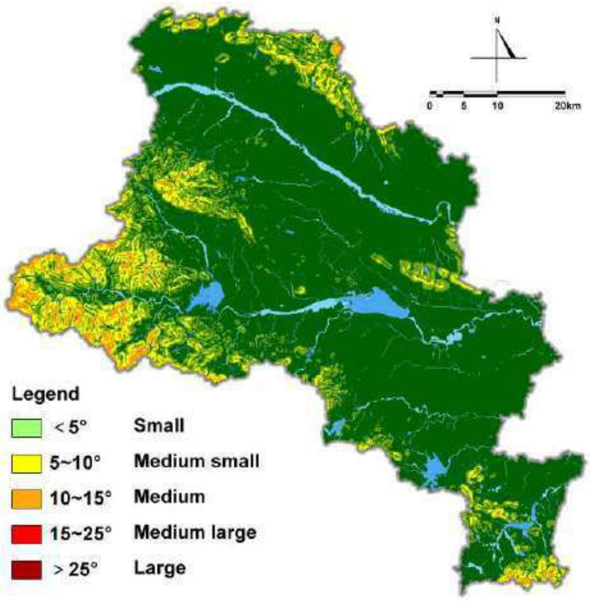

Figure 11: Slope of Pingdingshan

For the urban disaster prevention, geological subside disaster and flood disaster are the two main disasters in Pingdingshan. Because the urban economy has mostly relied on coal mineral exploitation for four decades, Pingdingshan is threatened by geological disasters such as landslides, landslides, ground fissures and mudslides. The coal mining subsidence areas are scattered and need to be strictly controlled and protected (Fig.12). Pingdingshan belongs to flood-disaster-prone areas, in particular, the area surrounding Baiguishan reservoir has a greater hazard of flooding. Therefore, it is necessary to plan the flood disaster prevention partition (Fig.13).

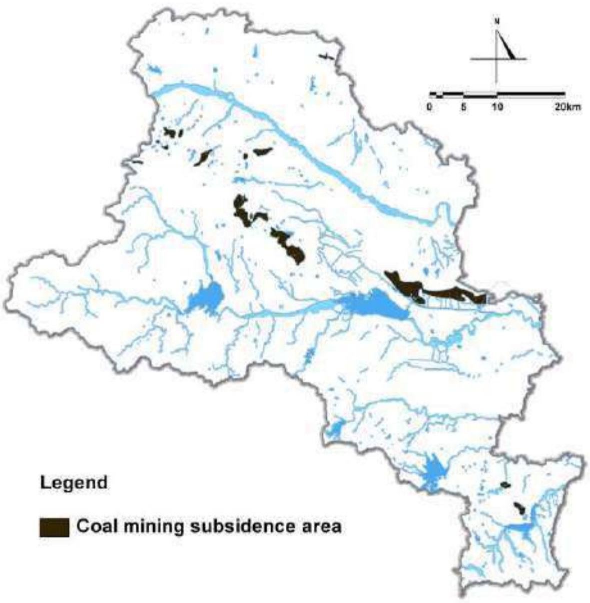

Figure 12: Elevation of Pingdingshan

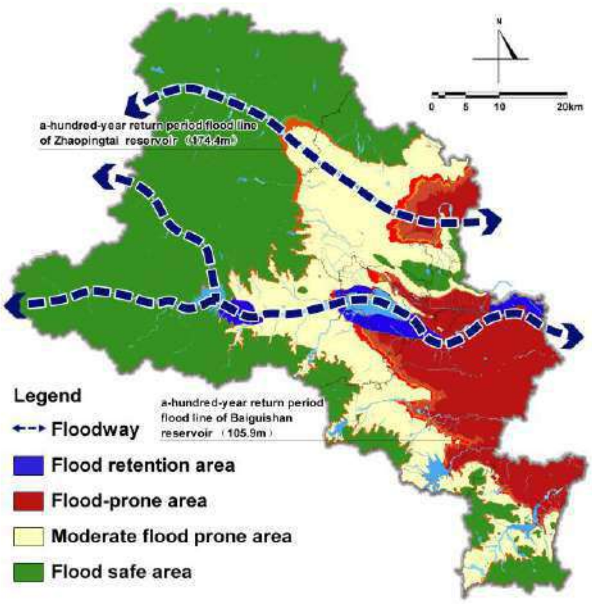

Figure 13: Flood disaster prevention partition

Table 8: Flood disaster prevention partition

Flood disaster prevention partition	**Location**
Flood safe area	the areas where elevation is higher than 174.4m, the one-hundred-year return period flood line of Zhaopingtai reservoir
Moderate flood prone area	the areas where elevation is between 105.9m and 174.4m, between the one-hundred-year return period flood line of Zhaopingtai reservoir and Zhaopingtai reservoir
Flood-prone area	the areas where elevation is lower than 105.9m, the one-hundred-year return period flood line of Baiguishan reservoir
Flood retention area	downstream of Zhaopingtai reservoir, Baiguishan reservoir, Sha river
Floodway	Dangze river, Sha river, Beiru river

2.5 Comprehensive Land Suitability Evaluation

Using GIS overlays the vegetation coverage, slope and elevation (other factors cannot be overlaid to the GIS due to the data type reason). The ecological sensitivity is divided into five levels. Ecologically high and medium high sensitive areas have high ecological value and need strictly protecting. These areas mainly locate in Lushan County, Wugang City, and Ruzhou City. There are also distributions in the north of Pingdingshan, the southwest of Ye County, and the northern part of JiaCounty. The low sensitive and medium low sensitive areas are suitable for construction. These areas are mainly located in built urban areas with low elevation, gentle slopes, and low vegetation coverage.

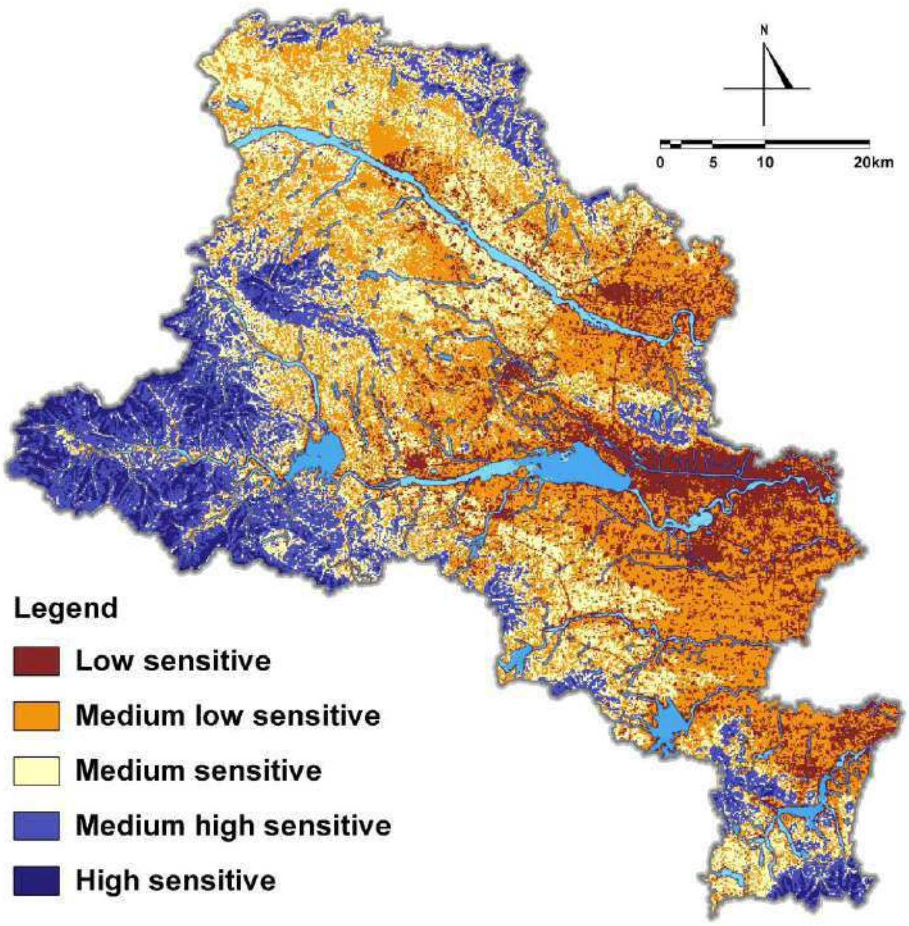

Figure 14: Ecological sensitivity area analysis

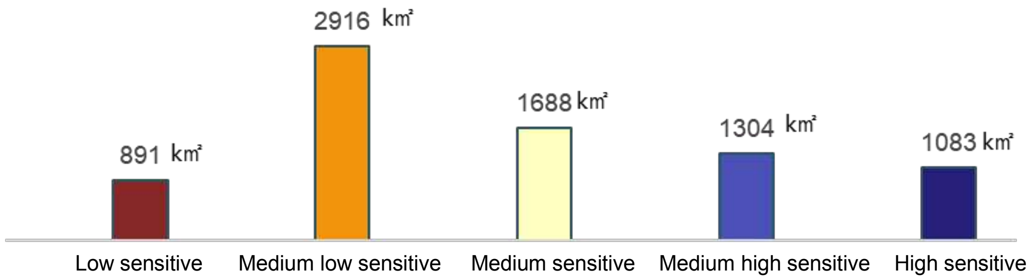

Figure 15: Area of Ecological sensitivity spaces

Table 9: The indexes of ecological sensitivity spaces

Index	Low sensitive	Medium low sensitive	Medium sensitive	Medium high sensitive	High sensitive	weight factor
Vegetation Coverage	＜0.1	0.1-0.3	0.3-0.45	0.45-0.6	＞0.6	0.4
Slope	＜5°	5°-10°	10°-15°	15°-25°	＞25°	0.3
Elevation	＜80m	80-100m	100-120m	120-200m	＞200m	0.3

3. Resilient Urban Planning for Pingdingshan City, China

3.1 Natural space plan

In current situation, only Jia county and Baofeng county has the ecological red line planning, the coverage is too small to protect the whole area. Therefore, based on the land suitability evaluation, plan ecological red line area 2433.7 square kilometres, accounting for 31% of the total Pingdingshan city. The ecological red line including vegetation preservation area and river & reservoir preservation area, any development and construction unrelated to the protection in the area shall be forbidden. For the vegetation preservation area, based on the five existing forest parks and five existing scenic spots, plan ten vegetation preservation areas with a total area of 1600.97 square kilometers. The river and reservoir preservation area are totally 832.73 square kilometers.

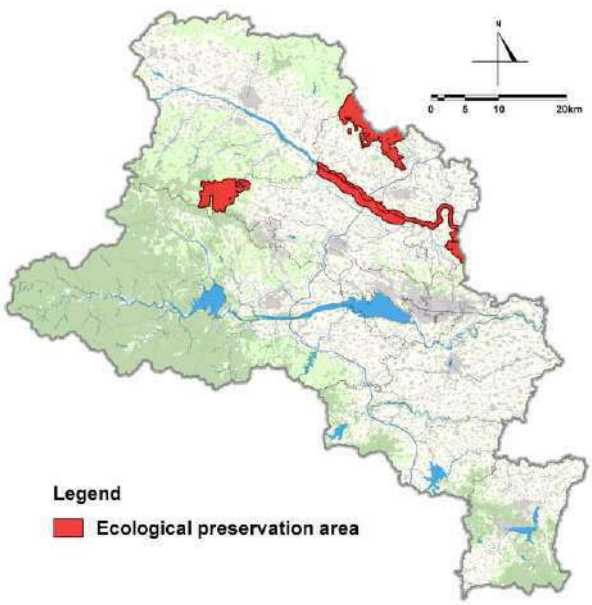

Figure 16: Current ecological red line

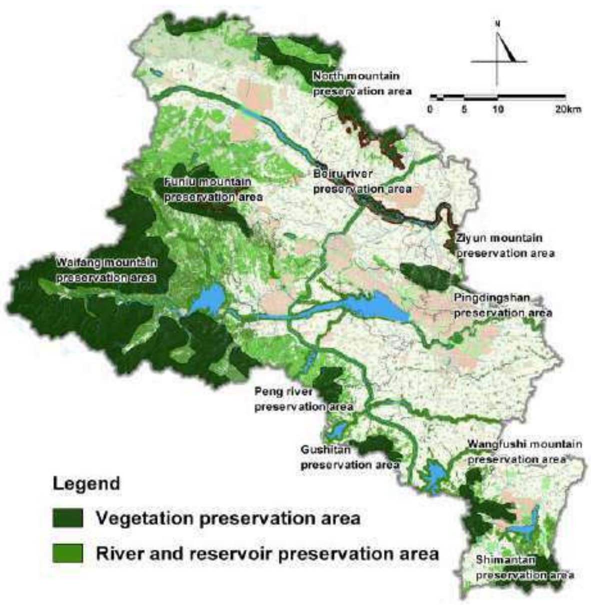

Figure 17: Planning ecological red line

3.2 Agricultural space plan

Based on the existing prime cropland planning of Pingdingshan, plan 3,049 square kilometers agricultural spaces, accounting for 39% of the total area of Pingdingshan. The agricultural spaces include 2,723 square kilometers of prime cropland, 79.6 square kilometers of general cropland, and 246.4 square kilometers of village area.

3.3 Urban space plan

According to the analysis of ecological sensitivity, plan the urban development boundary in the low and medium low sensitive area, and all the construction should happen within the boundary. The coal mining subsidence areas are totally 124 square kilometers, and the green belt not less than 500 meters wide between the living area and the mining area. In 2035, the area of urban development boundary is totally 690 square kilometres, and 60% of the area are concentrated in the core development area. The plan of urban development boundary follows three principles. The first principle is the protection of ecological core resources. Based on the existing ecologically protected red line and permanent basic farmland, protecting river ecology and agricultural core resources. The second principle is the protection and restoration of ecological fragile area, protecting ecologically fragile areas and gentle slope repair areas, avoiding subsidence areas and flood storage areas. The third principle is protecting natural patches inside urban development boundaries, including rivers, wetlands, mountains and important ecological corridor.

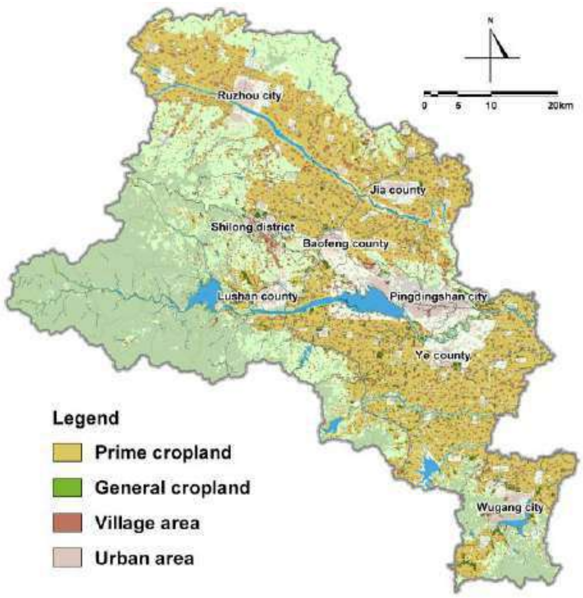

Figure 18: Layout of different cropland

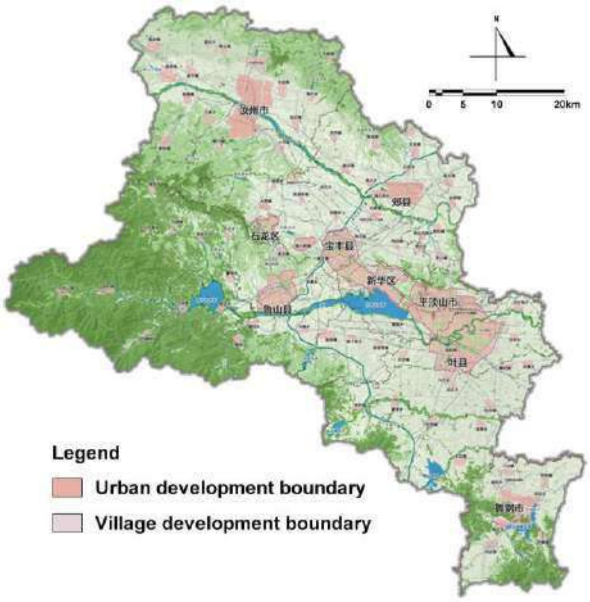

Figure 19: Urban development boundary plan

3.4 Resilient urban planning

Plan prohibited-construction, restrained-construction and construction area. In prohibited-construction area, any urban development and construction are forbidden. The area is 6,288 square kilometers, accounting for 80% of the total area, including prime cropland, mountain forest land, river reservoirs and ecological parks. Urban and rural construction should be avoided as much as possible in restrained-construction area. The area is 179 square kilometers, accounting for 2% of the total area, including geological subsidence area and independent construction land. The construction could appropriately expand based on the built-up area according to the traffic location conditions, and all the constructions should be controlled within the construction area. The area is 1415 square kilometers, accounting for 18% of the total area.

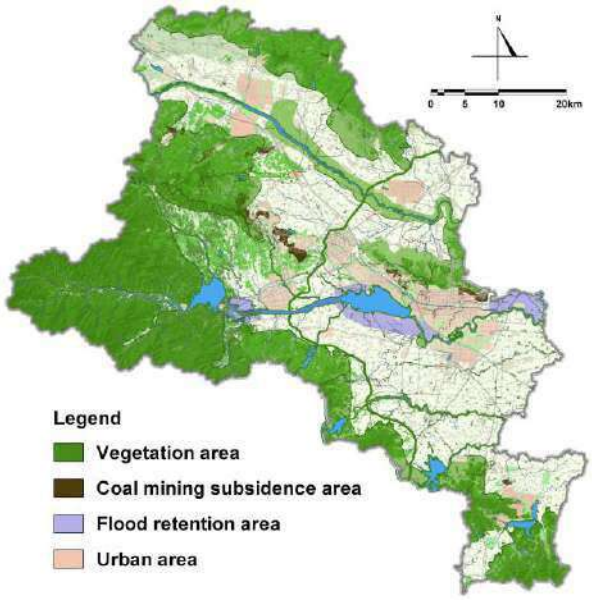

Figure 19: Natural, agricultural, urban elements

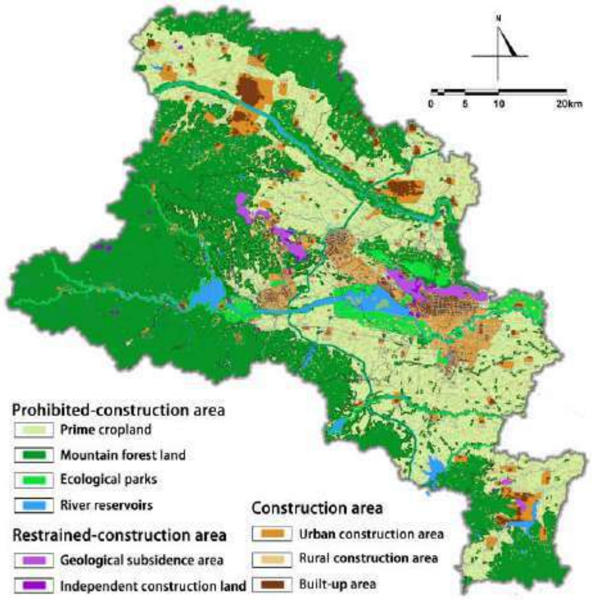

Figure 20: Resilient urban planning

4 Conclusion and Discussion

Overall, the output of this study can be used as the basis for land suitability evaluation in urban planning processes. In the process of ecological strategy planning, the land suitability evaluation model is used to identified the ecological valuable and sensitive areas, providing an ecological basic framework for land-use planning. The model has the capacity to provide decision makers with a clear and comprehensive picture of the urban infrastructure and ecosystems resilience development proposal and supports them in making better informed decisions to deliver cooler cities in our warming planet.

Hot climate and runnability: how climate affects outdoor running activities. A case study of Doha, Qatar

Ledwon, Slawomir; Al-Naimi, Mubarak, DOHA, Qatar

ABSTRACT:

Over the last decades, with the increasing reliance on car transportation, wealthy communities faced problems resulting from sedentary lifestyle and unhealthy diets. These contributed to increased risks of non-communicable diseases, such as heart related problems, strokes, high blood pressure, diabetes and many others. In order to reverse these trends many actions and strategies have been undertaken in cities. One of the simplest is prevention – promoting healthy lifestyle, which includes regular physical activity of citizens.

This article discusses runnability as a feature of built environment that allows and encourages running outdoors. Recently there have been many studies on walkability, connectivity, cycling (bike sharing, commuting etc.), but very little has been done to assess how urban space can be used more effectively for running. Running and jogging is one of the most simple physical activities that does not require much skill and equipment.

It is not only the lifestyle that affects activity levels, but also the environment – both the built one as well as the natural. They impact the way people can exercise outdoors. Apart from the discussion of the physical features the relation to climate is made. Doha, Qatar is a perfect testing ground for this study, as it is one of the hottest countries in the world. It has a dry, subtropical desert climate, with intensely hot and humid summers, while winters are quite pleasant, with average temperatures around 20 degrees Celsius. Moreover there is a large orientation of the government towards promoting and encouraging healthy lifestyle, which results in many strategies being implemented locally.

The article discusses: (1) impact of hot climate on outdoor physical activities, (2) use of infrastructure throughout the year in relation to weather conditions, (3) features of infrastructure that were designed to aid outdoor activity and (4) Doha's newest infrastructure for outdoor recreational activities.

The case study is based on dataset with running and cycling activities gathered by tracking devices and applications. The dataset consists of GPX linear tracks of individual activities recorded throughout the year. These are correlated to weather conditions outside. It also examines how the activities were related to the use of outdoor infrastructure, which were more attractive and why. Recently there were new parks and other areas opened, so it is also possible to draw conclusions on how these attract runners and impact their running habits – how the new infrastructure has changed the previous patterns. Moreover there is a discussion of desired qualities for good running space in warm or hot climate are also included.

The article also presents growing role of sports in local culture, despite hot climate, as well as the case studies of massive investments towards FIFA 2022 World Cup. These not only comprise of the stadiums, but also other infrastructure that is available to citizens, including a high-end sports district Aspire, with Aspetar – specialised orthopaedic and sports medicine hospital. Moreover there are plans for extensive cycle paths and running links.

The conclusions and examples presented can be used as a reference for planning and designing outdoor spaces to be running friendly in response to weather conditions in other cities. They will allow cities to be more runnable and encouraging for their inhabitants to exercise more and aid their well-being. Runnable cities are more sustainable, healthy and have happier citizens.

Smart City Governance – Co-creating Urban Planning and Inclusive Communities

David Ludlow, UWE, Bristol, UK

What are the challenges for the creation of integrated and open urban governance solutions and systems? How best to ensure the development of a robust model of urban governance and decision-making that effectively addresses the commonality of the drivers of change at global and pan-European level that impact cities? And what are the most effective transition pathways to the realization of visions of a new open governance model for Europe's cities?

This paper seeks to address these questions drawing on findings of a number of EU funded (FP7 and Horizon 2020) open smart city governance research and innovation projects supporting the development of open governance solutions for urban planning in collaboration with the partner cities of Rome, London and Hamburg, Helsinki, Antwerp, Milan, Bologna, Madrid and Amiens.

Transitions to Sustainability

The European Environment Agency (EEA) report Perspectives on Transitions to Sustainability (March 2018) demonstrates that transitions in the societal systems that drive environmental degradation and climate change are essential if Europe is to meet its sustainability goals in coming decades. Knowledge creation, sharing and use are fundamental to the governance of these sustainability transitions. Yet developing the knowledge needed to support transitions presents diverse challenges that also requires transformation of the existing knowledge system, including the creation of open governance structures that promote knowledge sharing across government and society more broadly, and the development of more forward-looking information.

Europe's persistent sustainability challenges are systemic, in the sense that they are tied in complex ways to prevailing economic, technological and social systems. These interlinkages often make it hard to effect rapid reductions in socio-economic and environmental pressures. Nonetheless, it is necessary to go beyond incremental improvement to secure fundamental transitions or transformations in core systems, entailing profound changes in dominant institutions, practices, technologies, policies, lifestyles and thinking. These include the consumption-production systems that meet key human needs, including food, mobility and energy. But there is also a need for fundamental change in other systems, such as urban, fiscal and financial systems, and knowledge systems supporting decision-making, and the governance model.

The notion of 'systemic challenges' was first taken up in the EEA Report European environment — state and outlook 2010, which identified the need for more integrated approaches addressing persistent socio-economic and environmental problems. However, associated research provided only limited insights into how transitions occur in practice, and how decision-makers at different scales of governance could catalyse and steer complex processes of systemic change towards long-term sustainability objectives. This raises questions concerning both the nature of the governance model that can most effectively deliver sustainability objectives, and at the same time the most effective means of creating this governance model and the associated transition pathways?

Research also indicates that some complex systems are actually causing environmentally and socially undesirable outcomes, and that in these circumstances, system resilience actually represents a problem. Indeed many factors that support resilience and also produce lock-ins in socio-technical systems, such as long-term investments and infrastructure, jobs and earnings, social norms and rebound effects. For example, the contribution of the division of labour into specialised silos within business or government locks each unit in optimising individual elements rather than holistic assessments. Hence, calls for trans-disciplinarity and the co-creation of knowledge to support sustainability transitions acknowledging the limitations of academic silos.

Many elements of transformations research focus on environment-society interactions in an urban context providing focus on land use. This focus on spatially defined systems directs attention towards interactions and trade-offs across different systems and resource uses within a particular area, as exemplified by food-water-energy nexus assessments, so emphasising the importance of spatial planning and land use.

Systemic change is understood to require multi-scalar, society-wide processes of innovation, experimentation and learning; upscaling, replication or adaptation of new technologies or practices; and disruption of the established regime, often as a result of external shocks. Transitions are multi-actor processes that involve interdependent changes in technologies, behaviours, rules, and values. Policymakers and institutions are generally perceived to be part of the system that needs to be transformed, rather than being separate actors with the power to steer society towards long-term sustainability objectives.

Governments and governance institutions may be part of the problem but also have an essential role to play, and it is vital to consider how governments can best use their powers to enable transitions — not only by means of hierarchical legislating but also by creating the institutions and infrastructures to enable markets and networks to function. These insights point to the critical importance of innovation and broader societal engagement in systemic change, as well as the need to embrace and promote a more diverse mixture of open governance approaches, including adaptive, polycentric and participatory styles of governance, based on social interaction and information sharing.

Furthermore, there is a need to complement sustainability policies with a much more diverse mixture of policy approaches. Regulations and environmental taxes have an important role to play, but achieving systemic change depends to a significant extent on creating an environment in which novel technologies, practices and business models can emerge through experimentation and subsequently displace established ways of meeting societal needs. This may necessitate adopting different governance styles at different stages of transitions.

Communities and cities emerge as key actors across the different perspectives, reflecting the capacity for innovation to emerge in local settings, and the potential for local systems. The impact and influence of local initiatives is enhanced by new platforms for networking and communication, including stakeholder platforms. Such platforms can facilitate the sharing of ideas and practices across 'communities of communities', which allow innovations to be shared, replicated and adapted.

Transitions also rely on innovation and reconfiguration across multiple areas of society. As multi-scalar processes, they are dependent on policy mixes and governance interactions across local, national and international scales. A major governance challenge therefore resides in steering such uncertain and wide-ranging processes of change towards desirable end points. Here, government interventions can contribute in a variety of important ways, to inform and shape visions, policy and governance at national, regional and local scales, engaging communities in participatory processes that develop narratives, which can help illustrate the implications of alternative futures.

In addition, achieving sophisticated policy mixes and coordinated governance is also likely to require changes in public sector institutions, competencies, skills, and knowledge systems. Tackling complexity and achieving transitions will depend in part on overcoming silos and enabling information to flow freely across government and across scales. It will also require the development of adaptive governance frameworks that operate via iterative cycles of planning, implementing, and monitoring.

The systemic nature of Europe's sustainability challenges highlights a key concern to specify the nature of the governance model that can most effectively deliver the sustainability objectives. The central requirement for integrated approaches to sustainability transition has long been advocated as an essential response to socio-economic interdependencies and the multi-scalar nature of governance responses in a pan-European framework. At the same time innovation and broader societal engagement in systemic change is promoting demands for open and participatory styles of governance based on social interaction and information sharing. Furthermore, enhanced communication overcoming silos and enabling free information flow across governments and scale emphasizes the common requirements for common foundations and interoperability in the governance system.

Disruptive Technology

Disruptive technology applications for urban governance and decision-making offer major opportunities for engaging multi-disciplinary partners and stakeholders, and integrating evidence based decision-making in governance process addressing societal challenge. The aim is to create planning scenarios delivering "win-win" policy co-benefits from optimised socio-economic and environmental solutions for local communities. In this regard it is critical to develop pathways for the introduction of disruptive technologies, developing new ways of providing public services and optimising work processes, and simultaneously develop business plans to ensure long-term sustainability of the services defined.

Disruptive technology applications for network governance combine more bottom-up engagement with greater degrees of cooperation and coordination. The emergence of these new governance modes reflects the dynamic of change, and changing roles and relationships of different actors, in which change is more rapid and fluid, with non-public sector actors, including social entrepreneurs and creative industries increasingly involved in delivery. This transformational governance therefore aims to harness the dynamic of both societal and technological innovation.

Transformational governance enables ICT to promote wholesale restructuring and repurposing of governance as open governance. This open governance approach is based on 3 pillars including modern stakeholder engagement, analytical technology and agile iterative implementation. Open governance deploys open data with open services and open process, but to be fully realised needs a broader open governance framework linking and integrating worlds inside government as well as worlds outside government, hence governance as a platform. Governance as a platform supports the modernisation of public services, however for this to succeed with a viable business model, the open governance framework also needs to be supported by a strong ICT backbone that is interoperable and based on common reusable modular public services facilitating the interoperability of European public administrations.

The principles of urban governance are based on the twin pillars of an integrated and participatory urban governance, that define requirements driving the development of a common model of governance globally, which in turn is driving the development of common methodologies of urban governance and land-use planning. Integrative governance addresses the complexity of the interconnected socio-economic and environmental considerations constituting city life, that must be managed in the urban spatial frame. Furthermore, all urban governance and land use planning decision-making processes require the provision of a political mandate for the urban plan and associated development proposals, generating the political will essential to implement the plan. In various ways stakeholders including citizens, business representatives and civil society organisations must be engaged in the decision-making process to facilitate political decision-making, providing endorsement of plans and development proposals, so securing necessary legitimacy for the decisions in a framework of democratic governance.

Technological innovation allied with an intersecting social innovation is providing a new and powerful dynamic of change that is promoting and shaping the development of common and generic applications of integrated and participatory urban governance. This dynamic is focused on the context of smart city governance whereby ICT derived tools and methodologies are applied to the operationalisation of decision-making within the framework of the policy cycle in respect of both integrated and participatory urban governance, enhancing the opportunity for more effective realisation of sustainable urban development objectives. Smart city open government initiatives building on innovation and research conducted globally involving city planners, research institutes and industry is creating new means of impact assessment, stakeholder engagement as well as simulation and visualisation of urban futures.

Urban Governance Challenges – Complexity

This real-world context for governance transformation emphasizes the challenges that cities face in trying to deliver sustainable urban development, and makes clear that the challenges are not only strategic, technical and financial but also relate to urban complexity, city management and institutional barriers.

The socio-economic architecture of the city-region defined in a territorial context determines the extent to which the cities of Europe positively contribute to Europe's global commitments to halt climate change by reducing greenhouse gas emissions, which are substantially associated with motorised forms of urban transport. The overall shape and structure of the city- region, the extent of urban sprawl, the density of population and the dominant mode of transport between homes and work, and recreational and cultural facilities substantially determine the level of greenhouse gas emissions. As a result of the interconnected nature of socio-economic drivers and environmental impacts, these socio-economic variables critical in city formation also fundamentally influence the health of the urban population, primarily as a result of air pollutants generated by motorised transport. Furthermore, the form of the city-region and its physical connectivity and interaction with its hinterland substantially determines the wider impact of the city on the natural environment, and the conservation or loss of biodiversity.

The interconnectedness of social, economic and environmental challenges in the urban context create complex conditions for urban management, and as a consequence barriers to delivery of a more sustainable urban development. This interconnectedness and complexity is illustrated in Figure 1, whereby the relationship between more compact city and city-region solutions or more sprawling cities is substantially influenced by the land use - transport relationship that impacts directly on air quality, noise and greenhouse gas emissions, and so influences human health, climate change as well as biodiversity degradation.

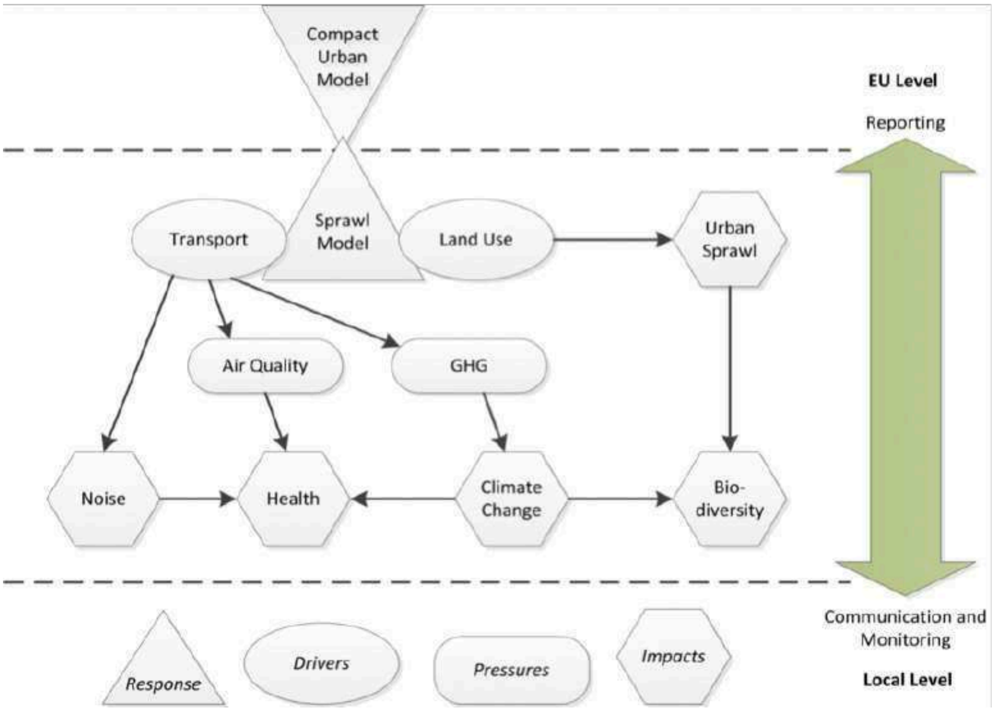

Figure 1: Urban interconnectedness and Complexity

Urban Governance Challenges - Fragmentation

All levels of governance, local, regional, national and European, have an impact on urban development, the difficulty is to merge the actions of these different levels of governance into a consistent and integrated urban policy due to the fragmentation of responsibilities and decisions. Inadequate governance arises as a result of the growing mismatch between administrative delineations and the ‘real’ urban structures that extends far beyond the limits of the municipality of the core city. In emerging large polycentric city-regions, urban structure is often composed of a network of small and medium, urban, peri-urban and rural municipalities located around the major urban centre. Urban policies have to be defined at a larger scale than municipality scale for operational reasons in order to provide better services for users (e.g. public transport), for cost-efficiency reasons in order to share costs (e.g. utilities, infrastructure, public transport); for strategic reasons in order to develop policies at the appropriate scale and involve the key actors (e.g. economic strategies and programmes); for territorial reasons in order to take into account the characteristics of the place (eg. protection against flooding).

Urban Governance Challenges – Stakeholder Engagement

In this fragmented environment (institutionally and spatially), urban governance is further complicated by the number and the variety of actors (private and public) operating at different territorial levels (e.g. Municipalities, Urban-Rural Region, Metropolitan area, City-Region) with various competences (e.g. agencies, services providers) and objectives. Besides public and semi-public sectors, the policy-making process involves heterogeneous actors from private sector, third sector and citizens. These private sector including firms and companies operate at national (e.g. infrastructure providers), regional, city and individual (e.g. property development companies) levels of activity. Third sector agencies including NGOs, civil society organisations, non-profit-making organisations (e.g. interests groups, ecological associations, neighbourhood committees) are also engaged.

As a consequence of the various challenges identified above transformational governance, which attempts to drive the socio-economic and environmental transformations necessary to deliver the sustainable development objectives adopted by all cities of Europe, is confronted with the limitations of the policy instruments that are inadequate to deal with urban complexity. Furthermore, current governance models are insufficiently agile to cope with the entrepreneurial environment encountered, and to respond to the pace of change in demography, societal expectations, and technology etc.

Transformational governance seeks solutions in integrated and multi-level urban governance, an arrangement for making binding decisions that engages a multiplicity of politically independent and interdependent actors, private and public, at different levels of territorial aggregation. Coordination, cooperation, participation and integration are the key principles of the multi-level urban governance approach. Accordingly, the practical implementation of this multi-level concept is a complex challenge for all levels of power. It is a relationship based on a permanent process of ‘negotiation-deliberation-implementation’ between numerous actors at different territorial levels and within each level. Urban governance is particularly characterized by the need for cooperation between a large variety of actors of many domains (e.g. utilities, housing, urban planning, health) and the necessity to engage stakeholders (e.g. citizens, business, NGO’s) in the decision-making process.

Cooperation and effective collaboration between levels of government (vertical dimension) and spatial cooperation (horizontal dimension), aims to enable efficient policymaking and service delivery:

• **Vertical Dimension:** involving linkages between higher and lower levels of government, including their institutional, financial, and informational aspects;

• **Horizontal Dimension:** concerning co-operation arrangements between regions or between municipalities, as a means to improve the effectiveness of local public service delivery and implementation of development strategies.

Transformational Governance - Participation

In addition to the integration model of governance outlined above, the involvement of civil society in the decision-making process is essential. For policy-makers and decisions-makers, dialogue with citizens is not only a way to understand society’s expectations but also to identify barriers and opportunities for transformation, supporting the effective implementation of policies. Engagement of stakeholders and the variety of domains actors is supported by both top-down and bottom-up approaches at the urban level:

- **Top-down approaches**: based on regulatory and economic instruments developed by EU, national governments and regional governments, for example, focused on sectoral policies (e.g. energy, waste, water, transport);

- **Bottom-up approaches:** including participation of the local level and society (e.g. citizens, NGO’s and sectoral actors) in the policy process.

Top-down and bottom-up practice-based approaches are both essential to strategically manage multi-level and multi-stakeholder change processes, but societal process is also critical, involving fundamental change in the structure, culture and practices of the societal system. To achieve transition towards sustainable cities it is necessary to critically examine institutions (e.g. global markets), the scale (e.g. district, municipality, city, city-region, region) the values and norms, and daily practices (e.g. commuting by car), as well as the characteristics of the place (e.g. territorial capital). Change needs to occur at many levels, at small and large scales, and among many stakeholder groups.

Transformational Governance – Co-Creation and Participatory Process

Transformational governance combines technical planning capabilities with greater collaboration, within and across traditional policy and administrative boundaries within and between cities and communities. Some cities have adopted ambitious policy agendas with targets to plan, organise and manage the city in order to achieve these goals. These approaches can be used to influence and facilitate societal changes and to orientate actions of all actors towards sustainable pathways. But transformational governance cannot be realized via a top-down approach alone, and efforts to shape or accelerate it are greatly enhanced by open co-creative and participatory processes, involving all relevant actors, including business, civil society, researchers, policy-makers and public administrations.

In this frame of transition management, policy-makers and city administration do not have full control of the process that is driven by stakeholders and citizens. At the start of the process, it is not possible to determine the nature of the vision which is determined by stakeholders. The results may not be fully in line with the initial goals and plans of the municipality, so policy-makers have to rethink their roles in driving decision-making in their communities, bearing in mind that lasting changes will depend on citizens. The target of the process is the empowerment and engagement of a community around a shared vision and agenda.

Transformational Governance – Planning and Decision Making

The above general principles of transformational governance are applied to the specific needs of urban planning and land use decision making. This requires the development of an overarching policy integrating various sectoral policies, setting collaborative networks, involving multiple actors, combined with a decision making process. Here the land use plan, including collective goals and long-term vision for the territory, provides the framework for operational decision making level, in which individual decisions on land use development proposals drive the implementation of the plan in response to the provisions of the land use plan and other relevant policy frameworks.

Operational decision making supporting the implementation of the land use plan is effected via the policy and decision making cycle in respect of the traditional top-down model of urban planning is identified in Figure 2. The policy and decision making cycle, in a sequential and iterative fashion, mobilises and operationalises intelligence, integrating governance, based on the following:

- **assessment** of socio-economic and environmental impacts of alternative development options
- **stakeholder engagement** regarding alternative development options
- **political decision making** and plan implementation

Figure 2: Planning Decision Making Cycle - Top Down Model (Managing Urban Europe 25, 2008)

In the traditional top-down model the planning requirement for ICT enabled solutions is based on a sequence of actions that deploys information and intelligence, communicates this intelligence between planning agencies in order to inform assessment as a basis for decision involving:

- assessment methodologies, visualisation, simulation
- integration of information and analysis (cross departmental/multi-scalar)
- limited engagement of stakeholders

Operational Decision Making – Co-Creative and Participatory Process

The co-creative model of decision making, in contrast to the top-down model recognises that transformational governance cannot be realized via a top-down approach alone, and effective decision making can only happen in a co-creative, participatory process, involving all relevant actors, including business, civil society, researchers, policy-makers and public administrations. The top-down model defines as essential to good governance effective collaboration across government departments and with non-governmental actors, requiring working across portfolio boundaries to jointly achieve integrated responses to the issues of policy development. The co-creative model stresses effective collaboration with societal actors in public service delivery and policy-making helping government agencies to improve their response to user needs and release their problem solving capacity. Effective engagement with societal actors also help citizens to actively participate in the decisions that affect their lives, to be involved in the co-creation of services, including design and delivery, as well as in finding solutions to societal challenges as demonstrated in Figure 3 below. Here the red elipses (crowdsourcing, participatory 3-D sketching, and participatory ex-ante impact assessment) indicate opportunities for ICT enabled co-creative process applied to the policy and decision-making cycle.

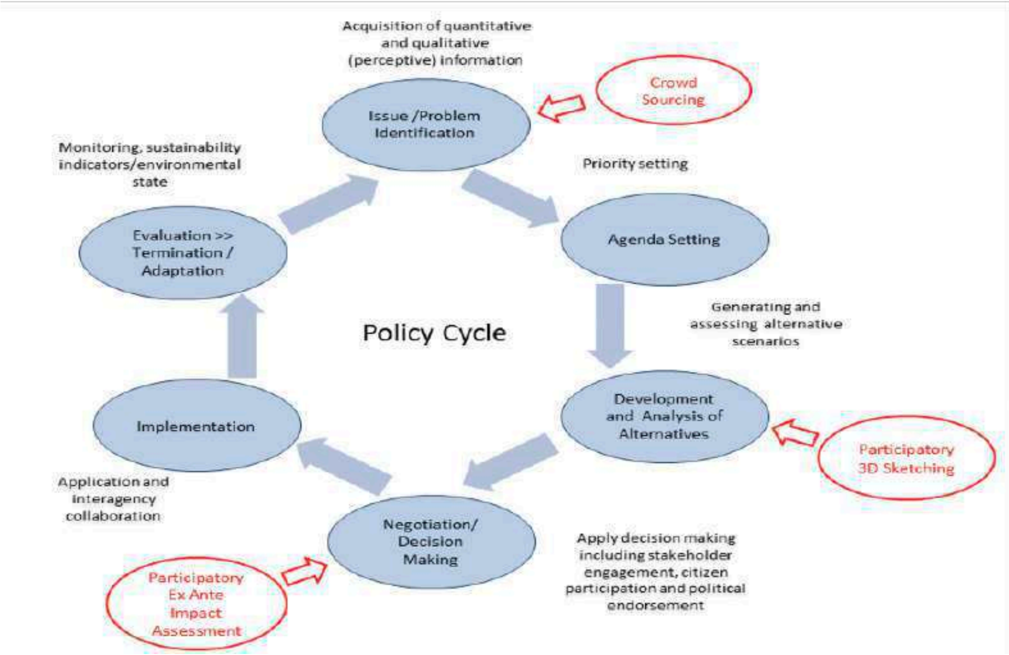

Figure 3: Planning Decision Making Cycle - Co-Creation Model

The co-creation model, forms the basis for all interventions in the land use planning and governance process, and thereby redefines the governance model. Here the land use planning requirement for ICT enabled solutions is based on a sequence of actions defined according to an open government paradigm driven by open public data and services and facilitating collaboration in the design, production and delivery of public services, with benefits including:

- making government processes and decisions open to foster citizen engagement improving the quality of decision-making for public institutions;
- open processes, activities and decisions enhancing transparency, accountability and trust in government. ICT facilitates bottom-up, participative and collaborative initiatives that tackle specific societal problems;
- open governance improving the efficiency, effectiveness and quality of public services by introducing new processes, products, services and methods of delivery enabled by ICT.

Common Solutions

The conceptual frame shaping common ground in urban sustainability described above is a transformational governance based upon the understanding that urban managers throughout Europe face common challenges in responding to the need to secure urban economic vitality, social inclusion and environmental sustainability in urban society in relation to the global challenges of urbanisation. The commonality of the drivers of urban change offers a major opportunity and requirement for the development of common solutions. These solutions are increasingly based on the dynamic of smart urban governance supporting the development of generic ICT applications and methodologies, harnessing social innovation, and grounded in integrated assessment process and wide stakeholder engagement. EU funded smart city governance research directly addresses these potentials, developing common models of policy formulation and implementation in respect of information generation and management, as well as stakeholder engagement, thereby supporting the potential for widespread application of the tools developed throughout the cities and regions of Europe.

The development of an integrated, more powerful and effective urban governance aims to manage the most intractable urban planning issues, including the management of the complexity of urban interactions, specified in socio-economic activity, set within both environmental limits and the territorial frame. This transformational governance requires greater stakeholder engagement in the urban planning process. Municipal experts providing a top-down view of the urban vision, and its local level specification, are no longer able to manage the inherent complexity of the sustainable city alone. Greater bottom-up stakeholder engagement thereby secures the quality of integrated assessment necessary to effectively plan the modern city, providing inputs in respect of the political diversity of views on the best way forward, all essential to secure the democratic legitimacy of the urban plan.

The specification of a common framework for analysis of smart city governance applications, is set against a background of the evolving dynamic of social and technological innovation, in which opportunities for development of the integrated and participatory governance model, together with it's requirements for enhanced intelligence and communication tools are identified. As a result powerful synergies between diverse initiatives may be harnessed, to support the development of a critical mass of capacity building for urban transition pathways, operationalising the integrated and participatory governance approach.

Planning for a changing climate: A GIS and Remote Sensing approach to urban flood modelling in the Gauteng City Region

Sabelo, MAHLANGU, University of Witwatersrand, South Africa

Abstract

The Gauteng City Region (GCR) is one of the fastest growing city regions in South Africa. Considered the economic heartland of South Africa, the GCR continues to attract increased populations and urban developments. Parallel to increased urbanization and city growth are increasing climate change impacts such as severe weather conditions and urban flooding incidents. Climate change impacts are affecting cities globally causing major damages to urban infrastructure, human settlements as well as natural landscapes. In the Gauteng City Region, climate change impacts are becoming frequent, requiring innovative, integrated, resilient and sustainable solutions to mitigate and manage climate change impacts. GIS and Remote Sensing technology have allowed urban planners and city policy makers to gain critical insights on various urban and rural development elements. This paper therefore explores the potential use of GIS and Remote Sensing in identifying potential flood-prone regions and climate change policy adaptation in the Gauteng City Region. The study focused on the proposed 'aerotropolis' of Ekurhuleni as an emerging urban growth region in the Gauteng City Region. Hydrologic modelling techniques using digital elevation models (DEM), watershed boundaries, hydrography, and land cover data were used to model flood risk regions. The results of the analysis were then compared with the municipal spatial development framework, disaster and risk management plans and strategies on risk preparedness whilst providing recommendations for integrated, resilient and sustainable solutions for responding to climate change in the Gauteng City Region. The study also promoted the use of GIS and Remote Sensing technology as a smart and inclusive approaches to plan and respond to climate change and its impacts on the growth and sustainability of the Gauteng City Region.

Key words: *Climate change, Resilience, hydrological analysis, co-production, GIS and Remote Sensing, Sustainability and SDGs.*

1. Introduction

Cities are experiencing rapid urbanization leading to a competitive demand on land for urban developments, this increasing risk vulnerability to climate change impacts such as urban flooding (Abhas, 2011; Moench, 2012; Mai and De Smedt, 2017 and Dalu et al, 2017). Changing climate conditions are increasingly posing a risk for cities around the world (IPCC, 2014; Kulkarni et al, 2014). In South Africa, increasing natural disasters such as severe storms and urban flooding are also causing damage and disruptions on urban infrastructure, mobility as well as socio-natural eco-systems (Abhas, 2011; Musungu, 2015 and). These global climatic changes are also said to affect vulnerable communities especially those living in informal settlements who are often located on floodplains (Mahmoud, 2017). It is further reported that urban flooding accounted for 43% of all recorded global natural disasters in the last two decades (Choy, 2018). In South Africa, the past 50 years have seen an increase in rainfall trends increasing the probability of flooding and disruptions to urban infrastructure (SANCCRS, 2004, Kruger and Nxumalo, 2017). As such, recent studies reaffirm increases in climate change as well as its impacts which affects livelihoods and the fragile growing economy of South Africa (SANCCRS, 2004:6). Climate change therefore requires more adaptive and resilient approaches to policy and urban developments.

Whilst there are various discussions and definitions for resilience in literature for resilience (Smit and Wandel, 2006; Fatti and Patel, 2013; Rollason et al, 2017). In this paper, climate change resilience is defined as the capacity for managing and mitigating climate change impacts through the adaption and reorganizing of planning tools and policies to reduce climate change impacts and increase sustainability (Folke, 2006 and Nelson et al, 2007). Vulnerability on the other hand is defined using McCarthy et al (2001)'s three characteristics which are expressed as (a) *adaptive capacity*, (b) *sensitivity* as well as (c) *exposure* (McCarthy et al, 2001). These characteristics are based on the assumption that preparedness for changing climate conditions can be affected by the unique risks, vulnerability as well as exposure to various climate change impacts that cities face. Smit and Wandel (2006) further argued that achieving climate resilience involves adapting a resilient framework that incorporates various multi-stable tools beginning with policy making, innovative tools as well as social ecological systems. GIS and Remote Sensing technology therefore presents the capabilities for comprehensive and integrated flood modelling techniques for better responses to climate change impacts (Correia et al, 1997). Studies on the use GIS applications for hydrological models on flooding have been carried widely in the global north, with very limited similar research in the global south (Musungu et al, 2011). Musungu et al (2011) further argues that limited flow of climate change information contributes to lack of involvement on mitigation measures especially in South African informal settlements. This has been a case in the City of Johannesburg, where residents of Alexandra Township resided on the banks of the Jukskei River (Modise, 2017). Residents refused location by the city due to poor Government to Citizen Relationships (G2C), resulting in severe flooding impacts and displacement during the rainy season (Modise, 2017). It is therefore argued in this paper that GIS and Remote Sensing tools can play a critical role in promoting information building adaptive capacity and resilience on climate change impacts. Innovative tools can increase opportunities for the co-production of resilient strategies and actions (Kulkarni et al, 2014). As a result, planning for changing climate conditions requires integrated and innovative approaches to modelling climate change resilience and sustainability which accommodates citizens and non-government actors to influencing policy and building adaptive capacity (Chen et al, 2008).

This paper therefore proposes the use of GIS and Remote Sensing as a means for building adaptive capacity and reorganizing planning tools for better climate change resilience. There are numerous other methods used for flood inundation and risk modelling which employ both hydrologic and hydraulic modelling techniques (Aksoy et al, 2016). These include more sophisticated 2D and 3D models such as HEC-RAS and FLO-2D (USACE, 2010). However, basic hydrological modelling in GIS using Remote Sensing data can still be useful in identifying flood risk as a first stage. As a result, this paper uses a basic hydrologic model in ArcGIS which uses a digital elevation data to model water flow characteristics. The results of the GIS analysis were then used to assess the appropriateness of the Spatial Development Framework (SDF) as well as the Disaster Risk Management Strategy of Ekurhuleni Municipality. Further discussions on the role of GIS and Remote Sensing in influencing planning approaches by considering climate change trends as well as development approaches the Gauteng City Region are presented. The following key assumptions are made in the paper; (1) that innovative tools such as GIS and Remote Sensing can play a critical role in transforming urban policy and development approaches towards resilience and sustainability. (2) That GIS and Remote technology presents a platform for disseminating and integrating complex geographic information for interpretation by various urban actors including citizens (Piketh et al (2014). (3) Climate change modelling can build consensus, local resilience and adaptive capacity. Grist (2018) argued that climate change resilience can also be built by building people's capacity to respond to climate change which includes access to better information and technical knowledge (Willemen et al, 2016 and Grist, 2018). It is argued that effective mitigation can be achieved if individual actors advance their own interests independently (IPPC, 2014:46). Therefore, citizens form a critical component in the mitigation of climate change impacts, both as actors and victims of the results of climate change.

Kruger and Nxumalo (2017) argued that South Africa already has a relatively extensive station network and rain trends data records. They however indicated challenges related to gathering and detecting rainfall changes (Kruger and Nxumalo, 2017). Other challenges cited by Kruger and Nxumalo (2017) were based on the organizational functions and facilitation of climate change risk management, which they argue is often not very inclusive to citizens and local based knowledge. These assertions are consistent with the observations by Musungu et al, 2011 citing the organization of risk management in the City of Cape Town. Research found that there is a need for understanding the human dimensions of risk generation and management. Lack of integrated perceptions to climate change risks poses limitations to developing inclusive resilience strategies and actions (Musungu et al, 2011). There is still a large number of South Africans living in flood risk areas, this is also true for the GCR. As a result, flood risk and other climate change impacts remain a high probability for vulnerable communities as well (Piketh et al, 2014).

1.1 Climate change resilience and policy contexts in South Africa

South Africa is a member and signatory of the United Nations (UN) Paris agreement on Climate Change. The Sustainable Development Goals (SDG), goal 13 calls for member countries to strengthen resilience and adaptive capacity to climate related hazards and natural disasters (UNFCCC, 2017). Goal 13 of the SDGs further highlights the need to incorporate climate change measures into national policy and strategic planning governance (UNFCCC, 2017). As a result, South African government and cities have put in place disaster management strategies and policies that aim to provide guidance towards the realization of sustainable and resilient cities towards climate change impacts (SANCCRS, 2004, Ngwenya et al, 2016 and EMMDRMS, 2017). The South African National Climate Change Response Strategy of 2004 paved the way for the incorporation of climate change strategies at various levels of government. The results of such measures can be noted on the incorporation of climate change mitigation plans into the National Development Plan (NDP Chapter 5, 2011) as well as the National Climate Change Response White Paper (2011) Since its inception, most South African cities including those in the Gauteng City Region have developed climate change strategies which take into account their contextual vulnerabilities to the impacts of climate change and mitigation measures (GCC: 40, 2011). These plans provide a good framework for organizing and integrating resilience and adaptive capacity efforts between various stakeholders in South African cities. However, some critiques on these plans and strategies have been focused on three main points (a) Forward planning (b) responsive measures versus prevention, what (Smit and Wandel, 2016) addresses as system driven and process driven approaches (c) Citizen engagement and co-production (Musungu et al, 2011). The Gauteng Provincial government has put in place a provincial disaster management strategy under its disaster management unit, whilst the various cities in the Gauteng City Region have put in place their own disaster management strategies which look at climate change and its impact at a broader spectrum.

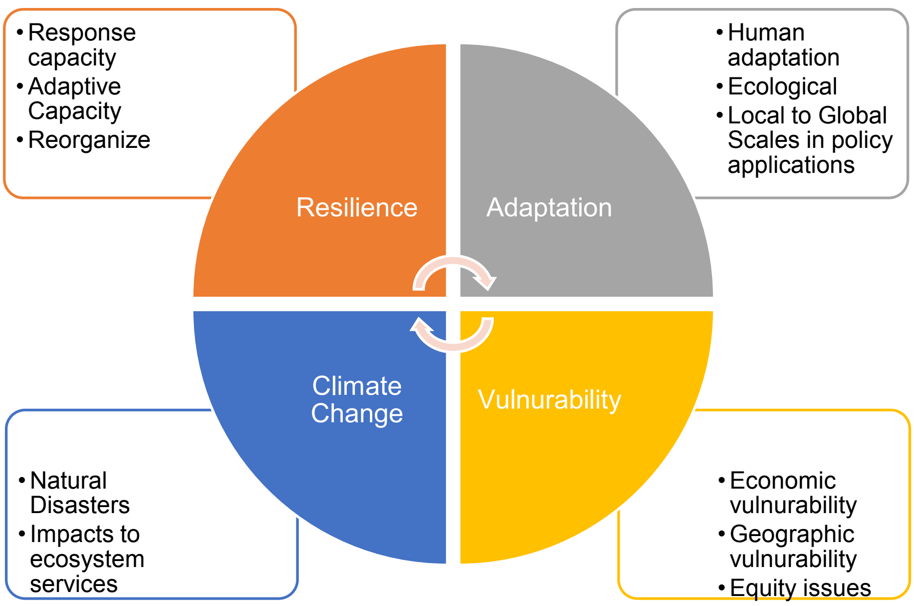

Figure 1: Research framework (Source: Smit and Wandel, 2006)

According to Smit and Wandel (2006), climate change resilience encompasses a dual function, the first one is to absorb shocks whilst the other focuses on self-renewal. Adaptation is concerned with the creation of systems, processes and actions to mitigate climate change impacts (Smit and Wandel, 2016).This framework was adopted in this study as a guide for discussions on the relationship between climate change, resilience, adaptation and vulnerability. As a result, the discussions in this paper present GIS and Remote Sensing approaches to creating resilient cities as adaptive capacity building tools.

1.2. Challenges in realizing climate change resilience in the GCR

Whilst the Gauteng City Region has evidently put in place disaster management strategies and policies at various levels of government, Spatial Development Frameworks (SDFs) still have very limited inclusion of GIS and Remote Sensing analysis climate change impacts. Spatial Development Frameworks are critical tools that guide urban growth, governance and spatial arrangements in South Africa (Afesis-Corplan, 2013). Identified urban development corridors and the protection of environmental sensitive areas are key considerations on SDFs. However, very limited information is provided by SDFs on the evolution of climate change impacts management and urban development. Previous localized studies indicated that residents were dissatisfied with municipal responses and actions towards climate change impacts such as flooding (Fatti and Patel, 2013). These studies further indicated that perceptions on flooding mitigation efforts by government were more reactive than proactive creating ineffective relations between government and citizens (Fatti and Patel, 2013). These findings and the evidence of increasing flooding incidents especially in rainy reasons indicate a systematic gap between municipal strategies and achieving resilience. In addition to this gap, whilst disaster management strategies indicate there role and need for incorporating citizens in climate change impacts mitigation, there is very limited engagement and interaction between citizens and other urban stakeholders.

As a result, these future spatial plans appear not to be considering and promoting integrated approaches that make use of technology such as GIS models for modelling climate change impacts on the urban landscape. The UN IPPC report highlights the importance of transformations in economic, social, technological and political decision and actions to promote sustainable developments. It further highlighted the introduction of new technologies, practices and structures of governance are key opportunities for attaining sustainability (IPPC, 2014: 80). Approaches to urban flood monitoring are still a key topic of discussion. In the Gauteng City Region, each metropolitan municipality has a disaster management strategy which provides guidelines on managing and mitigating urban flooding.

2. Methodology and study area

The aim of this study is to investigate and assess the use of GIS and Remote Sensing as crucial tools in planning for climate change resilience and sustainability in the Gauteng City Region. The method of enquiry used in this study involved a two stage process. The first process involved the delineation of watershed boundaries and stream order mapping within the Ekurhuleni Metropolitan Municipality (EMM). The Shuttle Rader Topography Mission (SRTM) 1 arc per second Digital Elevation Model data (DEM) was used as the input dataset with elevation information. This stage of led to the identification of flood-prone areas within the watershed boundaries of EMM using snap pour points in the hydrology toolset of ArcMap. Snap pour points are used to ensure the selection of drainage points of high accumulation in GIS. The second stage involved the assessment of climate change policies, municipal spatial development framework as well as disaster risk management plans. Primary and secondary datasets as well as literature were collected and analyzed to gain crucial insights on municipal policies climate change adaptive capacity, risks vulnerability mapping activities, climate change trends as well as urban growth strategies. Digital elevation models from USG Earth Explorer were collected, processed and analyzed in ArcGIS. Additional datasets on rainfall trends, soil saturation index as well as MSDF land uses were also collected for overlay analysis and confirmation of climate trends.

A simple hydrologic model is used to model watershed regions that are at risk of urban flooding in the Ekurhuleni Metropolitan Municipality. The results of the model are then compared and overlayed with the municipality's Spatial Development Framework (MSDF) to determine the relationship between potential flood risk, current and future land use complexes. The results are also used to make a case for the potential of GIS and Remote Sensing urban flood modelling influencing policy, participation and strategic planning. Recommendations on the potential use of GIS are then presented with an emphasis on web GIS applications and their potential in promoting co-production of climate change impacts for better preparedness and resilience. The hydrologic model presented a simplified approach to flood risk assessment a first step towards understanding flooding impacts. It is important to delineate flood prone areas well in advance to be able to take preventative measures to minimize any damage from flooding (Aksoy et al, 2016). GIS allows for the studying of urban flooding in a temporal and spatial scale (Aksoy et al, 2016). This technology has made it possible to model flooding more accurately and faster.

2.1 Using hydrologic models and DEMs for flood risk assessment

Hydrologic modeling has be widely researched as a useful tool for early flood warning and reservoir management (Borus et al, 2014). These models are also widely used for engineering purposes with different variations and complexities (Chen et al, 2009). Digital elevation models and contour data are typically relied on for surface based models such as hydrologic models due to their surface representation qualities. Elevation data can therefore be used for modelling streams and watersheds for better understanding of the movement of water on the earth's surface (Werner, 2001).These models can be very complex and advance for water drainage and storage simulation. Many scholars have experimented with different variations of these models (Wang and Zhang, 2005). Obtaining robust results from these models still remains a much debated factor. However, research indicates that their contribution in understanding stream flows and flood risk modeling remains relevant (Martinez and Gupta, 2010 and Bai et al, 2017). It is argued however that desktop hydrological models for flood prediction may have some limitations in promoting information and interaction between key urban role players such as citizens due to being highly technical (Kulkarni et al, 2014). Al-Shaban et al, (2003) argued that hydrological models for forecasting flooding hazards were often poorly suited for real time application. These limitations may affect the efficacy of these models in providing climate change resilience and early warning systems for flooding. Real time data on flooding risk can play a critical role as a decision support tool.

2.2 Study area

The study was based on Ekurhuleni Metropolitan Municipality in South Africa. Ekurhuleni forms part of the Gauteng City Region (GCR) which is a cluster of cities, towns and urban nodes making with a population of 12.27 million (StatsSA, 2011). The GCR population makes up 20% of the South African population. The Gauteng City Region is considered the economic heartland of South Africa (Wray, 2011) and continues to attract a substantial percentage of South Africa's population due to economic opportunities. Ekurhuleni Metropolitan Municipality is one of Gauteng's metropolitan cities with a population of 3.1 million (StatsSA, 2011). It is the home of Africa's busiest airport and considered the gateway to Africa (EMMAR, 2016). The municipality is one of the growing regions in the Gauteng City Region with the ambition of becoming Africa's first aerotropolis. It covers a total area of 1600 km² with new emerging urban nodes. In the last two year, the municipality has been affected by extreme flooding incidents leading to the closure of the airport and major road networks. The recent flooding events caused severe damage and loss of life, effecting economic activity as well as livelihoods (Piketh et al, 2014). The municipality was used as a case study for this paper as it forms part of the Gauteng City Region, with a growing urban footprint and new urban nodes such as the aerotropolis and the Moderfontein smart city development. Ekurhuleni therefore plays a key role in attracting an increasing population as a result of its industrial and commercial opportunities.

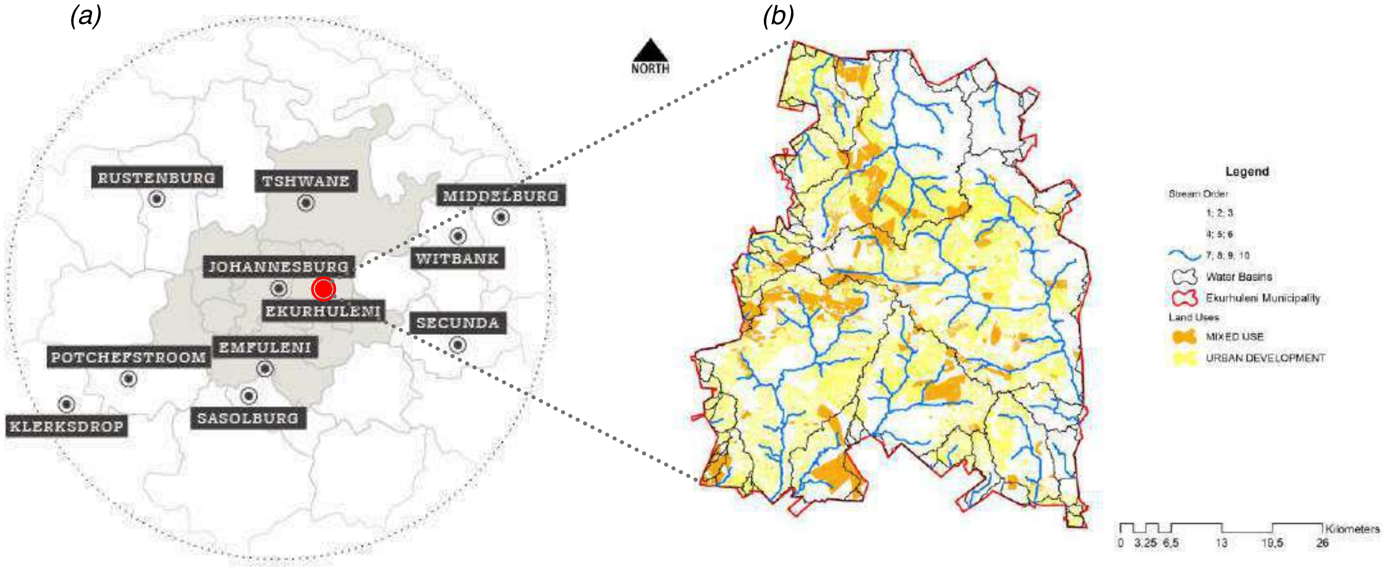

Figure 2: (a) The Gauteng City Region (source: GCRO), (b) Ekurhuleni (source: Mahlangu, 2018)

2.2. Land use cover and Hydrological properties on flooding

Land use patterns and topographical profiles of households, urban development zones and vegetation have an influence on the spatial distribution of flooding impact (Chen et al, 2009; Correia et al, 2013 and Dalu et al, 2017). Studies on Hydro-meteorological disasters have indicated an existent relationship between urban development and increased flooding potential in urban areas (Dalu et al, 2018; Guha-Sapu and Hoyois, 2012). As a result, in these cases hydrologic analysis approaches offered unique opportunity to understand water flows and accumulation from known catchment boundaries and well as modelling run-off water (Aksoy et al, 2016). These applications coupled with the power of GIS ensured that flood risk was identified and communicated sufficiently in time (Singh and Fiorentino, 1996). Foley et al (2005) further argued that complexities of modelling urban flooding arose from the various perceived sources of floods which were categorized as riverine floods, urban floods and coastal floods (Coaffee, 2013, Aksoy et al, 2016). Therefore Urban Developments and land cover change are contributing factors to the decrease in vegetation cover and its ability to mitigate flooding risks and impacts (Foley et al, 2005). Artificial urban storm water drainage systems are contributed to the increase of peak stream flow and discharge speeds (Ouma and Tateishi, 2014). These characteristics were excluded in this model, however rainfall quantities were used to confirm increased quantities as a result of climate change.

2.3. Data collection and processing

The SRTM 1 Arc-Second Global elevation (30 meters) was collected from the USG Earth Explorer and checked for voids. The fill tool in Arc Toolbox was applied to cleanout voids on the Digital Elevation Model allowing it to be used in the hydrological model. Additional datasets on the Ekurhuleni Metropolitan Municipality's Spatial Development Framework were collected and processed for errors and missing data. The MSDF was then symbolized on land use categories. Other datasets and journal articles were acquired from online journals and government online catalogues. Rainfall datasets were acquired for insights on rain patterns during the January to July seasons of 2017 and 2018. These were not factored in the hydrological model but rather used for understanding rainfall trends in the Gauteng City Region and comparing them to the national mean rainfall in millimeters.

Digital Elevation Specifications	
Projection and Datum	Geographic (WGS84)
Spatial Resolution	1 arc-second for global coverage (~30 m)
Raster size & C-band wavelength	1 degree tiles – 5.6 cm

2.4. The hydrologic model

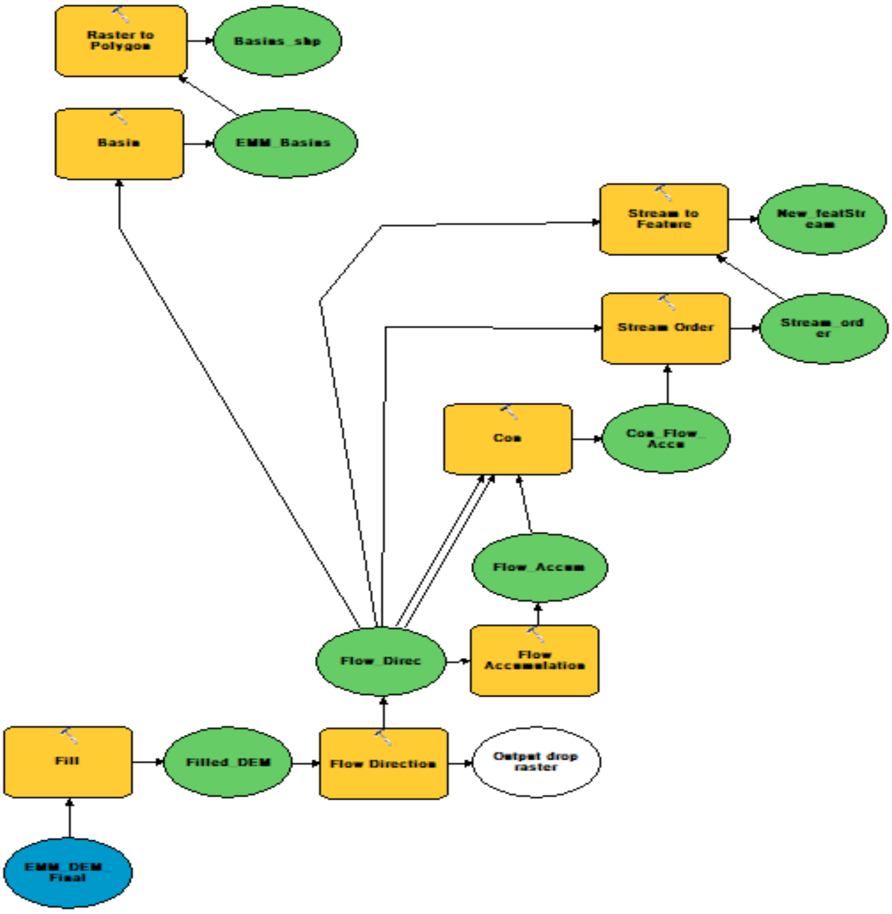

Figure 3: Hydrologic model in ArcMap (Mahlangu, 2018)

The DEM was used as the input raster dataset. Using the fill tool in spatial analyst, the DEM was corrected for voids and used to generate flow directions. Flow accumulations were then produced leading to the delineation of stream orders and basins. Watershed boundaries were established and used to identify areas of with the highest pour points per water basin area and stream network. These areas were classified as areas of high accumulation and high flooding probability. Lastly, the MSDF land use dataset was overlaid on the identified high accumulation basins and were analyzed for land use versus watershed qualities.

3. Results and discussions

It is argued that global warming has affected rainfall patterns leading to increased flooding risk especially in urban areas (Kulkami et al, 2014). This is the case in South Africa, according to Kruger and Nxumalo (2017), rainfall quantities in South Africa have been on the increase especially during the rainy seasons. In order to begin with the analysis and assessment of flood risk areas, data were collected for both rainfall quantities as well as soil saturation. These datasets are used to further discuss vulnerability based on rainfall (mm) and soil saturation (SSI) index as contributors to urban run-off and extensive flooding. As argued by Ouma and Tateishi, (2014), increased rainfall quantities and high soil saturation contribute to artificial urban run-offs which may also be impacted by man-made contributors such as poor Stormwater management systems and loss of vegetation. As a result, these results are presented first by considering the overall trends in rainfall and soil saturation for the whole country as well as the Gauteng City Region as a major urban center.

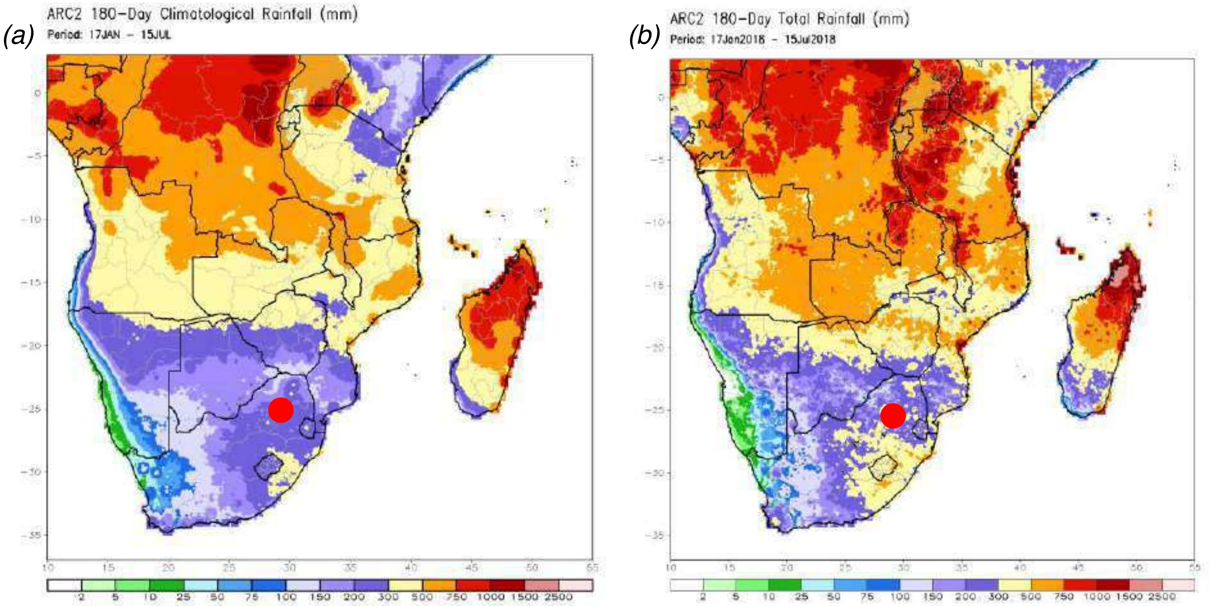

Figure 4: Climatological rain falls over the GCR (a) Jan-July 2017 (b) Jan-July 2018 (Source: Agricultural Research Council, 2018)

Figure 4 indicates rainfall trends over the Gauteng City Region, data were collected from the Agricultural Research Council (ARC, 2018). The rainfall data indicates that the Gauteng City Region falls within a region of South Africa with an average of 300mm rainfall between January and July. The data represented were collected for 2017 and 2018. The year 2018 had decreased rainfall quantities in the recorded timeframe, however the Gauteng City Region still averaged between 250 and 300 mm rainfall. This is an indication that the Gauteng City Region falls within a summer rain region of South Africa. This data is consistent with results from other studies on rainfall trends in the North Eastern region of South Africa (Carmin et al, 2009).

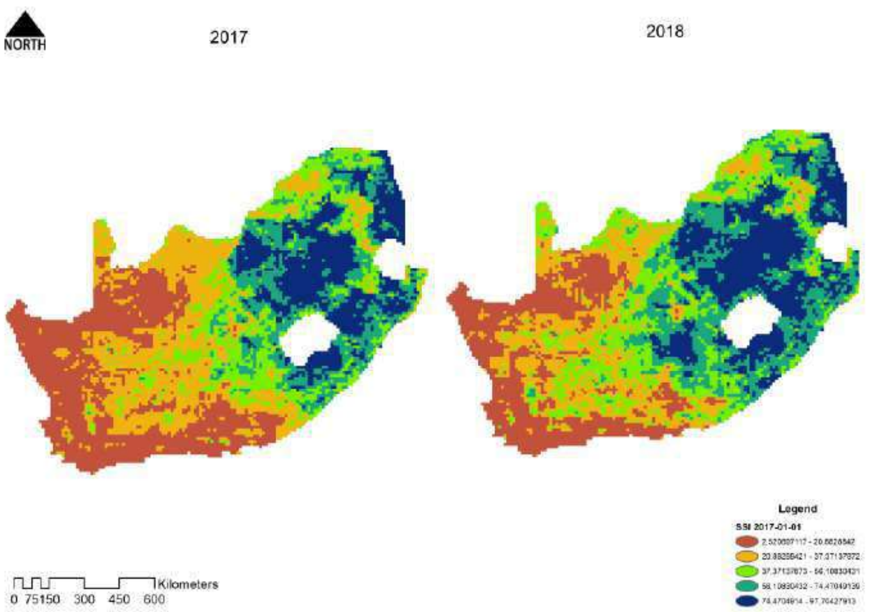

Figure 5: Soil saturation index (SSI) (Source: Mahlangu; SAHG, 2018)

Figure 5 is a representation of Soil Saturation in South Africa, recorded by the Satellite Applications and Hydrology Group which is a partnership between the Department of Water Affairs, The Water Research Commission as well as the University of KwaZulu-Natal. This research group uses satellite applications to record near real-time soil moisture for South Africa.

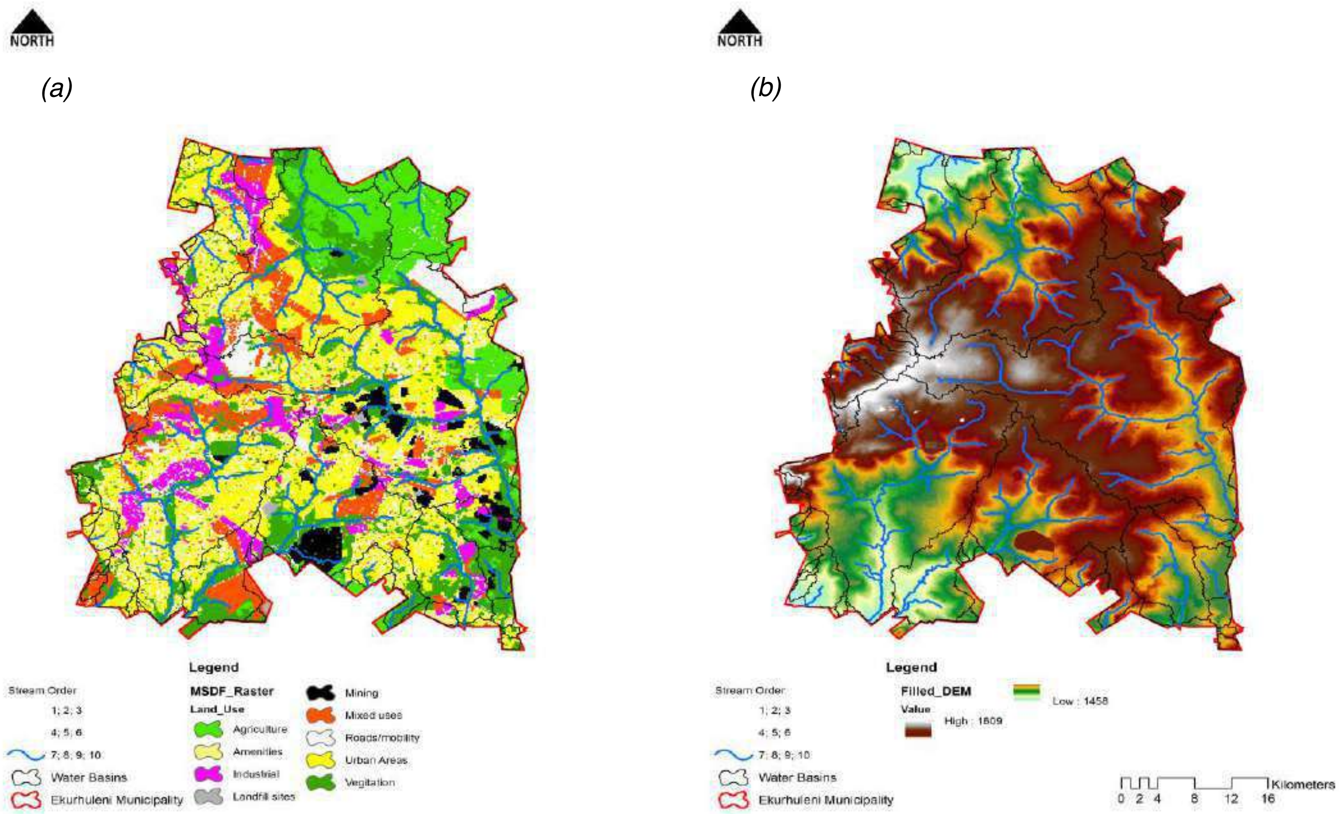

Figure 6: (a) MSDF Land Uses of Ekurhuleni (Mahlangu; EMM, 2018) (b) Ekurhuleni Digital Elevation Model (Mahlangu; USG, 2018)

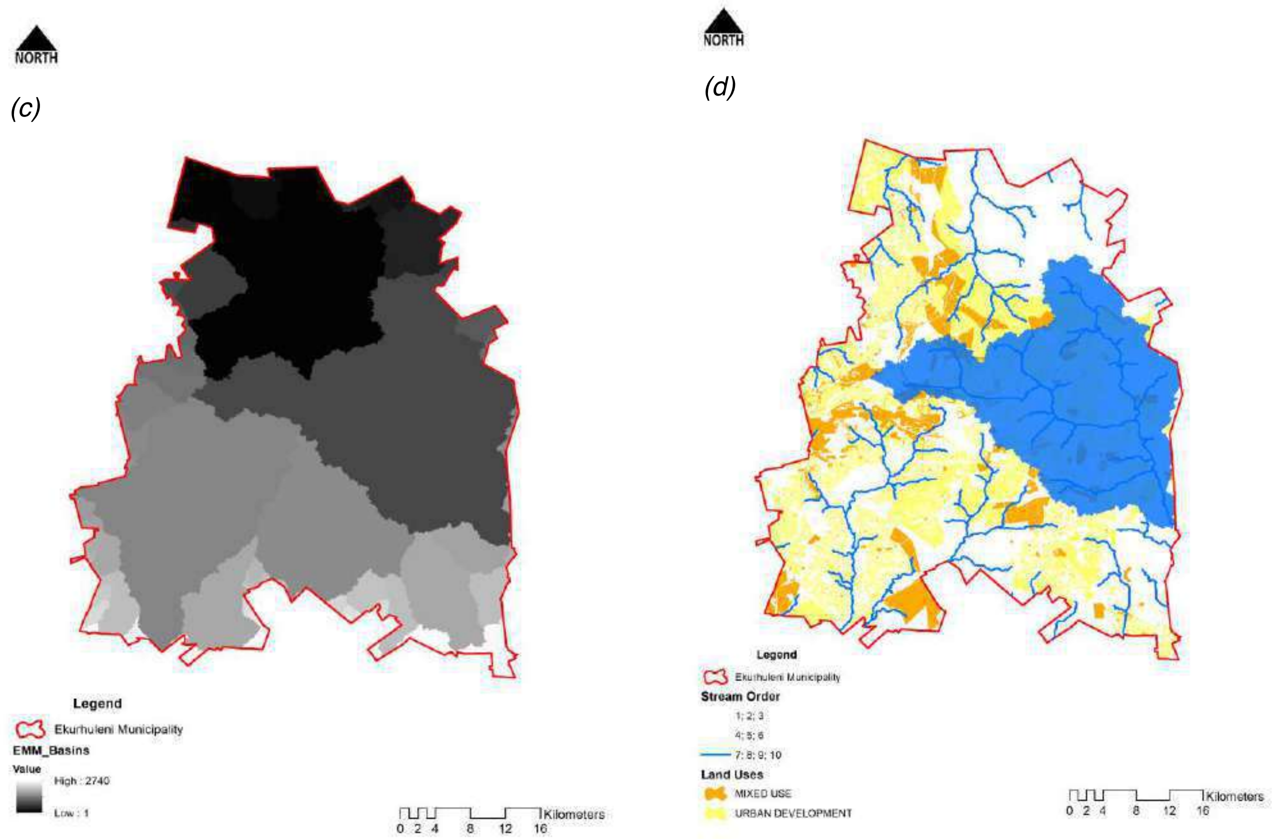

Figure 7: (c) EMM basins (Mahlangu; EMM, 2018) (d) Ekurhuleni Flood risk region (Mahlangu; USG, 2018)

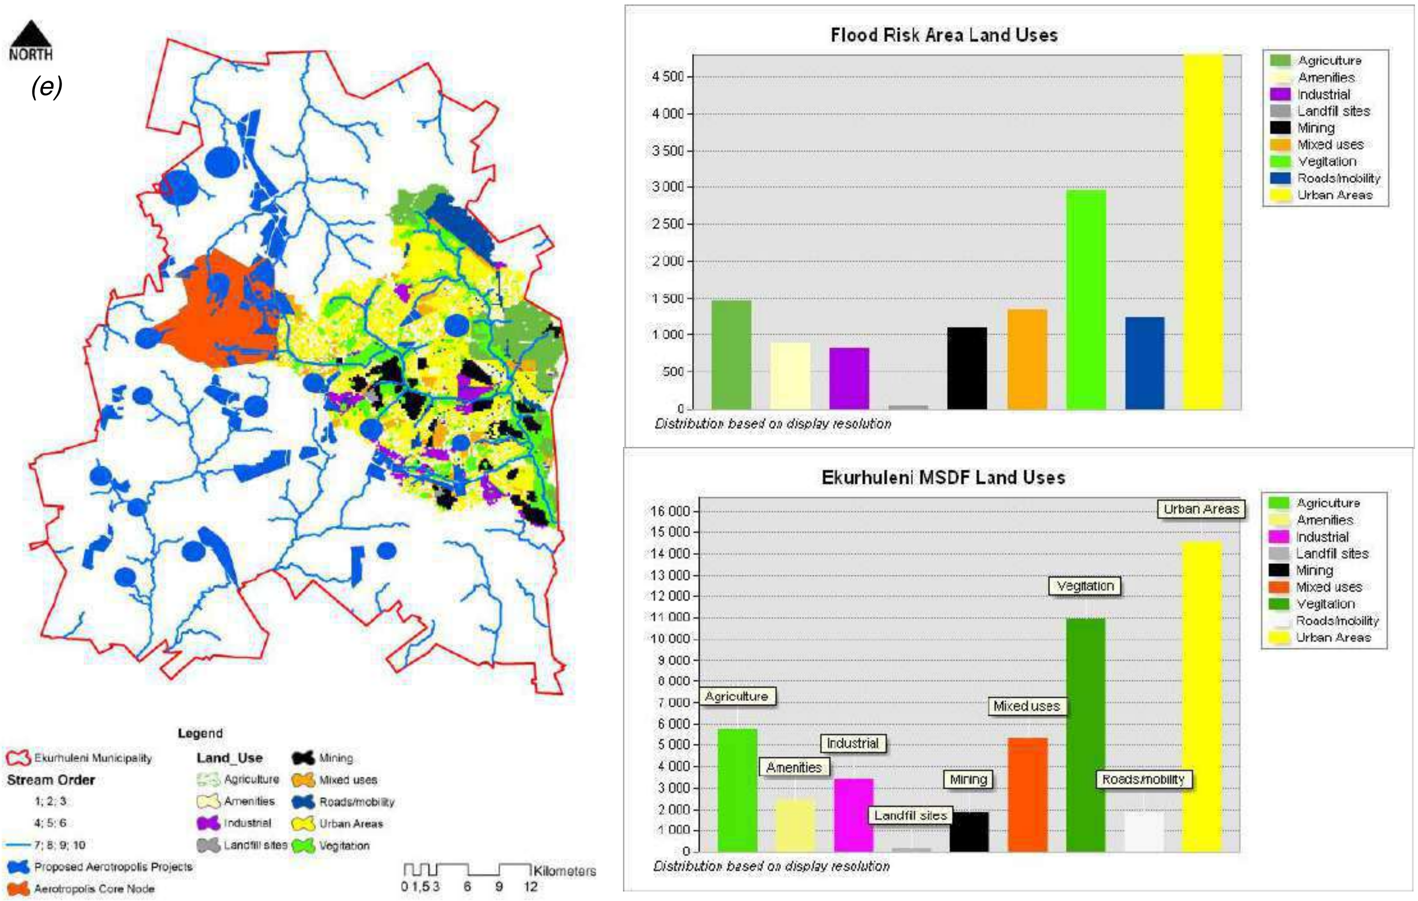

Figure 8: (e) EMM Flood Risk Basin (Mahlangu; EMM, 2018) (f) Land use composition (Mahlangu; USG, 2018)

Figure (a) presents the results of the Ekurhuleni Municipal Spatial Development Framework 2016/17 which is the municipality's spatial vision and development framework. The MSDF guides new developments and investments within the municipality and acts as a spatial policy linked to the municipality's integrated development Framework. Figure (b) is a representation of the EMM Digital Elevation indicating the relationship between elevation and stream network. Using the hydrology toolkit in ArcMap, the water basins represented in figure (c) indicate the drainage basins in the region. Figure (d) is the result of the hydrologic model's selection of pour points for selection of points of highest accumulation, they represent outlets from the watershed components. Using the raster surface of the watersheds, the snap pour points identified the highest flow accumulation in the selected watershed. This indicates that the watershed has the highest flow accumulation. It can therefore be noted that this watershed will contribute the highest flow within the EMM. As a result, the land use classes existing and planned in the region were converted into a raster and computed by cell statistics to represent the population of cells within a given land use class. Only land uses classified as urban development and mixed use zones were overlaid with the output watershed with high accumulation flow to determine how many cells are affected.

Figure (e) represents the highest accumulation watershed land uses, the EMM's proposed aerotropolis project sites as well as the core economic node. It can be confirmed from the overlay that the main economic node as well as some of the planned aerotropolis project sites fall within the watershed with high flow accumulation. Figure (f) represents the computed affected cells within the watershed area in comparison with the overall municipal land use class cells. The MSDF indicates that urban areas form the largest composition of cells when converting the land use classes into raster. According to (Coaffee, 2013), urban areas with higher urban land uses increase the risk of run-off water as a result of loss of absorption areas such as vegetation. This notion is also supported by Ouma and Tateishi (2014), who also argued that artificial urban drainage systems increase flooding probability. Other scholars argue that external and manmade elements may increase flooding probability as Stormwater drainage systems get clogged with hard waste and debris (Piketh et al, 2014). While hydrologic models alone cannot simulate flooding risk, they can model the flow characteristics of water on the earth's surface using natural earth features. These results indicate that the model is able to identify watersheds with the highest accumulation flow. These watershed can therefore be used to understand flood origin areas due to the high accumulation flow identified through snap pour points.

These results are consistent with findings from the municipal Stormwater management report (EMM EMF, 2007). The report addressed issues of pollution and its impact on Stormwater drainage systems within the municipality. The EMM State of the Environment report also noted that urban developments have had an impact on natural eco-systems and drainage channels. However, the MSDF and Aerotropolis Development Plans do not address issues relating to climate change and the impact of urban development on Stormwater and natural drainage systems 9EMM SOER, 2004). There is very limited incorporation of GIS and Remote Sensing analysis and flood modelling in the MSDF. The MSDF addresses wetlands and Pans without considering the incorporation of changing climate changes such as increased rainfall quantities. The EMM and the Gauteng City Region fall within a higher summer rain region, increasing the possibilities of runoff water. An assessment of the Gauteng Disaster Management Strategy, the EMM Disaster Management Plan, the Spatial Planning and Land use Management Plan as well as the Climate Change White Paper of 2014 indicate that policy structures are in place. The South African government has responded and complied with the International obligations on climate change responses (Ngwenya et al, 2016). However, the assessment of these plans indicates the following shortfalls:

- Climate change and disaster management plans have very limited incorporation of forecasting techniques such as GIS and Remote Sensing.
- Building resilient strategies that involve the participation and contribution of all urban actors still remain a key challenge in the EMM and the City of Johannesburg. There is a lack of integrated information systems for sharing and co-producing climate change information, resilience strategies as well as adaption mechanisms.
- The Spatial Development Framework as a spatial policy and development vehicle does not incorporate innovative tools such as GIS for modelling climate change impacts, rather it accommodates socio-political and economic elements.
- The role of vulnerable communities in policy making for climate change resilience is minimal, as argued by (Musungu et al, 2011). Other studies have found affected communities did not only include those living in informal settlements (Musungu et al, 2011).
- Surface run-off water is estimated to have increased by almost 300% above the natural drainage yield (EMM SOER, 2004).

4. Conclusions

GIS applications offer an opportunity for co-production of knowledge and engagement between various parties. The modelling and viewing of the spatial characteristics of water flows incorporating hydraulic models that consider rainfall quantities, slope, land use/land cover data and soil saturation index can therefore be further explored as an opportunity for predicting flood risk areas from urban run-offs, Building climate resilience and planning for adaptive capacity requires engaging and sharing climate and flooding risk with communities. GIS and Remote Sensing technology such as hydrologic models offer innovative, proactive opportunities to understand water flows and accumulation from known catchment boundaries. The results of these models can be used to inform Spatial Development Plans and Risk Management Strategies on distributing resources for resilience. This paper has demonstrated the relationship between policy, GIS and Remote Sensing and the existing gaps in planning for resilience for a changing global climate.

Smarting the Cities: A Catalyst for Acculturation in Ghana?

[1]Alexander Boakye, MARFUL, [2]Daniel Y. A. DUAH and [3]Joseph Agyei DANQUAH
[1,2,3]Department of Architecture, Kwame Nkrumah University of Science and Technology, Kumasi, Ghana.

Abstract

Cities and towns, which have been engines of growth and incubators of civilization and have facilitated the evolution of knowledge, culture and tradition as well as industry and commerce, are experiencing a dynamic metamorphosis through the application of Internet of things (IoT) and smart technologies. Post-oil Ghana has become a melting pot for new developmental concepts and urbanization drive of which smarting of communities is getting to the forefront. The smart city concept, which is rapidly being embraced by governments and city authorities, is premised on the use of intelligent applications for new technologies whilst incorporating social and environmental capital to transform city life and work. It is this transformation that this paper seeks to question and investigate whether it can serve as a catalyst for acculturation of the communities and the cities in Ghana. Acculturation is defined as the changes that occur as a result of contact with culturally dissimilar people, groups, and social influences. As an exploratory research, a mix method was adopted in collecting data from persons within Kumasi and the campus of the Kwame Nkrumah University of Science and Technology, Kumasi to gauge the level of acculturation and know their perception of the concept of smart communities. The research also explored the epistemological assumptions underpinning of smart communities and acculturation processes through literature review and case studies. Findings indicated that acculturation is taking place at alarming among the Asante people, one of the historic and dominant tribes in West Africa. A catalyst for this phenomenon is the advent of IoT. Education, language greetings and marriage were perceived to be the most acculturated aspects. It is recommended that innovative measures using the same IoT and smartness be adopted to stem its acculturation and marginalization but rather promote and enhance the culture instead.

Key words: Smart City, Internet-of-Things, Acculturation, Culture

1.0 **INTRODUCTION**

The world's population currently stands at 7.63 billion as of July 2018. It is projected to reach 8.5 billion by 2030. The phenomenon is accompanied by a similar increase in urban population (Worldometers, 2018). Countries in Sub Saharan Africa such as Rwanda, South Africa, Nigeria and Ghana are undergoing a digital revolution and it is projected to be the fastest growing mobile subscription base in the world (Ericsson, 2014; Olsen, 2018). By 2020 about 720 million smart phone users will be in Africa. The rising trend is due to high investments in deep sea cable installations to increase internet of things (IoT), the people and smart technology (Rice-Oxley, Mark; Flood, 2017).The global mobile connection stands at 3.5 billion with a projection to 5.9 billion by 2025 largely driven by Asia, Sub Sahara Africa and Latin America. In the same era IoT connections will reach 25 billion with smart homes, buildings, cities, enterprises and innovations in ecosystems (Olsen, 2018).

The twentieth century has witnessed an explosion of communication and information technology distorting the conventional use of connectivity to mass media which hitherto was a face to face dialogue between neighbors and friends. This has made the world shrink in size is now called a global village as ascribed by Marshall McLuhan (Ratti and Claudel, 2016).This form of technology has made it possible to connect humanity to any part of the world from any and every location breaking the boundaries of cultures and exposing the diversity of cultures to all. With the prospects of the smart technology, Ghana have been seen as the future of Africa by Google in terms of technology (Asemota, 2018), the adaptation and usage of this technology will speed up the initiation of smart city concepts in the country as well as be a potential catalyst to the acculturation of the Ghanaian culture. It is important to the global community of networks, which Ghana cannot be excluded from its advancement, that this threat is highlighted for the preservation of the Ghanaian culture through proactive measures.

2.0 THEORETICAL FRAMEWORK

2.1 Smart City Concepts

The world in the 21st century is witnessing the digital revolution in urban design for resilience and sustainability in our cities. The smart city concept has become the mantra for governments and city authorities, which basically depends on the use of intelligent applications for new technologies whilst incorporating social and environmental capital, to transform city life and work (Deakin, Mark.,Al Waer, 2012). Smart city and smart community are given the same meaning and defined from various perspectives depending on specific attributes which range from industry to technology and environment (Giffinger and Strohmayer, 2014). To the government it will mean the use of technology to transform its basic infrastructure, energy and resource usage. To the people it will mean the use of technology for convenience, through transportation and connectivity, and to the entrepreneur it means an enterprise or city that sells itself through resilience by increasing profit and lowering cost. Now, many cities are embracing the concept as a solution to their complex issues. For example, Amsterdam Smart City Initiative is integrated e-services whilst the Malta Smart City Strategy use business parks to leverage economic growth (Deakin, Mark.,Al Waer, 2012). The European Union (EU) recognizes governance as key in building smart cities through collaborative digital environments to boost local competiveness (Curwell *et al.*, 2005; Deakin and Allwinkle, 2007; Paskaleva, 2009). Smart is further more used to describe a city's use of modern technology in everyday urban life (Giffinger and Strohmayer,

2014). However there are many who believe that the use of the term smart in describing urban economies are misguided as they tend to mostly dwell on IT. (Schaffers, Komninos and Pallot (2012) expressed concern of what they called fragmented city leading to what Hollands and Hollands, (2008) called self-congratulatory tendencies. Various global ranking indexes use different definitions to rank smart cities as seen in Figure 1.0. The reasons for these rankings are based on the parameters used for the survey.
The smart cities concept can thus be said to be a response to the rising challenges of the urbanized world in terms of how it manages resources efficiently and sustainably (IHS, 2014).

City Ranking	***CIMI-2017 IESE***	***Global Cities Index-2016***	***Cities Prosperity Index***	***Global City Competitiveness Index***	***Global metro Monitor***
1	New York City	New York City	Oslo	New York City	Tokyo

6	Amsterdam	Los Angeles	Vienna	Sydney	Paris
7	Chicago	Chicago	Melbourne	Paris	Osaka
8	Seoul	Singapore	Montreal	Stockholm	Shanghai
9	Geneva	Beijing	Toronto	Chicago	Chicago
10	Sydney	Washington Dc	Sydney	Toronto	Moscow

Figure 1.0: Ranking of Cities in Some Global Indexes on Smart Cities
(Source: Extracted from literature)

Critics such as David Walter's and Mitchell (Leydesdorff and Deakin, 2017) and Gu (2008), posit that the smartest places should be the mix of both physical and virtual worlds where tele presence and virtual worlds merges in a particular location. In fact these initiatives and concepts in various countries are spearheaded by super tech companies such as IBM, to take advantage of the digital revolution to advance their corporate branding other than social intelligence critically needed for them to be smart. In an attempt to bring exactitude to the definition of smart city, it draws a semblance of the intelligent city's four components as espoused by Komninos (2008) which are: 1. Applying various electronic and digital technologies, 2. Using ICT to transform the life and work, 3. Placing such ICT in the city, and 4. Customizing the above three to bring ICT and people together to enhance innovation, learning, knowledge and problem solving.

The smart city concept must therefore begin with the people and human capital before IT to transform and improve city living (Hollands and Hollands, 2008). The result will ultimately be finding a solution to the rather splintering urbanism perception as suggested by Graham et al, (1996) where the diverging forces of the digital environment is balanced by the converging forces of human interaction in the physical space (Walters, 2011). There is now a rapidly growing sophisticated digital world with information portals and platforms for e-learning, e-governance, community participation and decision making which are being used in smart cities and communities, but this cannot be effective if the vital concepts and tools of physical urban design forms the basis of the electronic discourse (David Walters & Linda Luise Brown, 2004)

2.2 Smart City Characteristics

The smart city or community concept has been assigned varying degrees of factors that characterize any city seen or perceived as smart. This has made it a very subjective matter depending on the author's point of argument. But the use of technology through the IoT to enhance the work and life of the urban dweller has become the central point which characterizes any smart city, be it in the aspects of governance, people, environment, transport or living. Thus for a city to be seen as smart, six broad characteristics (Giffinger & Strohmayer, 2007, 2014) are used in the ranking of smart cities of medium-sized cities in Europe (Figure 2.0).

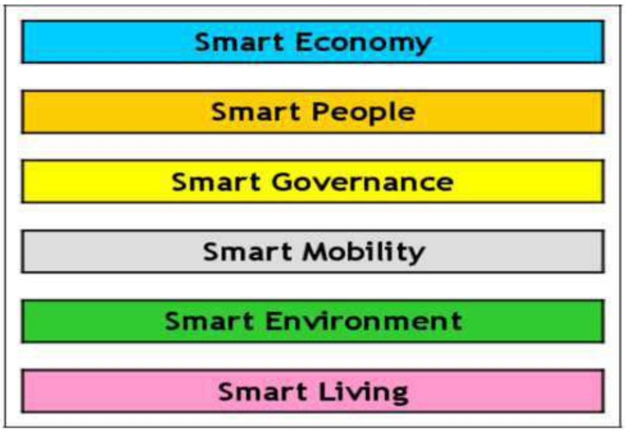

Figure 2.0: The six smart city characteristics
(Source: Centre of Regional Science, Vienna UT, 2007)

Each of these characteristics has a number of features within them. In **Smart economy** features like the economic competitiveness of the city's economy which ranges from innovation, internationalization and the ability of the city to transform are essential. The human and social capital features are embedded in **Smart people**. A critical feature of interest is how they receive the outside world issues of interfaces regarding assimilation and acculturation. **Smart governance** features the levels of political participation in decision making, provision of critical services as well as management and administration, the level of transparency, and how diverse political strategies and viewpoints are. ICT and transportation infrastructure is the nerve center of **Smart Mobility**. It ranges from both local and international accessibility and the available options in the ICT and modern sustainable transport systems. **Smart Environment** describes how resilient and sustainable the natural environment portrays- climate and green space. How is the city dealing with pollution, protection of the environment and management of resources (Giffinger, 2007)? Lastly **Smart Living** measures the quality of life and work of individuals within the city taking into consideration aspects of safety, health, culture, housing, education, tourism, cultural facilities, tourism and social cohesion (Giffinger and Strohmayer, 2014)

2.3 The concept of Acculturation and its processes:

Acculturation is a general phenomenon that arises when groups of people with different cultures come into first hand contact with consequent changes in the original cultural patterns of either groups (Redfield et al, 1936). Kim et al (2009) add that the acculturation process involves changes that the individual goes through in relation to their attitudes, values and identity following being in contact with other cultures. There are more than 100 theories of acculturation posited by various theorist (Rudmin, 2003).

Whilst the concept of acculturation is used to define the cultural diversities ensuing from these group of encounters, the concepts of psychological acculturation and adaptation are employed to denote to the psychological changes and eventual outcomes that occur as a result of individuals experiencing acculturation (Berry, 1997). Schwartz et al (2010) refer to acculturation as the changes that occur as a result of contact with culturally dissimilar people, groups, and social influences. Originally, acculturation was conceptualized as a uni-dimensional process in which preservation of the heritage culture and acquisition of the receiving culture were cast as opposing ends of a single continuum (Schwartz et al., 2010).

Individuals who migrate to another country will inevitably go through acculturation. Immigrants expects to take on a new cultural identity and therefore are more willing to adjust and adapt (Tsang-Feign, 2017). The stages of acculturation can be illustrated in the following four phases:

1. **Elation** (Enthusiastic Acceptance): This is usually based on experience that one finds quite stimulating that most of the things are so unlike or different back home and are eager to experience this new culture.
2. **Resistance** (doubt and reservation). The second stage occurs from comparisons one makes between their home culture and the host country making everything back home seem so much better. It is at this stage that people of same ethnic background often relocate or settle in enclaves within their host country.
3. **Transformation** (Adjustment): The third stage takes place at a later stage when individuals familiarize with the environment and start to see the good side of the host country. This stage is also referred as integration or adjustment as individuals are now able to adjust to the cultural norms of the dominant culture.
4. **Integration** (Accommodation and Evaluation): In this case, cultural barriers are bridged. Individuals learn to appreciate both their own heritage and the new culture (Bradbury, 2017) .

   Other theorists add a fifth stage called ***marginalization*** where both the culture of the host country and the home of origin are rejected (Berry, 2003)

2.4 Smart Cities and Acculturation

Culture is the bedrock of every community and communities live and breathe, like a human being, not as structures or enterprise to be engineered. The cities ecosystem, the support, the expressions of social life, the shared interest and capabilities as well as the linkage between the city's institution and individual citizens are all vital elements for development (Robinson, 2012) the cultural environments of any society basically include beliefs, norms, customs, lifestyles, food, religion, governance, music amongst others. These are elements that identify any cultured society. But these elements are shaped by the physical environment they are bound to which include urban fabric, rural and peripheral fabric, public open spaces, the green infrastructure and road and transportation infrastructure. These are the linkages to the cultural environment. The unique society is thus seen from both the cultural and the physical environment. The internet and the social media for example, have tremendously shaped the way we communicate with others.

A study by social media today (Asano, 2017) indicate that the amount of time people especially teenagers on the internet is rising at an alarming rate. An average of nine hours a day is spent on social media with 60 percent of this done on smart mobile devices.

Smart city infrastructure therefore must be designed in context of the aforementioned two environments- cultural and physical (Robinson, 2012). The smart technology has resulted in a powerful collision of physical and the digital era that compliments both which hitherto was not possible to merge traditional urban patterns with cyberspace (Ratti and Claudel, 2016). The resultant of smarting a city brings about the dynamics of the complex interplay within the city which manifest as a cultured or accultured city. A representation of the smart city in context looking at the six components - goals, people, ecosystem, soft infrastructures, city systems and hard infrastructures is shown in Figure 3.0

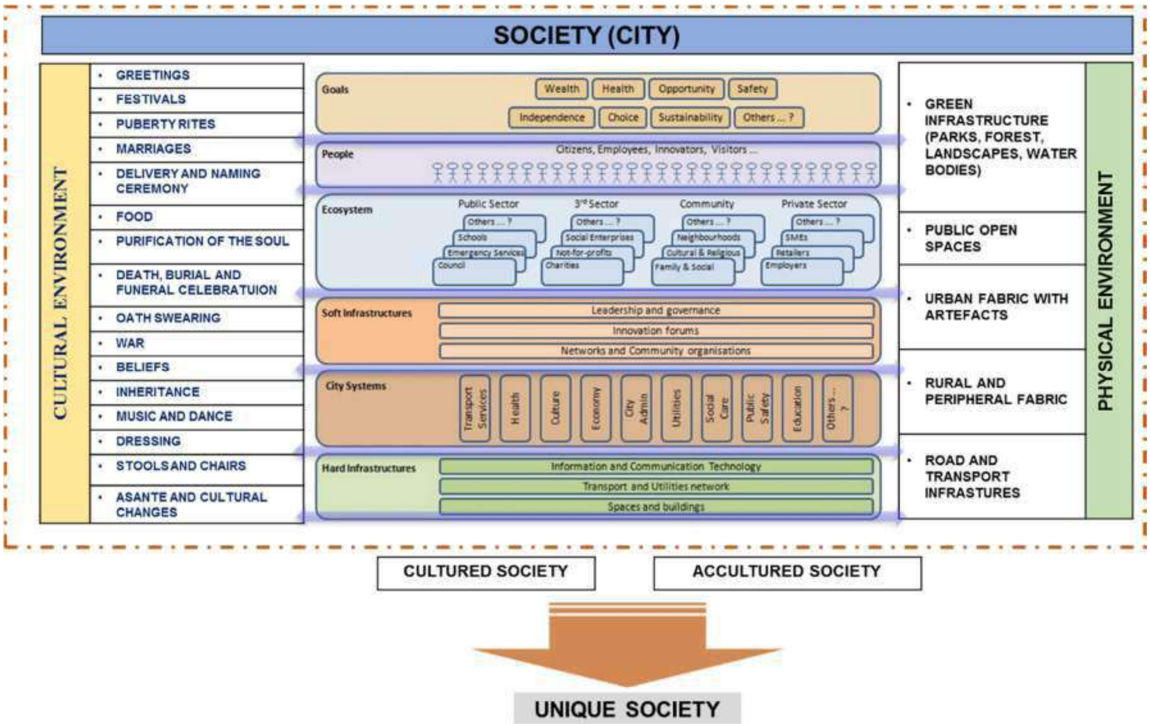

Figure 3.0 Linkages between Smart City Initiative and Acculturation
(Source: Authors Construct, 2018, with extraction from Rick Robinson, 2012)

Every smart initiative has goals specific from sustainability to economic growth with the people whether employers, citizens or visitors in focus. Thus user centric or citizen centric smart city initiative should be the ideal concept through a process of co-creative dialogue processes. This rather achieves much success than the top down approach of imposing products on citizens whether needed or not. It can be seen that each of the six components are impacted by both the physical and cultural environments and vice versa.

2.5 The Asante culture

Urbanization serves as a conduit for accelerated acculturation due to complexities and heterogeneous nature of the urban fabric. Culture continues to play the critical role of possessing the spirit, soul and life of every society making it the biggest asset and genesis for the development of any society (Asante, 2013). Ghana is located in West Africa with a population of 29 million, six main ethnic groups and more than 100 ethnic groupings. The dominant ethnic groups are Akan, Ewes and the Ga Adangbe. The diversity in Ghanaian culture and Asante culture in particular have both been acculturated and enculturated due to colonization, urbanization, education, religion and the influx of western cultures (Anquandah J. , 2015). The Asante tribe from the Akan ethnic group is one of the most culturally rich societies that cuts across national boundaries. They were originally known for the fearless battles, magnificence and power and wealth. Kumasi the capital city houses the center for national culture and the seat of the monarch of the Asante kingdom Otumfuo Osei tutu II. A culture reflected in every fabric of the society from elaborate funerals to celebration of festivals, religion and even music and rhythms (Asante Appau et al, 2015).

Their rich culture is seen in their architecture, governance, music, and food, customs such as funerals and marriage rites as well as religion. For example their architecture of the traditional courtyard as seen in figure 1 below depicts the outdoor activities performed in the open space bounded by the four sides of the building with verandahs and ornamentation of the facades (Asante Appau et al, 2015).

Figure 4: Verandahs of Asante Common House
(Source: Civilization Fanatics Center, 2014)

Another cultural practice that was distinct was the greetings in various forms which was a duty of any native when he meets a person. It was considered disrespectful not to greet your elders. Greeting styles such as which was dependent on the relationship you had with the person such as '*maakye*' or '*maadwo*' will elucidate a response of '*yaa oburu', 'yaa opeafo'* or '*yaa amu'* (Arowolo, 2010). Now most greetings especially from the young adults and teens greet using the western greetings of good morning, good afternoon or good evening with the same phrases as a response. Perhaps the dilution of the education practice as was in force before colonization could account for this. The trio-educational practice of firstly receiving initial education from family: secondly acquiring special sills in apprenticeship and thirdly having a community sponsored education was typical of the Asantes.

Other practices include; Puberty rites, marriage rites and naming ceremonies. Babies born are given names after eight days from birth with given names according to their day of birth.

The belief that every baby comes with a god given name which is usually the day they were born. This is seen in Figure 5.0

DAY	MALE	FEMALE
Sunday	Kwasi	Akosua
Monday	Kwadwo	Adwoa
Tuesday	Kwabena	Abena
Wednesday	Kwaku	Akua
Thursday	Yaw	Yaa
Friday	Kofi	Afia
Saturday	Kwame	Ama

Figure 5.0: Names given according to day baby is born in the Asante culture
(Source: Authors Construct, 2018)

A middle name is given to indicate the era and event that surrounded the birth of the child. Now it is not strange to see names such as *"Quasi" or "Aquiya*" representing a male Sunday born or a female Wednesday born respectively. Asante names have both cultural and social contexts that identify the bearer. These are quite different from the western names which are predictable, because a child's name cannot be accurately determined until is born with the surrounding circumstances (Agyekum, 2006)

Occurrence	Name And Meaning
Happenings	Dwabɔ: for somebody born on a durbar day Amantuo: for somebody born when running to seek refugee status in another state
Situation	Hia: for a baby born when the parents were poor Yadeɛya: for a baby when one of the parents was not healthy Afriyie: a good year
Festive Days	Adae: for someone born on Akwasidae or Awukudae festival
Deity	Anowuo: for somebody whose parents went to seek help to get pregnant from the Anowuo deity
Important Days	Buronya: for somebody born on a Christmas day
Child's Features	Buroni: for somebody born with light skin like an European
Place Of Birth	Takyiman: for somebody born at Takyiman. Dɔkota: for somebody born at the hospital

Figure 6.0 : Some Asante Names Based on Occurrences surrounding their birth
(Source: author's construct, 2018, with information from afropedia and Wikipedia)

Education amongst Ghanaians has suffered a significant acculturation from the west and the European cultures which has been attributed to the cultural capital and language facility over other cultures (Organista et al, 2010). The colonial history of the country has also been attributed to this phenomenon with most Ghanaians seeing education abroad as a great achievement and a guarantee for good prospects in life Irungu (2013).

There is a growing trend nowadays in the way Ghanaians are rapidly embracing foreign cultures especially from the west. This has led to the marginalization and gradual erosion of the sacred customs, beliefs and practices of typical Ghanaian. Major aspects of culture which have suffered most are dressing, music, food and education. Currently almost open space and food joints are serving foreign dishes to the detriment of local foods due to the craving for foreign dishes (Ibok, 2018). Similar sentiments have been spoken on the music culture where most people especially the youth are copying foreign culture through explicit music from these cultures (Anquandah J.,2015; Mawuli, 2005).The once beautiful rhythms of African songs and drums that resonates the expressive thoughts, emotions and beliefs of the Ghanaian way of life (Boafo-Arthur, 2014) is being brought back. For instance, a Government have even initiated national Friday wear to encourage the wearing of the traditional cloth for all occasions in the hope of encouraging the citizens to be proud of their culture and also introduce national chocolate day to encourage the local patronage of Ghana Chocolate and cocoa products.

Certain customary practices like purification of the soul, death, burial and funeral of the dead as well as divorce were very sacred and often solemn. Most marital cases were settled by families of both parties and if peace could not prevail the marriage is dissolved with the woman returning the drinks offered to her by the man. The woman was also restricted from making love to any other man for a period of three months as a surety of not carrying the husband's baby. The belief in the soul as a deity which should not be offended and when offended must be pacified was another core belief of the Asantes. This can be seen in the elaborate and expensive reverence given the dead in the kingdom. Knowing that death is just a transition to another world every preparation is made for the dead to transition comfortably to the other world. (Asante E. A., 2013) (Johnson, 1970). Cultural symbols such as stools/chairs, umbrellas and drums are very important in the chieftaincy institution of the people. The type of stool depicts the kind of authority and position a chief holds whilst the shape of drums are tailored to make unique sounds for different occasions. These are used to play beautiful Asante orchestra such as '*adowa', 'kete', 'sikyi', 'penpensiwa'* with the *'fontonfrom' drum.*

2.6 *Smart Community Initiatives and Acculturation - Case studies*

Two smart cities based on their peculiarities were studied as part of literature based on their smart city initiatives, location, culture and acculturation

2.6.1 Case Study 1: Singapore

Smart city initiative started form a smart nation vision that was established in 2014. Singapore is a city nation singling it out as a special case for study. The initiative is pivoted on the three key parameters – ICT, Networking and Data to respond to the urban challenges of ageing population, density and energy sustainability. With a population of 5.5 million, it is said that one in five is aged 65 and above. Today it is one of the most digitally connected cities in the world (Infocomm, 2018); the national data revealed that 650,000 own vehicles, 83% and 81% have at least one computer and internet respectively whilst mobile penetration stood at 137% .Though Singapore's smart initiative is in the early stages their ambition of becoming the world's first true smart nation is progressing steadily. Their slogan driving their objective is *everyone, everything, everywhere* (E3A). They seek to rely on their strong smart services – intelligent transport systems and e-governance, and strong government funding to build smart nation hinged on the six characteristic features of smart cities as discussed above. This ambition has been in existence for over four and half decades. Their major achievement so far include the integration of different governmental agencies on one platform ranking them first in delivering e-government; first in smart living in Asia after recording the highest quality of living as reported by Mercer (Mercer Survey, 2018) and in smart economy, it is ranked second as the most networked country in the world economic forum report (Report et. al, 2015)

Singapore has one of the most sophisticated information technology systems to enable smooth flow of traffic and safety on the roads. Smart mobility actions include one motoring which is a common platform for all vehicle owners to access traffic information, express monitoring and advisory systems and vehicle recovery service, your speed sign – a smart real time speed check device alerting drivers on speed violations, parking guidance system to guide drivers to available parking lots and bus information system called mytransport.sg smart application which provides real time information for commuters. The nation seeks to be a "car less" nation by 2050 with the injection of huge infrastructure in light rail transport to the tune of over 40 billion dollars. This is to make sure no Singaporean own a vehicle (Infocomm, 2018). Overall the ambition of the nation city to become a smart nation seems to have a promising future and special observation will be how their unique system of physical integration yet operating discretely will work together with the utilization of highly advanced smart systems (Kim, 2016).

The Singaporean culture is very complex and dynamic, rooted in geography and history, and diametrically different form the western culture (Yeo, 2016). Their culture developed over the years has a very welcoming and inclusive society, yet on issues of religion, race and language they are sensitive and often reserved. The country is an abode for all the nine member countries of the ASEAN with each having a strong presence in Singapore. But the Chinese culture bores an inseparable part of the Singaporean which dates back to the wars of china against japan. India and Malaysia are two other countries that have profound links to the Singaporean culture (Yeo, 2016) and it is now said that each Singaporean has a multiple identity. The openness and cultural diversity has given rise to the nation picking the best from each and incorporating them into their culture whilst maintaining a good cultural mix (Pitlane Magazine, 2018). However it is the British and the American culture that have had serious impact on Singaporeans in the area of writing (education) and governance. The colonization of the country brought them under the western culture through the development of the industrial age. These technological and digital age has accelerated the exposure of the younger generation to identify with the pop, music and dance and fashion culture from the west. Now there is growing concern about the craving for personal gain, material wealth, status gain and traits of ethnocentrism which hitherto was foreign to the Singaporean.

2.6.2 *Case Study 2: Tel Aviv:*

The city of Tel Aviv started its smart city project in 2011 with a unique approach of bottom up which focuses on residents rather than the infrastructure. The city is captioned with a slogan as the non-stop city. In their method of application they used a set of decentralized and low-cost processes to build a modular approach. This was rewarded in November 2014 at the world smart city expo, Barcelona when they were declared the world's smartest city. The smart model relies on strengths such as focus on residents, low cost, ability to receive feedbacks and liaising with entrepreneurs and private sector. (Aviv and Toch (2016) ; J. Kim (2016) cite a global ranking as the world' second best ecosystems with 70 start-ups and 1000 entrepreneurs in 2014. The core objective is to improve local resources and improve local resident's engagement in governance. This has created more trust between the municipality and its citizens. Through citizen oriented innovations, local solutions are found to address specific localized problems. (Curwell *et al.*, 2005; Batty, 2013) The city's perspective on smart city is in agreement with (Hollands and Hollands, 2008) and Angelidou (2015)as a process of driving technology into the fabric of the city making it an ongoing process with the human being as the conduit to achieve effective results.

Tel Aviv's smart services hinges on connected set of information sources and systems extensively used in the digital media often operated through citizen interactions on mobile applications, social media and municipal websites. This case draws some insightful lessons for future adaptations by cities. Firstly smart city projects must address a very specific pressing need of the society. Secondly the power of individuals was unleashed through local competition initiatives. Thirdly smart initiatives can be started with little budget and not necessarily relying on government for huge funding. Fourthly, the city is micro managed through the use of small scale projects to control the city's budget. Lastly there is active participation through active participation of all. Persons with Disability (PwD's) are able to communicate their ideas and proposals to the city authorities through the various platforms provided. The global attention given to this approach of smart city initiative puts Tel Aviv up as a global city. One challenge of this approach is how to converge all these different operating platforms. This is recommended for sustainable smart cities with a bias towards ICT (Townshend, 2002; Paskaleva, 2011).

The country of Israel is a young country of just seventy years with a population of nine million. Majority of the population are Jews and Arabs or Palestinians forming about 20 percent. The Israeli parliament has just passed a law that principally classify the country as a Jewish state and makes the Hebrew language the official language of the country (BBC, 2018). This sums up the cultural identity of the people of Israel which determines to be known as a Jewish state with Hebrew as the state language. This is a defining moment in their history. Israel's large information technology industry is amongst the largest in the world with 80 percent of the population having internet access (Internet World Stats, 2017). The Israeli cultures continue to be closely guarded against losing their Jewish identity, a reason people believe resulting in the passing of the bill. The culture is hinged on their religion of a monotheistic God which defines every aspect of their life. Festivals, practices, dressing, language, food and housing etc. all have links to their Jewish religion (British Library, 2017). In spite of the technological advancement spearheading the country's development not much traits of acculturation can be seen from other cultures.

3.0 METHODOLOGY AND PROFILE OF STUDY AREA

3.1 *Methodology:*

The study was conducted in Kumasi, the capital of the Ashanti Region of Ghana. The study adopted the mix method of qualitative and quantitative methods in a QUAL-QUANT ratio of 50:50 as it sought to investigate a phenomenon in real life context (Yin, 1984). Mixed methods research was adopted due to its representation on research that involves collecting, analyzing, and interpreting quantitative and qualitative data in a single study or in a series of studies that investigate the same underlying phenomenon. This is often preferred over a single method for this kind of research because it has a superior advantage over the two major paradigms due to its pluralism therefore affording the reader a better understanding (Harrits, 2011). The qualitative aspect of the study involved the case study of the Kwame Nkrumah University of Science and Technology (KNUST) and Kumasi City whilst the quantitative aspects dealt with the precedent studies of Singapore and Tel Aviv in in Israel by virtue of their smart initiative strategies. Perception of levels of acculturation was assessed on the KNUST campus. Data was gathered through a structured questionnaire survey and interviews in accordance with existing theories and findings from literature. A purposive sampling method was used to gather this data from a cross section of people both students and lecturers. They were asked to identify and rank aspects of the Asante culture perceived to be acculturated as well as perception on smart city concept for Ghana. In all 98 people were sampled.

Data collected was analyzed through SPSS and Excel in table and graphical representations of results. Ranking was done using a score of 1 to 5 with 1= lowest and 5= highest to measure the respondents perception about factors on smart concepts. In calculating the scores for the variables in each category, weights were given to the ranking (1= -2; 2= -1; 3= 0.5; 4= 1; and 5 = 2). The sums of average scores of each category were summed up to obtain overall score on total score of 200.

3.2 Profile of Study area:

Kumasi is often referred to as the cultural capital of Ghana due to its rich cultural heritage. It is the home to about 1.9 million inhabitants and is the second largest city after the national capital Accra. It is the home of the king of the Asante, the king of the great Ashanti kingdom. The Asante region has the highest population of 4.7 million out of Ghana's population of 29.4 million. (Ghana Population, 2018). Kumasi is divided into ten administrative regions as seen in figure 7. The study area Kwame Nkrumah University of Science and Technology lies in the heart Oforikrom sub-metro district of Kumasi metropolis. The University is well-known for its strides in science and technology innovations for the country since independence (KNUST, 2017). The campus provides services to over 55,000 people of all ages ranging from educational, health, recreational, commercial, religious and residential. It is the greenest zone on the city map and a major commercial hub for surrounding towns and those avoiding transactions in the undue traffic towards the central business district

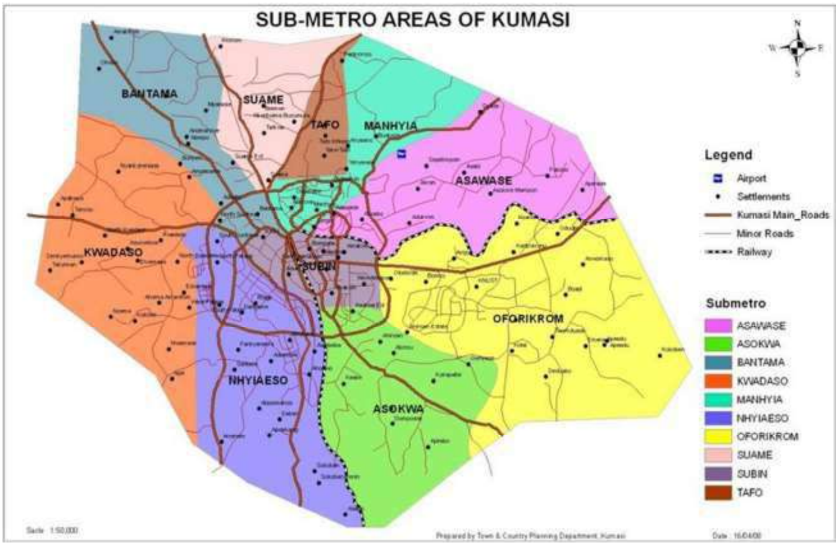

Figure 7.0: A Map Showing the administrative areas of Kumasi city
Source: Town and Country Planning, Kumasi.

The campus has good infrastructure facilities. Over 90% of all roads are tarred and in good condition with major road spines having pedestrian walkways and well-lit street lights boosting the level of security and safety on campus residents. Security has being complemented by the recent installations of CCTV at major junctions on campus. Bus shuttle and taxi services are available with bus/rest stops at vantage points.

4.0 RESULTS AND DISCUSSIONS

4.1 Characteristics of Sample Population

A total of 98 people were sampled from postgraduate students, lecturers and the other workers on campus during the second semester of 2017/2018 academic year (January-May, 2018). The cross mix sample population was chosen to give a true reflection of this exploratory study of the people in Kumasi. Respondents were voluntarily asked to participate in the survey. The successful respondents comprised 74 students, 14 lecturers and 10 from other occupations.

4.2 Mobile Phone Usage and Data Accessibility on University Campus

The respondents indicated a 100% access to mobile phones as well as the internet, with 93.8% owning smart phones, 4.2% with a feature phone. The university campus has good reception for most of telecom companies with staff and students having a prescribed data package every month for use. This has enabled many to have access to the internet to perform varying tasks. In spite of this, many of the respondents (76.5%) still relied on prepaid data bundles as their main source. Free Wi-Fi services accounts for 12.7% of data source and the remaining 11.8 relied on postpaid data.

The respondents spend 4.8 to 15 Euro equivalents/ month on extra data. Most of these data are used for smart application such as the social media, way finding and navigation, information and research amongst others. This confirms an earlier research the use of smart phones on a similar study on smart campus initiatives as seen in the Figure 8.0 below.

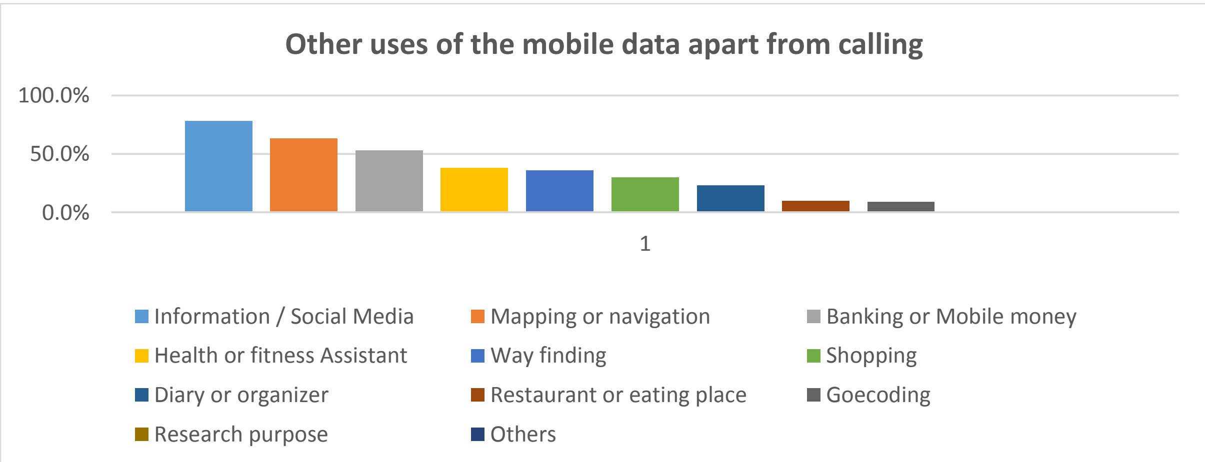

Figure 8.0: A Graphical representation of respondents other usage of mobile phone data
Source: authors construct, 2017.

4.3 Perception on Smart City Concepts

The majority of the respondents when asked about smart city concepts (69%) indicated their knowledge of the smart city concept from four different sources- literature, social media and course study, and conference/workshops. When asked of their opinion on whether it is a threat or an opportunity for national development 75% agreed that it was an opportunity. Though most agreed to the concept as good, they thought it is expensive with 62% in this category and 38% think it is less expensive. On the question of whether Ghana is really ready for such initiatives the opinion was divided with 60% agreeing the country is ready for it.

4.4 Perception on Smart City Concepts in Kumasi

To further explore the smart city concept potential with the city the respondents were asked to rank the smart city characteristics from 1(lowest) to 5 (highest) according to what they believed was the city's performance. The table below (Figure 9.0) indicates the responses showing the varied perceptions of each variable. On scale of 1 to 200, smart people concepts scored the highest (59.79). This is rightly attributed to the number of tertiary institutions within the city. The city is home to over 20 public and private tertiary institutions. The rest fell below expectation with smart mobility and smart living obtaining a fair outlook. Smart environment had the lowest score, perhaps an indication of the environmental degradation and pollution within the city. Smart economy came second with a mean score of 37.13. The city has a potential of business enterprise and development due to their strategic location with Ghana and the sub region. Most of the countries of West Africa use the city for business and commerce.

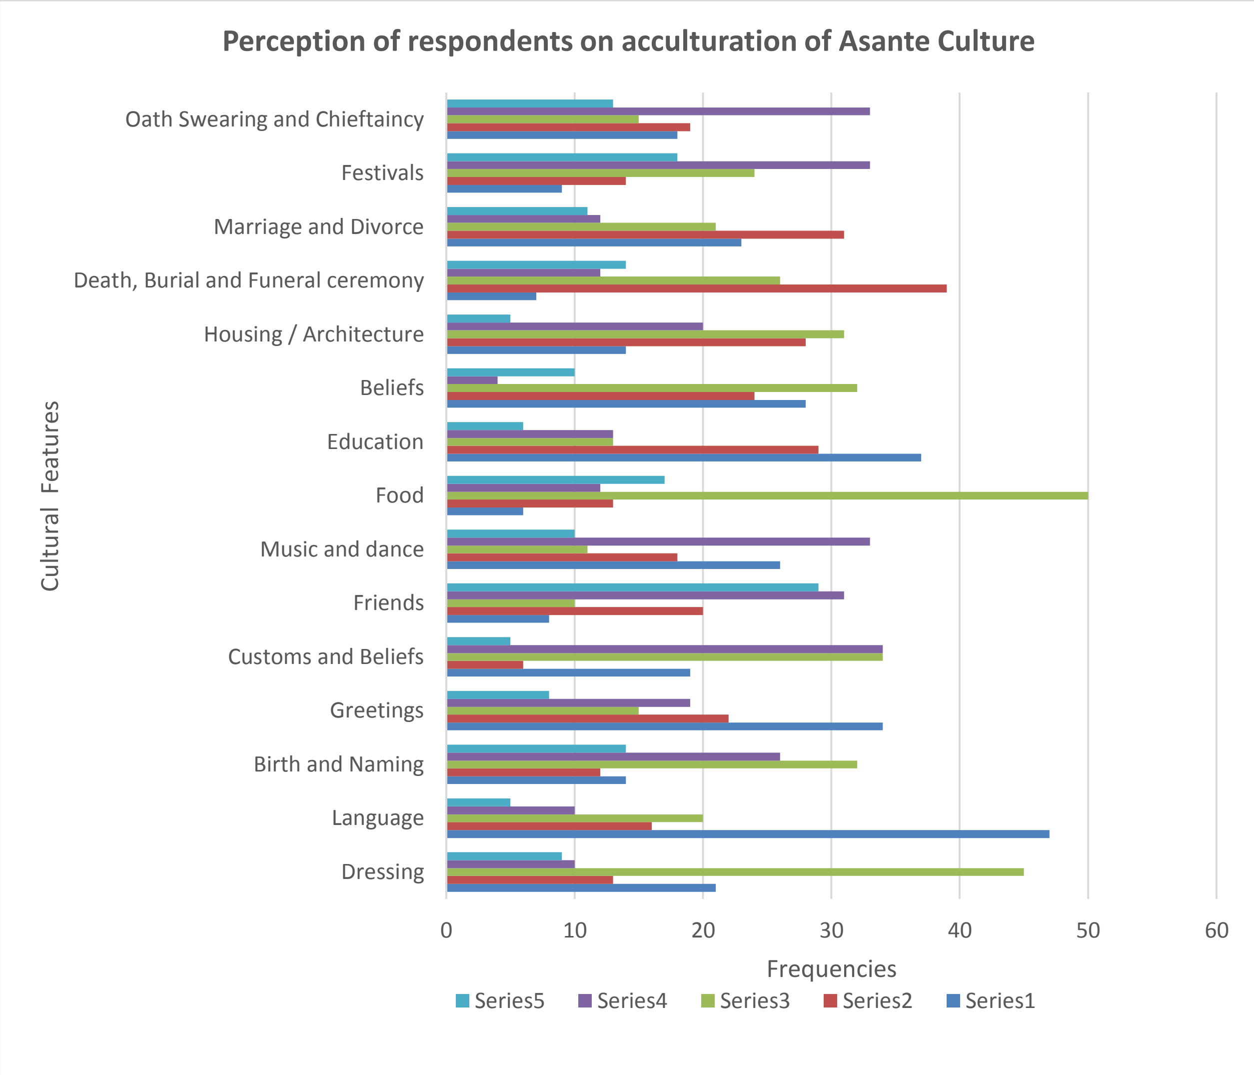
ITEM	***FACTORS***	***MEAN SCORE***
1	Smart Economy	37.13
2	Smart People	59.79
3	Smart Governance	21.19
4	Smart Mobility	33.10
5	Smart Environment	19.63
6	Smart Living	33.77
	Overall Mean Score	**34.10**

Figure 9.0: A Table showing overall Score of the Kumasi City on smart city concepts (Source: authors construct, 2018.)

However the Kumasi city performance on the overall mean score of 34.10 was below average performance. Though the city has a lot of potential in its citizens and economy, there is much to be desired in addressing major issues that gives the city a negative perception on its smartness.

4.5 Perception on levels of acculturation in the Asante culture

Out of the 98 respondents 81 indicated that they were Ghanaian, 11 were African and 6 foreigners, 70 of them were between 20 and 40 years whilst 28 were above 40 years. All the 98 respondents believed that acculturation has been accelerated by smart technology in the Asante culture, though with varying levels of dominance. Again when asked whether smart technology has accelerated its impact, 2 out of 3 respondents perceived that it has. Figure 9.0 shows the perceived acculturation levels of the Asante culture.



(Series 5= very high; Series 4= high; Series 3= average; Series 2= low; and Series 1= very low)

Figure 10.0: A chart showing levels of acculturation of the Asante culture
(Source: Author's construct, 2018)

The survey indicated most people perceived that education, marriage and divorce, beliefs, greetings and language are the most acculturated aspects of the Asante culture. Education and language for example had 69.3 and 64 percent of respondents respectively indicating a high to very high levels of acculturation, whilst greetings and marriage and divorce aspects had 57.1 and 55.1 percent respectively. Food had a significant 51percent indicating an average level of acculturation with 19 percent indicating a high to very high level of acculturation.

Death, burial and funeral ceremonies as well as architecture and dressing all had average levels of acculturation. Aspects of the Asante's culture that had low levels of perceived acculturation included friends (61%), festival (51%), and oath swearing and chieftaincy (46%).

These findings are reflected in the prevailing culture within the region. Formal education has become the seemingly only option for every child and opting for the traditional way of education which involved tutelage under elders and apprenticeship is seen as a failure and frowned upon. Even the citizens are willing to pay huge sums of foreign cash in order to have an education abroad which is seen as a success and preferred over Ghanaian degrees. Closely linked to this is the language spoken. With the country adopting a foreign language (English Language) as the official language, the use of the local language (Asante Twi) is frowned upon even in schools as it is an optional subject and not a medium of instruction.

This language imposition by the colonial masters of United Kingdom and the eventual adoption by succeeding governments as the official language has given rise to a psychological cultural dominance of the English culture to that of the Asante culture which is reflected in all aspects of their culture. For example most couples prefer the white way of dressing and marriage to that of the Asante traditional dressing and marriage as seen in Figure 11. And to satisfy both their psychological preference and family/society tradition many are now doing both bringing unnecessary cost to marriages nowadays.

Figure 11: The traditional and white wedding practices in the Asante culture.
(Source: Pictures taken from yen.com.gh and onobello.com and edited by author, 2018)

In furtherance to finding out the levels of acculturation it was important to also find out the respondents perception of the foreign cultures impacting on the acculturation of Asante culture. In this regard respondents were asked to indicate one potential foreign culture of dominance to the Asante culture. The results are shown in figure 12.0. Respondents were of the view that western culture, the Chinese and the European culture are the three foreign cultures that has the potential of accelerating acculturation of the Asante culture through technology. The onset of the digitization of the media landscape has given rise to free to air channels of which most are in these three aforementioned cultures.

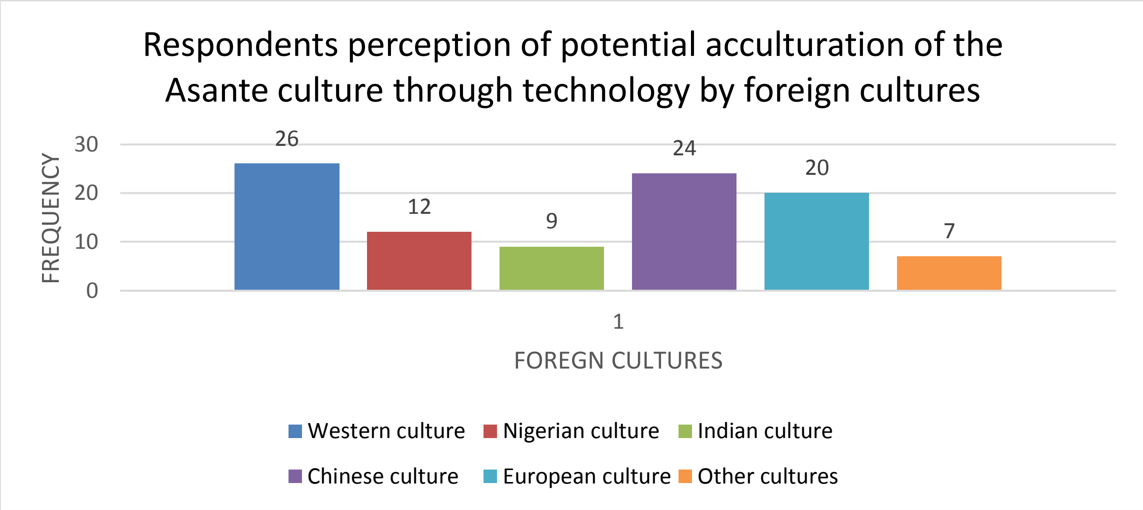


Figure 12.0. A graph showing the potential foreign culture dominance over the Asante culture (Source: Author's construct, 2018)

At the same time they are responsible for most of the technologies that are being used for smart cities concepts. Nigeria is the only African culture mentioned as a potential for acculturating the Asante culture. This might be due to the preference for Nigerian films, music and lesser extent their dressing over the local ones.

5.0 Conclusions and Recommendations

The population of the worls currently at 7.63 billion is projected to reach 8.5 billion by 2030. This phenomenom is accompanied by a similar increase in urban population. There has been a global rise in IoT connections projected to reach 25 billion with smart homes, buildings, cities, enterprises and innovations in the urban ecosystem. The groth in the urban population and IoT has had negative influence on the culture of peoples leading to acculturation of many cultures. A number of countries have attempted to use the IoT as a positive influence although acculturation exist. This study sought to explore how marting the city of Kumasi had affected it conclusions.

The study makes the following conclusions

1. The study revealed that acculturation is a phenomenon that is taking place in many countries at different levels depending on the cultural orientation of their citizens.
2. Acculturation has occurred in the Asante culture with technology speeding up its integration into marginalization.
3. Acculturation is high in areas such as greetings, education and language.
4. There is a high potential of acculturation being accelerated through smart city initiatives.

The study thus makes the following recommendations

a. Smart city initiatives should be citizen sensitive or the bottom –up approach processes be engaged from throughout such initiatives
b. There should be a conscious effort by key holders such as traditional authorities and government to proactively sensitize the citizenry on their culture
c. Further research is need to investigate and identify the actual relationship and the extent to which smart city initiatives can have on acculturation of culturesIntegration strategies as well as policies to slow down the transformation in the midst of smarting the city.
d. The use of Emojis and Apps should not replace greetings and languages but reinforce it into enhancing barrierfree and inclusive communities.

e. The culture of food, dressing and education, mobility could be integrated through careful anthropological research that can reduce marginalization tendencies of IoT for the cultures of the various local communities.

Tourism and ICT; a new urban challenge to planners

Maria da Graça MOREIRA, University of Lisbon, Lisbon School of Architecture/CIAUD, Portugal

Abstract

Tourism has been one of the economic activities that have developed most in urban space, in the last decades. The growth in the number of people who make tourism along with the changes in information and communication technologies (ICT) are having a significant impact on the appropriation of urban space.
The climatic alterations will have an increasing impact on the tourist activities, reducing some, but valuing others. Information about the weather and the time that is felt in every place is an important aid for planning tourist trips.
The evolution of Information and Communication Technologies (ICT), from static to relational information, the mobility and connectivity of the devices and the possibility of secure transactions have had a very rapid and exciting development.
From the national level to the local or neighbourhood levels, technology is changing the way information reaches the local and foreign population.
But urban planning is far from being able to predict or control these new forms of appropriation of urban space and accommodate them.
The easy way to disseminate tourist information through public services such as municipal services, allowing each territory to disclose what they consider most interesting or where they want to invest, or even the most innovative place without any intermediation, is significant and can be or not, a sustainable way of economic development.
The development of useful APPs for tourism activities that disseminate information and facilitate the appropriation of the urban or rural space in a much larger way than traditional tourism use to do is amplifying the economic impact but also opening new territories to tourists that were not prepared for that.
The "anarchic" way in which private housing owners put their apartments in the international market in undifferentiated buildings and without the consent of neighbours is another type of new situation that can create many problems in some quarters, challenging the resilience of territories to these sudden changes.
At the outset of technology use, ICTs have proved to be very useful to everyone, but more and more problems are emerging at the local level.
This presentation intends to analyse some of these new challenges to the urban planning and city management, created by the tourist activity at the local level. It also wants to reflect on new urban management instruments, which are faster and adapted to the speed of urban changes.

1. Introduction

The intelligence represents, from a territorial approach, a new planning paradigm, based on knowledge-based economies and in a globalised innovation. This new planning paradigm, in general, related with smart cities, has not been researched in all facets, in special the negative ones or at least not wholly positive results for urban quality of life. One of the functions that have been profiting from the new technological changes with the use of the internet, in a radically new way, is tourism.
This research **a**nalyses the change in the tourism (urban and cultural) and the behaviour of the tourists in the last decade according to the development of the access of internet in the

city and in particular in mobile phones (smartphones) and the relation with climate exchange. The methodology used for this research involves the analysis of the technological evolution of the devices, that can distribute information about tourism and related subjects.
Analyze qualitatively the information, and the impact it has on the behaviour of people namely the tourists.
Relate it to the traditional methods used in the planning and management of the territory to draw conclusions, about the changes that must be made in the knowledge areas of planning and land management.
The first smartphones were in the market in the middle of the 90's of last century, but the real change happens in 2007 with the iPhone from Apple, and since then the APPs are increasing every day (fig.1).

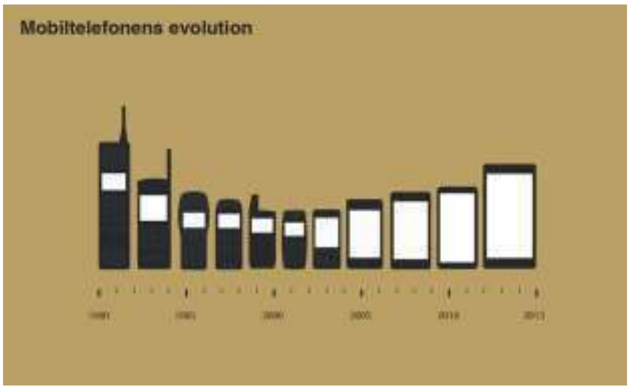

Figure 1 Evolution of Mobile phone
Source: https://www.engadget.com/de/2015/05/04/infografik-die-evolution-der-handys/?guccounter=1

In 10 years communication technologies have abruptly entered into partnerships in the tourism sector, and are used not only, by the economically more prosperous population, not just the youngest but by all the socio-demographic groups that travel.
To study the impact of some APPs and sites in the spreading of tourism in residential areas of the city or at least non-tourist areas can be very useful for urban planners and the evaluation of the importance of these changes in the management of the city is the great value.
The APPs that give information about the weather are, in general, entirely credible on the extreme phenomena that with the climatic alterations are more frequent. This information, at the time, allows tourists to take the best options to occupy their time safely.

2. Importance of tourism in the region and the city

The tourist activity is more and more relevant; in Europe last year had 4% increase in overnight stays, and in Portugal, the tourism represents 12% of PIB, in 2017 (INE,2017).
It is an activity significant around all European countries as we can see in Fig.2, and with special relevance by the impact of many foreigners in some communities like the north of Scotland and the Algarve.

The activity is very relevant to regions and cities considering it, in functional terms, because of the importance of the economic and innovative activities linked with the tourists (Ahas et al., 2008) (Cavus, 2014)
The localisation of the activities used to be very limited because the centrality that foreign people need is well known by the planners.

The increasing number of people using the public spaces and their animation can be seen as a demographic challenge because some urban areas were desertified some years ago, but often the management of the territory goes to tow of new locations.
The new valorisation of tangible and intangible heritage connected with the economic importance of some places but also with the valorisation of the culture of each territory is empowering local population. The urban regeneration that is increased by the investment in buildings is also notaries in the cities.

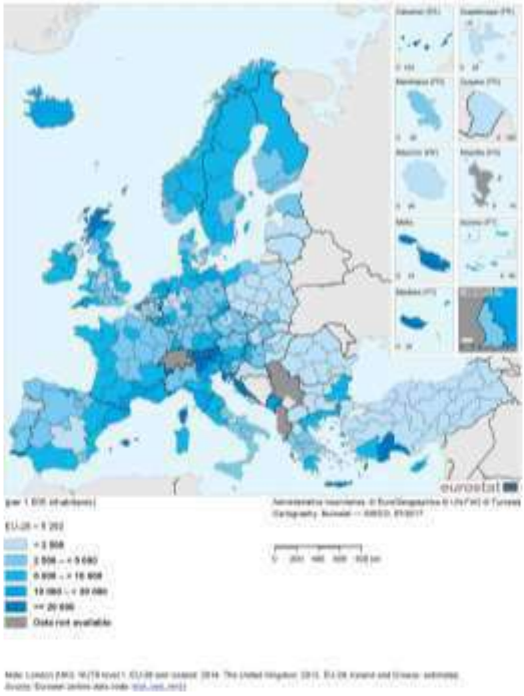

Figure 2 Number of nights spent at tourist accommodation establishments relative to population size, by NUTS 2 regions, 2015 (per 1 000 inhabitants)

Source: Eurostat

All these activities of tourism or leisure can be located anywhere since they are presented on the web, linked with a map APP. The GPS leads, customers or visitors, wherever you are to the point of attraction.

3. ICT and Tourism

The development of Information and Communication Technologies (ICT) in last two decades can be seen according to the development of the infrastructure and in special of the broadband, from analogical access, mostly offering static information only in some areas, to digital access with the exchange of information and services and mobile devices with ubiquitous access in the country and abroad.
Analyzing the evolution of mobile phones in the population, in Europe, we can evaluate the potential of users when people travel (fig.3) by the number of phones they have. For example, in Sweden, they have 2,210 subscriptions by hab. Which, that when travel will use it, but even Croatia has 1.1habitant, this means that everybody has a mobile phone.
The evolution of ICT from static information till relational one and the possibility of secure transactions have a very fast and interesting development, in particular, in the tourism area.

The development of internet infrastructure is spread around the cities, with many places like coffee shops and restaurants giving free access as a marketing element.
The development of the contents to tourism activities is increasing very fast, in the public sector with the information about urban life, cultural heritage and economic activities; in the private sector in economic activities like restaurants, hotels, transport services, recreation activities and weather.

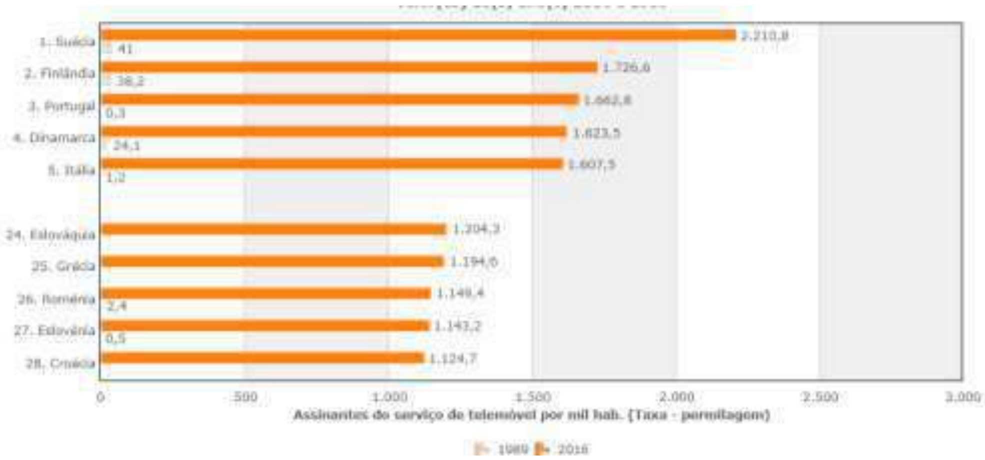

Figure 3 Mobile phone service subscriptions by Thousand ha. in Europe (1989 and 2016)
Source: Pordata

4. Tourism and ICT In Portugal

Tourism mobilises 82% of searches, on Portugal, made on the net, and this interest 52 times greater than shown by the information business (Turismo de Portugal, 2015).
Researching the access to internet by age in 2015, the data shows that till 44 years old, all the Portuguese of this group use it, in the group between 44 and 54 the use is more or less 65 %, the group 55 to 64 the use is 50%, and the older ones have a minimum of 30% (fig.4).

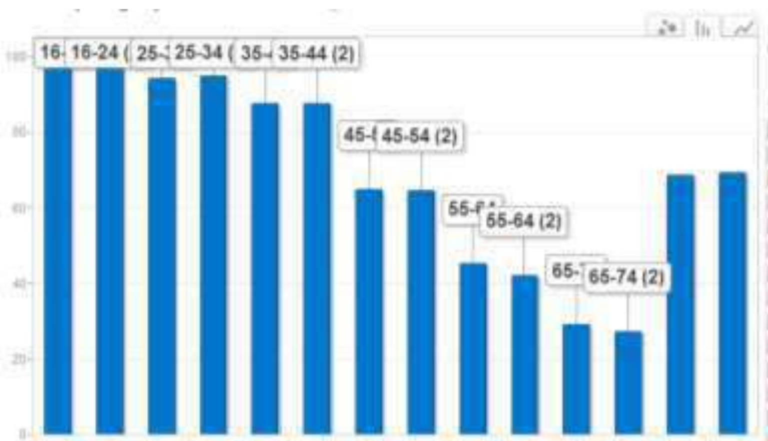

Figure 4 Individuals who use computer and internet in % of the total of individuals by age groups in Portugal 2015
Source: Pordata

If we cross this data with the penetration rate of smartphones that is 73.6% in Portugal in 2017 (Anacon, 2017) can be concluded that when they do tourism, they use it in a massive way.

The use of broadband in mobile devices, in Portugal, is mainly on mobile phones, 91% while in other types of handsets it is only 8.3%, in 2017(Anacon, 2017).

So the impact of ICT on the tourism covers several areas like:

- Cartography and GPS based mobile application making very easy access to big scale information with photographic recognition, which allowed the liberty of movements and independence from the knowledge of the language;
- Transports, with the possibility of self-organisation of the movements to a place and in the city;
- Touristic places allowing discovery of personal interest places, development of particular interests groups, but also the possibility of local authorities to do their marketing;
- Accommodations development in new urban areas where foreign people can stay with hotels out of the traditional touristic zone or new types like Airbnb, spreading tourists around residential areas and in peripheral neighbourhoods with the mix of local and foreign population in the same building;
- Restaurants with the equal opportunities than accommodations that allow the increase of publicity and clients

If the use of mobile phones is all around, the use of broadband is not homogeneous in the country (fig.5). The behaviour and information of tourists and local people can be entirely different.

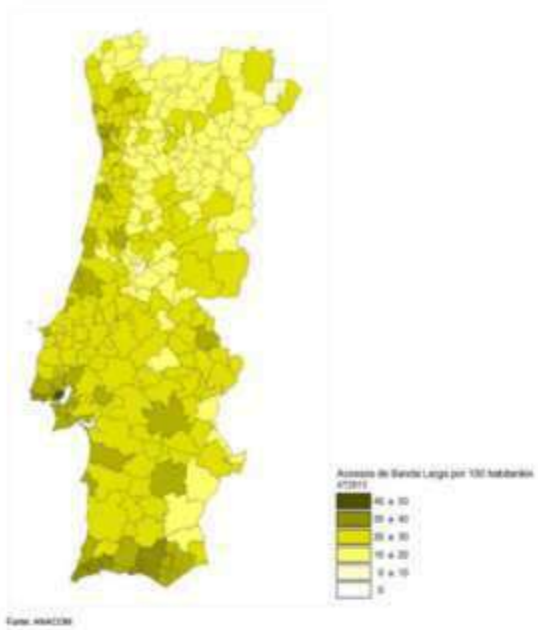

Figure 5 Geographical distribution of mobile broadband by 100 habs. in Portugal

Source: Anacon

Access to broadband and the information that is distributed by it is especially important when climate change brings unusual situations, that may be very relevant for tourism in rural areas and low-density territories, such as extreme temperatures or torrential rains, which may lead to less noticeable people.

Information on natural conditions can also be very relevant to the coast, such as sea conditions, such as ripples or water temperatures.

In a country that is affirming itself in sea sports, such as surfing and body boarding, the quality of information is very important.

By another side, organise tourism activities without disrupting urban life namely in public transports and housing, and prevent the resident population feels used for tourist purposes is more challenging for planner and territory management when the tourism can be ubiquitous.

Technological changes have been very rapid and profound, mainly in 10 years. Changes in population behaviour that are related to the current access to information, happen simultaneously in the world, and for the first time, there are no countries or regions that are pioneers in the effects of technology.

are always being challenged by technological evolution, and they need new tools, for example, with data from localisation of smartphones to be aware of the new flows of tourists and quickly create but adequate measures to a good quality of life for all.

5 Conclusion

The effect on tourism and leisure of climate change can be minimised or even exploited when ICTs and their APPs are applied to information for travellers, as for the general population

The introduction of ICT in urban life and in particular in tourism activity allows a wider distribution of economic benefits brought by tourism.

But at the same time developed unpredictable targeting tourism and the deregulation of services dissemination of tourism by not tourist areas.

Create difficulties for the resident population cope with the impact of tourists and also challenges for the public authorities to control the types of tourist offer.

There is a recognition of the need to use new methods and new data, more on the changes that are taking place in the planning and management of the territory.

Research on Urban Spatial Structure in Shanghai from Human Mobility View Based on Cell Phone Data

Xiyuan REN, Tongji University, China
De Wang, Tongji University, Professor, China

Abstract: With the development of traffic information technology and acceleration of life and work rhythm, in modern metropolises like Shanghai, the high frequency mobility of massive population has caused huge influence on urban internal structure. How to measure human mobility and explain its dynamic structure in the city is of great significance to understand the law of intra-urban population flow. Previous research has mainly focused on human mobility patterns. In this paper, we aim to go one step further from exploring how the whole structure look like when individuals' mobility are aggregated into spatial analysis units using relatively high-precision and large-scale cell phone data. Shanghai as a typical metropolis of China is selected for research. To address such question, we divide Shanghai into 5432 census tracts and calculate basic population in every spatial unit by identifying every user's stable location during 4:00 p.m. to 6:00 p.m. when human mobility is the lowest. Then we compare basic population with daily visit frequency to calculate the amount and the ratio of human flow in each spatial unit. Finally, we combine the strength of human flow with the influential range, the composition, and the temporal law of human flow to extract a dynamic structure of urban space in Shanghai. The result shows that People's Square enjoys the highest amount of human flow, approaching 2.95million visitors passing by per square kilometer, which is more than 10 times of its residents, while in suburban areas the average level of human flow is just 4.80 thousand visitors per square kilometer. Additionally, the dynamic structure of human mobility extracted from four dimensions of index is composed of four kinds of features: dynamic surface, from city center to subarea, shows the strength level of daily human mobility; dynamic center, including five center and eleven subcenter, becomes the most influential areas in the flowing network; dynamic cluster, can be divided into six groups according to the structure, influential range, and temporal variation of human mobility; dynamic corridor, strongly related to metro lines, highways, and Huangpu River, provides transportation supports for crowd flux. The findings of the paper help to illustrate a dynamic structure caused by human flow upon the static material spatial structure. The relationship between human mobility and urban structure can also be considered as s key issue which is continue focused on in housing, community development, and transportation field.

1. Introduction

With the development of traffic information technology and acceleration of life and work rhythm, the high frequency mobility of massive population has caused huge influence on urban internal structure, which has brought new challenge to urban spatial policy. How to measure the intensity of human mobility and explain its dynamic structure in the city is of great significance to understand the law of intra-urban dynamic structure and support real-time population management. Traditional population surveys such as nationwide censuses are conducted every 10 years. These survey data reflect only long-term changes. While human activities often result in large-scale population movements within a short period of time. Such rapid and irregular changes in urban space exceed the scope of traditional census data, which has become a shortcoming of population management in recent years. How to describe, measure and evaluate collective human mobility in urban space? Does the distribution of human behavior fit into the urban spatial form and structure? These problem are difficult to solve with the traditional urban structure model and static spatial analysis method.

The developing succession of urban spatial structure is influenced not only by the external influences of the region's natural and humanistic environment, but also by factors such as internal division of functions and land use. The structural laws behind it are constantly revealed by scholars. Relative researches has reached a considerable depth in the evolution and morphology of urban spatial structure with a series from classical theories such as concentric circle models, fan-shaped models and multi-core models Burgess (1925), Hoyt (1939), Harris and EL Ullman (1945) to Further empirical research by some scholars like Zhang Tingwei (2001), Wang Xufeng et al (2011), Bumsoo Lee (2007), Qi Feng et al. (2012). However, limited by the research data and methods, there is always a certain distance between macroscopic scale structure and the real human behavior. Whether our urban structure conforms to real law of urban life, there isn't a quantitative explanation that can be generally accepted.

In the era of big data, an increasingly broad array of user-generated data like cell phone data derived from location-based services and Global Positioning System (GPS) provides new possibilities to analyze human behavior and their spatial distribution. Mobile positioning big data have opened up the interaction between human behavior and urban spatial structure, which not only enables quantitative analysis of urban structure under greater spatial and temporal granularity, but also breaks the long-term research barrier of "interpreting space with space", revealing the spatial law behind complex form of the city from the perspective of collective human activity. Relative research has proved that the cell phone data can be used to identify these daily activities, such as commuting, traveling, and space-time path (Ahas et al., 2015; Widhalm, P et al., 2015; Phithakkitnukoon, S. et al., 2010; C. Song et al., 2010; John Doyle et al., 2014). However, cell phone data still have great potential that needs to be exploited to further advance human behavior studies. At the same time, it should be noted that along with the opportunities it brings, there exist many remaining challenges that need to be dealt with when taking the application of mobile phone data further (Csáji,B.C., et al., 2013).

Therefore, the paper aims to explore urban dynamic spatial structure from the perspective of collective human mobility by revealing the strength, structure, and spatial-temporal variation of daily human mobility, and describing the feature of its spatial distribution. Two-week cell phone data of 2G users in Shanghai are used as basic data. The remainder of this paper is organized as follows. Section 2 gives a panorama of relative research on urban structure and human behavior. Section 3 makes a detailed introduction to how cell phone data can be applied to urban spatial structure research. Section 4 illustrates the results of the case study performed, which shows collective human behavior in Shanghai. In Section 5, we make some discussion about the results, presents a conclusion of this paper, and provides insights for further research. The results can provide reference for the formulation of urban space policy and population management strategy.

2. Literature Review

This study, firstly, analyzes the spatial characteristics of urban population flow based on cell phone data, and then summarizes the urban spatial flow structure. In the end, recommendations on spatial policy are proposed after comparing the results with urban spatial structure. Before conducting such research, it is necessary to understand some basic theories through literature review: 1)The definition of human mobility in urban area and its relevant research 2) Previous research on human mobility with cell phone data 3) Measurement on human mobility, in other words, how to describe and evaluate human mobility and its spatial structure?

2.1 Definition

The Chinese household registration system makes population movement more complicated in cities of China compared with other countries, therefore, some general definitions are not applicable in China. However, some scholars have proposed their understanding on population movement in cities of China. Zhao(2005) compared population statistical stats of different countries and suggested to divide population movement into three types: "Population Migration" -- defined as movement that cross the boundaries of certain jurisdictions, which might bring changes in household registration; "Population Move/Movement" -- simply referring to the changing of residence within a certain period of time, including short-term, long-term and permanent relocation. It can also be classified into regional and inter-regional relocation; "Human Mobility" -- reflecting spatial positional changes in a short period of time. It usually occurs inside the city and continuously changes over time. In this research, we focus more on the human mobility in cities of China.

Dynamic spatial structure of human mobility is always an important topic in the field of Population Geography. Many scholars have visualized spatial and temporal patterns of human mobility based on traditional data such as survey and census (Qin et al., 2013). Some have stimulated dynamic spatial distribution of population (Wang et al., 2014), and analyzed the internal mechanism of population mobility and industry, land use and other related elements (Yang et al., 2015; Rao et al., 2015). However, due to the spatial and temporal limitation of conventional data, for example, there are missing data on temporary population who stay less than half a year as well as the data of short-term population changes; Besides, the research scale of previous study are mainly at regional level (Bian, etc., 2013), interprovincial level (Li et al., 2015) or city and county level (Wang Lu et al., 2014); and the data utilized are mostly in years (Pan et al., 2013). Few research are conducted in smaller scale and focus on the changes over several years. In addition, a small number of studies mainly use data such as census (Foley DL, 1952), population flow observational statistics (Foley DL, 1954), OD matrix (Akkerman A, 1995), travel survey data (Roddis SM et al , 1998) and high-resolution remote sensing data (Sleeter R et al., 2006) to visualize, estimate and predict the spatial distribution of human mobility (Mao et al., 2010; Qi, 2013; Kavanaugh P, 1990). In brief, few studies are able to analyze dynamic spatial structure of human mobility through agglomerating individuals' activities, thus, further research are needed, especially with the advent of big data.

2.2 Human mobility with cell phone data

In recent years, with the increasing availability of big data, cell phone data is widely used in the human behavior and urban spatial studies. The reliability of cell phone data on human mobility research has also been verified by many scholars.

In terms of identifying behavioral activities, Ahas et al. (2010) used one-year cell phone data of Estonia to construct a stop point recognition model so that to identify individuals' stop points (including residence, work place, other places, etc.), after which the population registration data were utilized for comparison and verification. Based on communication data from 100,000 people in Portugal, Csáji et al. (2013) simplified data through clustering and principal component analysis. He identified their residences and workplaces, and compared them with census data. Widhalm (2015) explored cell phone data and call detail (CDR) data in Vienna, Austria and Boston. Considering low accuracy of cell phone data, Widhalm constructed Markov network model and propose a method for identifying the behavior patterns of residents.

When it comes to the description of behavioral patterns, Phithakkitnukoon (2010) visualized and analyzed nearly one million cell phone data of users in Boston central region. He found that people from same workplace have strong correlations in their daily activities. Ahas (2015) defined four indicators: “midnight”, “morning start-time”, “noon” and “day length” based on the call details (CDR) data of three cities -- Harbin, Paris and Tallinn. By comparing those indicators within and among cities, he revealed the differences in the spatial and temporal behaviors of residents in different cities and in the central and suburban areas within cities. Yuan (2012) used cell phone data of Harbin to study the correlations among mobile phone usage and radius, eccentricity and entropy. The results proved that characteristics such as age, gender, social time and built-up environment had impact on the usage of mobile phone and residents' activities. Ran (2013) identified user's travel trajectory through call detail (CDR) data, and analyzed the distribution of resident population and employment population, commuting pattern, OD matrix, commuting pattern in specific regional and commuting characteristics of floating population.

At the same time, recently, some research topics have gradually shifted from the identification and description of behavior to the simulation of human mobility. C. Song (2010) explored the possibility and limitations of cell phone data for predicting human mobility. It is considered that irregular human mobility (except for commuting and leisure travel) is inherently unpredictable. In the same year, C. Song (2010) used cell phone data to construct a random walk (CTRW) model so that to quantitatively stimulate human mobility. John Doyle (2014) visualized population movements across Ireland with call details (CDR) data, by using Markov chain model to rank population hotspots, John found that the results are strongly correlated with census data. Till now, research on the simulation of human mobility are still in their infancy.

Existing research have proved the feasibility that cell phone data can be used to identify daily activities, such as commuting/leisure travel, temporal and spatial patterns, etc. Some studies have further explored the possibility of simulating human mobility with cell phone data. However, on the other hand, most of research focus more on the description or restoration of travel activities, while the explanation of influencing factors is insufficient in these research, as well as practical guidance on spatial policy, which will be the focus of this research.

2.3 Measuring human mobility

Measuring human mobility usually includes description and evaluation of spatial structure. Existing research are mainly from the perspective of spatial-temporal distribution and dynamic space of flows. The spatial-temporal distribution of human mobility mainly refers to the city's population density distribution of different periods. Akkerman A (1995) evaluated the densely populated areas of Saskatoon in Canada based on the matrix of residents' residences and workplaces; Qi (2013) Constructed a “population-day and night-land use” model based on the understanding of cities of different spatial-temporal behavior characteristics. He then used grid as the unit to estimate Beijing's day and night population and analyzed its spatial distribution characteristics; With cell phone data of Oregon, Sleeter R (2006) stimulated the population density of coastal communities, based on which these community space were evaluated. Zhong and Wang (2017) used cell phone data to build a dynamic "population-time-behavior" analysis framework and then explored the dynamic spatial structure of population and activities in Shanghai.

While the perspective of dynamic space of flows focuses on population OD flow and urban spatial network structure. Castells M 's (1996) research did not follow the proximity theory, which greatly promotes the study of dynamic urban spatial network; Shen and Gu (2010) defined space of flows based on the analysis of the flowing society. The concept of space of flows consists of three spatial elements: nodes, lines and surfaces; Cheng and Zhang (2016) used spatial data from branches of the Yangtze River Delta to analyze the spatial organization characteristics of urban agglomeration and quantified its evolution trend, indicators that they used includes centrality, inflow and outflow ratio, etc. Xi and Qi (2013) constructed the residential mobility index system, which covers four aspects: human flow, cargo flow, information flow and activity flow. They employed entropy to measure the mobility of residents.

All in all, three conclusions can be drawn through literature review. Firstly, based on research with conventional survey and census data, the intrinsic mechanism and spatial coupling relationship of population flow has already been deeply studied, but it is necessary to integrate big data and focus more on smaller research scope. Secondly, existing studies have proved that cell phone data could support the identification of human mobility, but for further analysis , most studies are still working on the description of the results, while the impact factors and application need to be further deepened. Thirdly, the measuring of human mobility has two perspectives: spatial-temporal distribution and dynamic space of flows. These two perspectives can be considered together with the support of big data. Therefore, this research will analyze the space of flows based on human mobility collected from cell phone data, which could provide some new perspectives.

3. Methodology

3.1 Data preprocessing

First, we address the station drift of cell phone location data to obtain the correct location for each user. Station drift has a specific characteristic whereby a personal movement trajectory drifts, in a short period of time, from one place to another place that is almost impossible to reach in that time interval. When the speed of a user is faster than 100m/s, we treat such point as a station drift. Moreover, if the lac cell ID of several points next to each other is the same, we merge these points and use the latest timestamp.

Next we change preprocessed data into travel-chain data which includes information like the location(longitude and latitude) and timestamp of every origin(O points) and destination(D points) in a user's travel trajectory. We use a distance threshold to judge whether users leave their O points. Considering the distance between two lac cells grows longer from city center to subareas, our distance threshold should change accordingly in order to maximize the identification of travel trajectory. Figure 1 shows the calculation of distance threshold: 1) divide 6 sectors with the base lac cell as the center, each 60 degrees; 2) calculation linear distance from the nearest lac cell in each sector, and get 6 distances; 3) choose the maximum value in these 6 distances as distance threshold. We use a time threshold which is 20 minutes(duration of two nearest timestamp should be longer than 20min) to judge whether users arrive their D points instead of just passing by. Table 1 shows the final processed travel-chain data which includes 14 days' travel-train information of 16.34 million users, this table is prepared for further analysis.

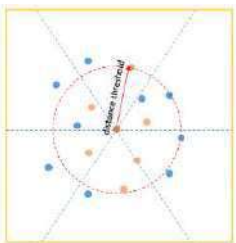

Figure 1: Calculation of Distance Threshold

……	……	……	……	……	……	……

Table 1: Travel-chain Data

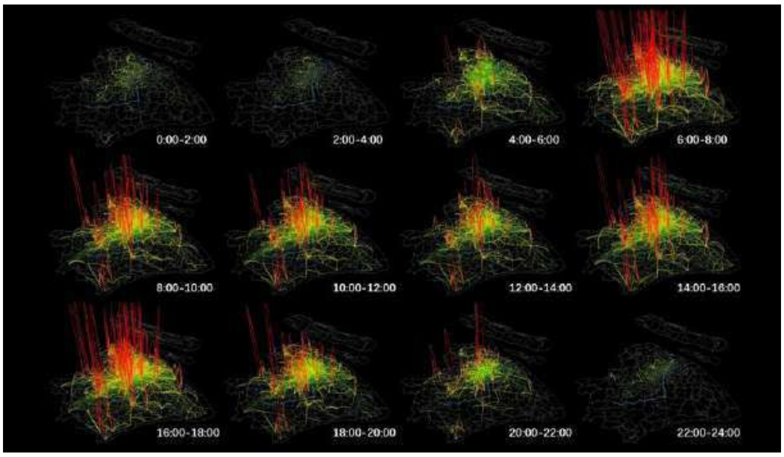

Figure 2: Travel-chain OD visualization

3.2 Description of collective human mobility

We describe collective human mobility from four dimensions, they are respectively mobility strength, mobility structure, influential range, and temporal variation. Figure 3 shows the indicator system of collective human mobility.

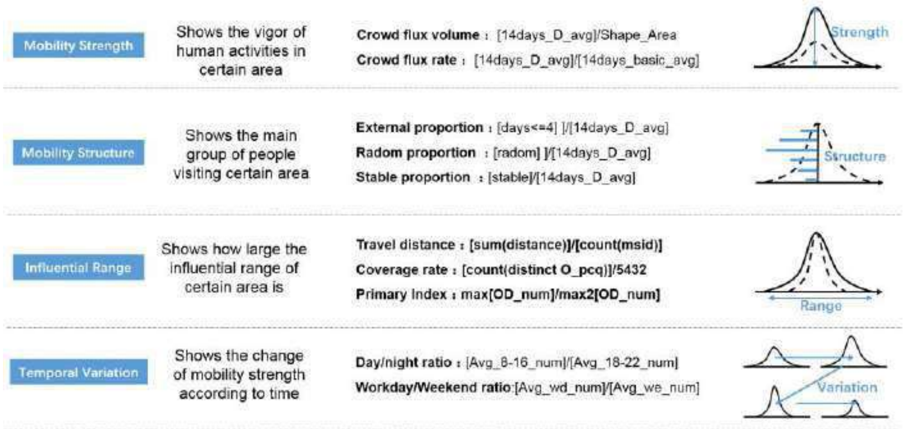

Figure 3: Indicator System

Mobility strength shows the vigor of human activities in certain area, including crowd flux volume. We aggregate D points into 5432 census units and calculate their density, so crowd flux volume reflects how many people per km2 choose a certain census unit as a destination every day. Since crowd flux volume is strongly influenced by population density, we divide it with basic population of each census unit(stay more than 3 hours here from 0:00 to 6:00) and get crowd flux rate which reflects how many times is every-day visiting population larger than basic population here.

Mobility structure shows the main group of people visiting certain area. We divide visiting population of each census unit into three parts. If a user have O/D points which are no more than 4 days in two week, he/she will be identified as external population since he/she maybe a tourist or come Shanghai for business. If a user choose a census unit as a destination only once in two weeks, he/she will be identified as random population since he/she won’t come here again in a relative long period of time. If a user choose a census unit as a destination more than 5 times in two weeks, he/she will be identified as stable population since he/she has a strong relationship with this place.

Influential range shows how large the influential range of certain area is. We calculate average travel distance of people visiting each census unit, the longer travel distance means the census unit can attract visitors from a larger range of area. Coverage rate presents the percentage of area a certain census has relationship with(more than 50 number of OD links). Primary index is introduced to judge whether travel from a census unit have a direction oriented connection with others.

Temporal shows the change of mobility strength according to the time. We calculate average crowd flux volume per hour from 8:00 to 16:00 as day volume and from 18:00 to 22:00 as night volume, then day/night ratio equals day volume divided by night volume. Also, we calculate average crowd flux volume in workdays and weekends, then workday/weekend ratio equals workdays volume divided by weekends volume.

4. Results

4.1 Mobility strength and structure

High mobility area in Shanghai can be divided into four grades according to their crowd flux volume (Figure 4-left): the first grade enjoys a visiting population larger than 100 thousand person per km2 such as the People's Square, Jingan Temple et al., the second grade has a visiting population between 60 to 100 thousand per km2 such as sub centers like , Daning, Wujiaochang, the third grade has a visiting population of 40 to 60 thousand person such as some community centers, and the fourth grade are several new towns like Songjiang, Jiading et al.. The distribution of basic population(stay more than 3 hours in a certain census units at 0:00-6:00) is similar to the distribution of resident population from the 6th National Population Census, with Pearson Correlation Coefficient reaching 0.699(Figure 4-middle). Employment center Lujiazui has the largest crowd flux ratio of nearly 12.0, indicating that the number of visiting population in Lujiazui is 12 times that of the basic population. Pudong airport, Hongqiao transportation hub and area along line 2 inside the inner ring road are obvious high value areas and crowd flux ratio in Chongming and the southeast of Shanghai is low(Figure 4-right).

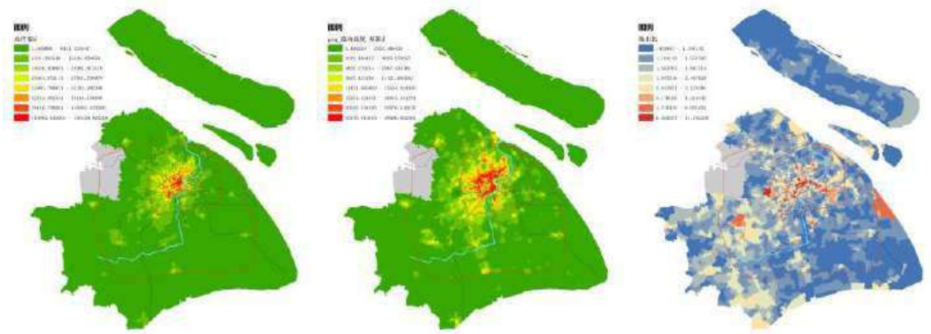

Figure 4: Crowd Flux Volume, Basic Population, and Crowd Flux Ratio

Combine crowd flux volume and ratio we can get comprehensive mobility strength of these census units in Shanghai(Figure 5). The areas with highest mobility strength in Shanghai are in turn: city center > sub center (high volume) and transportation hub (high ratio) > regional center > new town. Songjiang has higher mobility than other new towns, followed by Jiading, Baoshan, and Jinshan, while Nanhui new town has a low mobility.

Figure 5: Comprehensive Mobility Strength

Hongqiao transportation hub has the highest external proportion, 27% of the visiting population is external population, external proportion of transportation hubs is obviously larger, and the second is the main employment center(Figure 6-left). The random proportion city center, employment center and transportation hub are relatively high, for example random proportion of the People's Square, Lujiazui and Hongqiao hubs are all over 55%(Figure 6-middle). Residential areas and outer suburbs with small visiting population have relatively high stable proportion. For example, Nanhui new town has extremely high stable proportion of 60%(Figure 6-right).

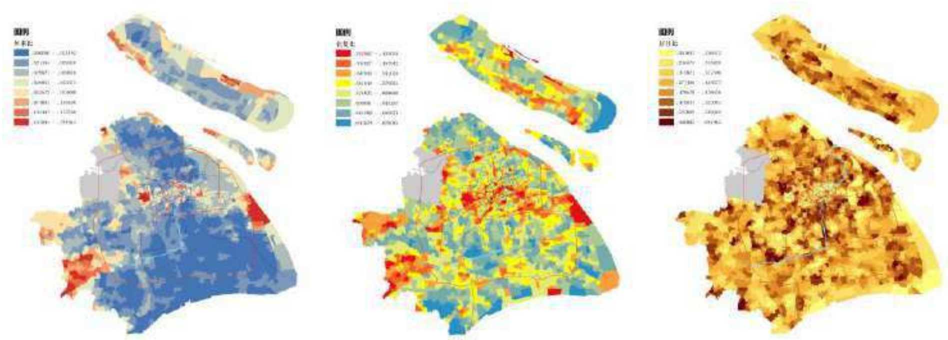

Figure 6: External, Radom and Stable Proportion

According to the proportion of the three groups of people, 5432 census units can be divided into random oriented type, stable oriented and basic oriented three types(since average external proportion in Shanghai is low compared with other index, we put external population into random population). The Figure 7 shows the distribution of these three types. It can be seen that there is almost no basic dominant in high mobility areas, so for these high mobility regions visiting population should be taken into consideration as well as resident population.

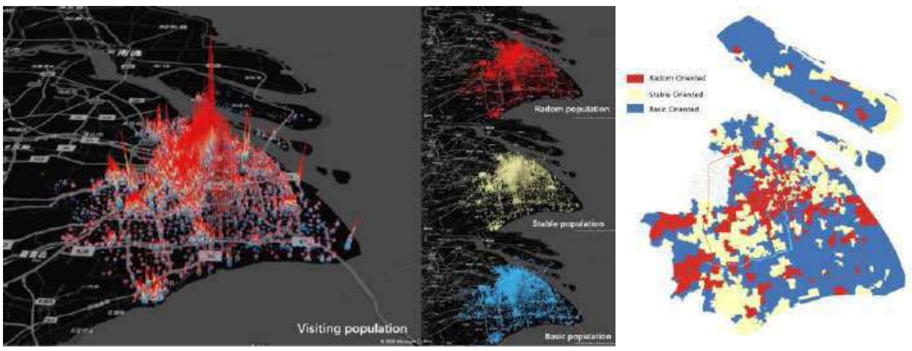

Figure 7: Comprehensive mobility structure

4.2 Influential area and temporal variation

The travel distance of transportation hub is longer, with Pudong airport reaching 18.8km. Areas inside the inner ring road have relatively short travel distance, while there are some exceptions such as the people's square, Tiantong road, Lujiazui, and Xujiahui. These areas can attract visitors from an average distance of 5.5-6.5km(Figure 8-left). When it comes to the coverage rate, areas along Line 1, 2, 8 form a "cross high value area", Lujiabang Road has the highest coverage rate reaching 25.7%, which means it connects a quarter of census units in Shanghai(Figure 8-middle). Nanhui new town, Pudong airport and Changxing island have a high primary index, reaching 6.0, that is, the crowd flux of the largest OD link is 6.0 times the second large OD link(Figure 8-right). Primary index of employment zones is relatively high, indicating that the attractiveness of employment has a clear direction. Since primary index shows the special link between two areas, we won't put it into the calculation of comprehensive influential range.

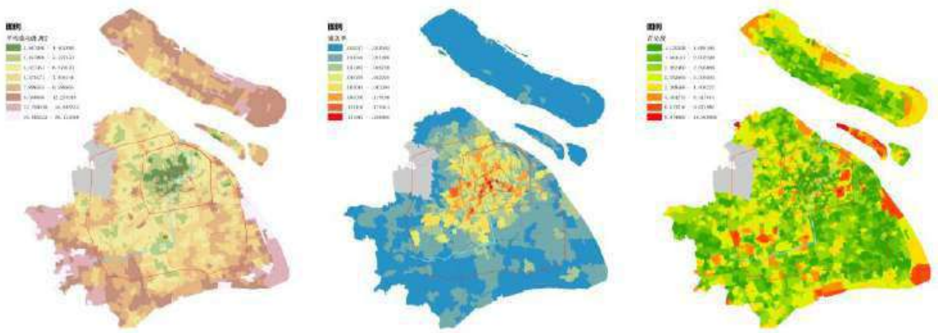

Figure 8: Travel distance, coverage rate, primary index

Combine travel distance and coverage rate we can define whether the influential range of a certain census unit is large or small. We can see from Figure 9 that influential range of suburban areas are the most extensive. The people's Square, Lujiazui, Xujiahui, Shanghai Railway station inside the inner ring road have large influential range. The high value zone is banded and has strong coupling with metro lines, indicating that the metro station can indeed expand the influential range of areas nearby. Moreover, transportation hub and employment zones have a larger range, while the residential areas and community centers have a smaller range.

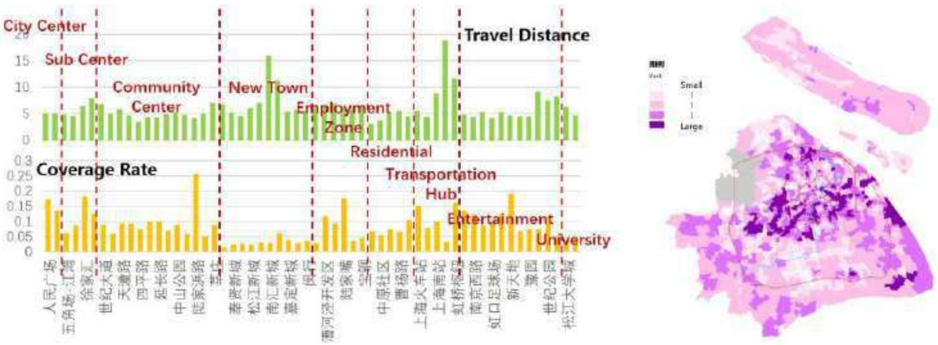

Figure 9: Comprehensive Influential Range

Caohejing Development Zone, Gucun Park, Town God's Temple (employment center, view spot with opening time) are high in day and night, reaching 2.2 respectively, day/night ratio of city center is about 1.5, and day/night ratio of residential areas is about 0.9. Day/night shows a "high-low-high" distribution pattern from the central city suburb to outer suburbs(Figure 10-left). Workday/weekend ratio of Caohejing was the highest, its visiting population in workdays is 2.1 times as large as that of weekends. While workday/weekend ratio of sub centers and view spots is lower, such as Wujiaochang and Gucun park reaching 0.8(Figure 10-right). On weekdays, visiting population in the center city is slightly higher than other areas, and visiting population in employment zones are much higher than those of others. The comprehensive temporal variation of the central city and outer suburbs is relatively high, that is, the mobility strength of these regions varies greatly with time(Figure 11).

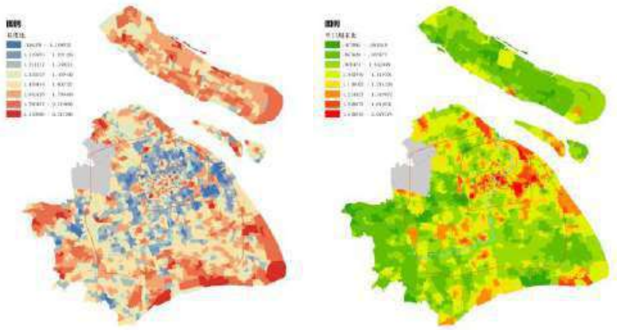

Figure 10: Day/Night Ratio and Workday/Weekend Ratio

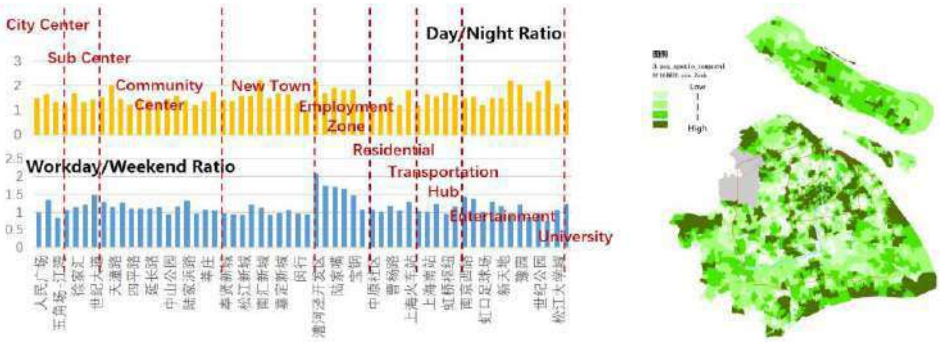

Figure 11: Comprehensive Temporal Variation

4.3 Spatial structure under view of human mobility

Figure 12 shows how we extract spatial features from four dimensions of indicators. The spatial structure under view of human mobility extracted from four dimensions of index is composed of four kinds of features: dynamic surface, from city center to subarea, shows the strength level of daily human mobility; dynamic center, including five center and eleven subcenter, becomes the most influential areas in the flowing network; dynamic cluster, can be divided into six groups according to the structure, influential range, and temporal variation of human mobility; dynamic corridor, strongly related to metro lines, highways, and Huangpu River, provides transportation supports for crowd flux.

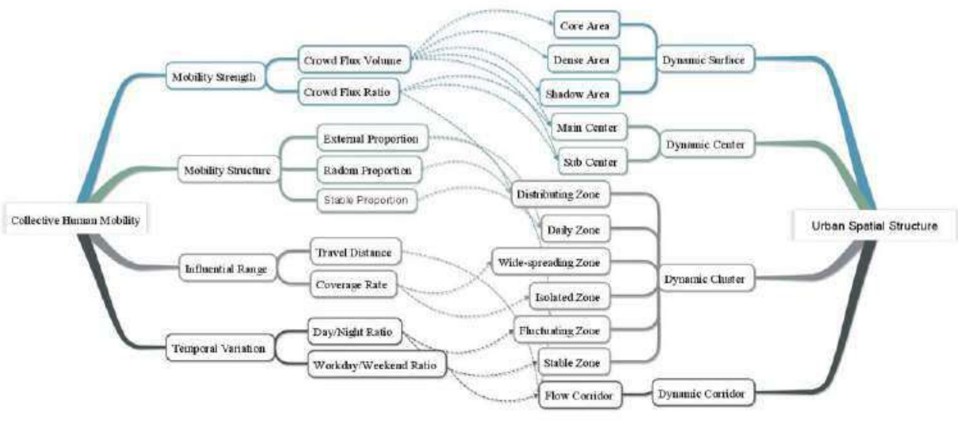

Figure 12: Spatial Elements Identification

Figure 13 shows the final spatial structure under the view of human mobility, we can see that the central city is mainly covered by core area, six dynamic clusters mainly distribute between the outer ring road and the beltway. New towns like Jiading, Songjiang and Qingpu are main mobility centers, other local community centers in suburbs compose sub mobility centers. The spatial distribution of dynamic corridor has strong relationship with metro lines and Huangpu river.

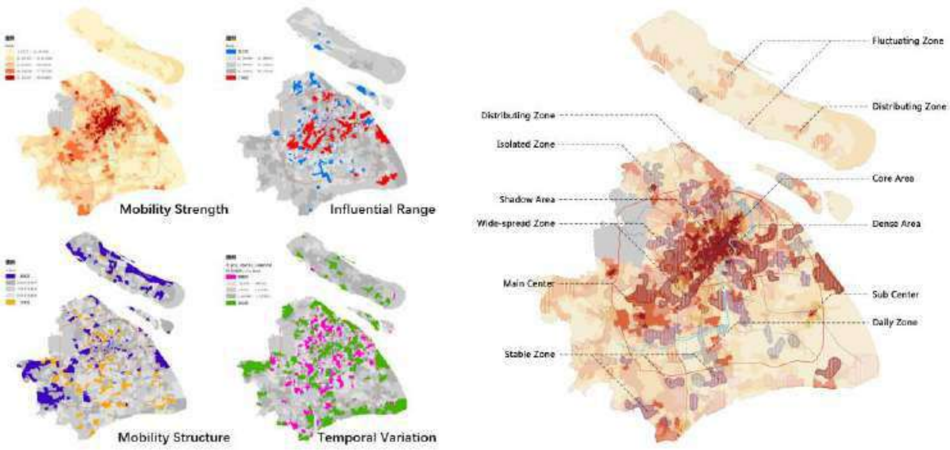

Figure 13: Spatial Structure under View of Human Mobility

5. Discussion and Conclusion

Urban spatial structure has been widely discussed in studies with conventional data. Recently, more and more scholars have used big data to conduct similar research. However, in Shanghai, the findings are mostly focus on human mobility pattern instead of the whole structure from collective human mobility view. In this study, we used cell phone data to provide some new findings about urban spatial structure, especially dynamic spatial distribution from crowd flux perspectives to make up the research gap in the context of Shanghai.

Four dimensions of indictors are employed to illustrate collective human mobility. New findings of this study suggest that:
(1)The visiting population associated with a census unit is about 5 times that of the resident population. The characteristic of collective mobility can be revealed using mobility strength, mobility structure, influential range, and temporal variation.
(2)The spatial distribution of mobility strength in Shanghai is in the form of "central hard core + suburb mobile center". Radom and stable population obviously larger than basic population in high mobility areas, so for these high mobility regions visiting population should be taken into consideration as well as resident population.
(3)From location perspective, influential range of suburb areas is the most extensive, high value zone is banded and relationship with metro lines is strong, temporal variation of edge areas in Shanghai is more obvious, and its spatial distribution presents "high-low-high" from the central city to outer suburbs. From function perspective, residential areas and local community centers have a smaller scope of influential range, mobility strength of employment centers and view spots varies greatly with time.
(4) Spatial structure can be extracted from four dimensions of indicators, which is composed of four kinds of spatial elements: dynamic surface, dynamic center, dynamic cluster, and dynamic corridor. The results can be further drawn into a spatial structure under mobility view showing the general rule and classification characteristics of urban space.

However, there are still some limitations exist and could be discussed in future work. Firstly, due to the limitation to data source, we only used two-week cell phone data in 2014 for study. The results may not have great significance to reflect current situation. Secondly, the predefined rule that we used to identify travel chain need further proved, different time and distance threshold may brings certain difference in results. Thirdly, the relationship between spatial structure under mobility view and traditional view needs to be analyzed quantitively. For further work, it is necessary to discuss the reliability and rationality of this measurement whether it is the most appropriate way to characterize different groups of visiting population. Moreover, detailed comparison should be conducted to find relationship between spatial structure under mobility view and traditional view in order to provide reference for the formulation of urban space policy and population management strategy.

The use of Living Lab in some Italian urban settings to test the feasibility of the Smart City.
Making the needs of communities compatible with applications of new technologies

Giovanni SERGI
Architect and lecturer in Town Planning at the Department Architecture and Design,
University of Genoa – Polytechnic School, Italy

Paolo ROSASCO
Lecturer in Real Estate Evaluation at the Department Architecture and Design,
University of Genoa – Polytechnic School, Italy

Synopsis

Since 2007 several Italian Municipalities have tested the Smart City model. With reference to the EU Helsinki Manifesto which outlined the Living Lab in 2006, some Municipalities have worked to verify harmonization of the Smart City model with the need to focus on citizens. The Living Lab cases examined by this paper concern experiences in the Municipalities of Varese, Bologna, Turin and Padua between 2011 and 2018.

1. The European Union and Living Labs for checking the effects of a Smart City

Through the Helsinki Manifesto in 2006 the European Union showed how its commitment to the introduction of new technologies both in the productive sectors and in the Institutions should meet the need to put European citizens at the centre of these technological innovation processes. These processes should be favourable for European citizens.

Living Labs are a pragmatic and flexible tool to reach this objective. They can be defined as aggregations of public bodies, small and medium-sized ICT companies, Universities, research centres and groups of citizens who work to make sure that the implementation of projects for technological development and innovation in services are based on the need of end users supporting their contribution and participation in the main steps of the process.

In 2006 the UE was aware that new technologies could develop beyond control thus bringing huge advantages for specific productive sectors, especially those connected to ICT and real disadvantages for some segments of productive sectors in EU countries as well as some groups within the European society: low-income groups, old people with a low education level, young people with insecure jobs, groups at the margins of society.

2. Recent criticism about the Smart City in the USA

According to some recent critical approaches towards the Smart City in 2018 such as “From Disruption to Dystopia: Silicon Valley Envisions the City of the Future” by Joel Kotkin and “Stop Saying Smart Cities. Digital stardust won’t magically make future cities more affordable or resilient” by Bruce Sterling we can identify some dangers connected to the new urban development dynamics summarized using the attractive concept of Smart City.

These two writings show how several big US companies operating in the ICT sector, such as those in the Silicon Valley, have proposed communication, production models and ways of life which abandon the idea of a society characterised by residential settlements with low or medium population density. As a result, they give up the Fordist approach which allows the separation of working life in a company and private life. These new models seem to be based on an urban system with low or medium population density characterised by housing types with limited dimensions for single people, couples or small families.

The new settlement model is an urban system inhabited by people focused on the Internet environment and where the work-life balance is not well defined. Close to consumers who have a low cultural level and mainly buy products on the Internet, we can find a minority of people with high professional skills who put their job at the centre of their life and are the milestone of a production and social system dominated by the big and medium-sized US companies in the ICT sector which employ a growing number of young people from emerging countries who are ready to spend all their life time in the company.

This scenario clearly shows what is happening in some areas of California such as San Josè, San Francisco, San Diego as well as in other US cities. With reference to this issue, it is useful to read a book published in 2004 by Richard Florida “Cities and the creative class”.

In the most recent analysis which tried to analyse how ICT companies see the development of our society and therefore our urban organisms, we can’t find a theorisation of these trends but a reality which is spreading in several cities worldwide. It seems that a new form of city is partly outlined by the new communication models and by artificial intelligence, as explained by Andrea Granelli in his book “Città intelligenti?” published in Italy in 2012 and by Nick Bostrom in his book “Superintelligence. Paths, Dangers, Strategies” published in Oxford in 2014.

3. Smart City and Living Labs in Italy

In Italy a constant redefinition of urban life models outlined by ICT and the most recent forms of artificial intelligence has spread in several urban settings, although this situation is quite different from the one in the US cities.

According to the National Association of Italian Municipalities ANCI in 2016 more than 158 Italian Municipalities with 15 million inhabitants worked, in different ways, on the Smart City to introduce in their urban systems some new technologies which can contribute to the a more efficient, balanced and inclusive development.

These Italian projects on the Smart City have been defined, in some cases, using a sectorial approach which deals with one or more sectors of the urban system such as mobility, environment, energy, economy and in other cases a holistic approach based on the interactions between new technologies and the whole urban system.

Together with the development of these initiatives, the first tests have been carried out through the activation of several Living Labs. According to an unofficial survey, to date about 50 Living Labs have been implemented in Italy which focus on problems caused by technological development in several sectors: institutions, services, industry and many more.

Some of these have been developed to analyse urban regenerations programmes for specific quarters or urban quadrants as well as for limited parts of the urban system which shows critical aspects.

The case studies below concern urban regeneration programmes developed in Italy between 2011 and 2018 in Varese, Bologna,Turin and Padua.

4. The Living Lab on Repubblica square, Varese: 2011-2013

In May 2011 the Ministry of the Interior signed a Pact on Security with the Municipality of Varese regarding Repubblica square, a central area hosting several events and commercial activities as well as the Apollonio theater. Moreover, this square hosts an unde rground carpark with five floors which made it difficult for the municipal administration to guarantee adequate security.

According to the Municipal Administration of Varese it is fundamental to sign Pacts on Security which allow cooperation between the Municipal Police Department, the National Police Force and Carabinieri together with the use of images recorded by camera systems with the aim to guarantee security. The Pacts on Security were funded by the Italian Ministry of the Interior. This framework includes the “Sinecura” project proposed and funded by Finmeccanica an important public holding.

This project was implemented in 2011 by the company Electron Italia - Elsag Datamat and later by Selex ES Italia owned by Finmeccanica (today Leonardo spa) specialized in security.

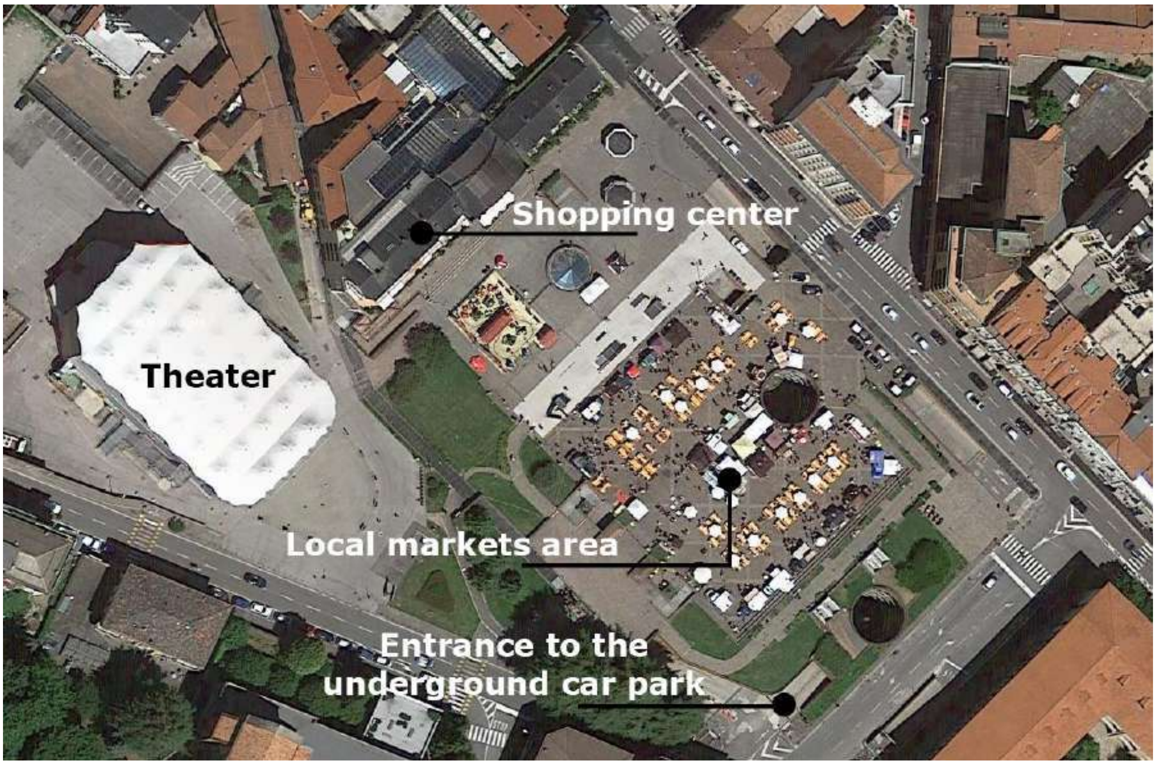

Figure 1: Varese, view of Repubblica square. Source Google Maps

This project was presented to the Municipal Administration as a Living Lab because it had been outlined by public Institutions and companies which use advanced technologies in cooperation with representatives of the Municipal Administration and associations of citizens and economic operators

The system used to guarantee security on Repubblica square is based on the use of Bluetooth technology which allows citizens and economic operators to download a specific application if their smartphone supports the Java software, otherwise another application is available on the municipality website for other types of smartphone.

If a citizen feels in danger, he/she can push a button of his/her smartphone and sends a signal which activates the eight new cameras provided by the Sinecura project: five with fixed optics and three Dome cameras with moving lens. These new cameras improve the system which already included four cameras. This system would be managed by a control room attended by the Municipal Police Department.

A camera, following the signal emitted by the smartphone would orientate towards the affected citizen and a member of the Municipal Police or policeman could observe his/her movements. Besides the camera-based control, an audio analysis system was installed based on optical sensor able to interpret several types of noises such as that of a broken glass or an unusual noise.
In this way the citizen could require in real time the Municipal Police Department to immediately intervene. It was clear that the citizen who felt in danger and decided to send a signal to the Control Room of the Municipal Police using his/her smartphone would be an express form of consent to be localized in case of call. Substantially this procedure would ensure the compliance with the legislation on privacy. The Municipal Police Control Room including two video terminal boards would represent the Focal Point of the whole project.

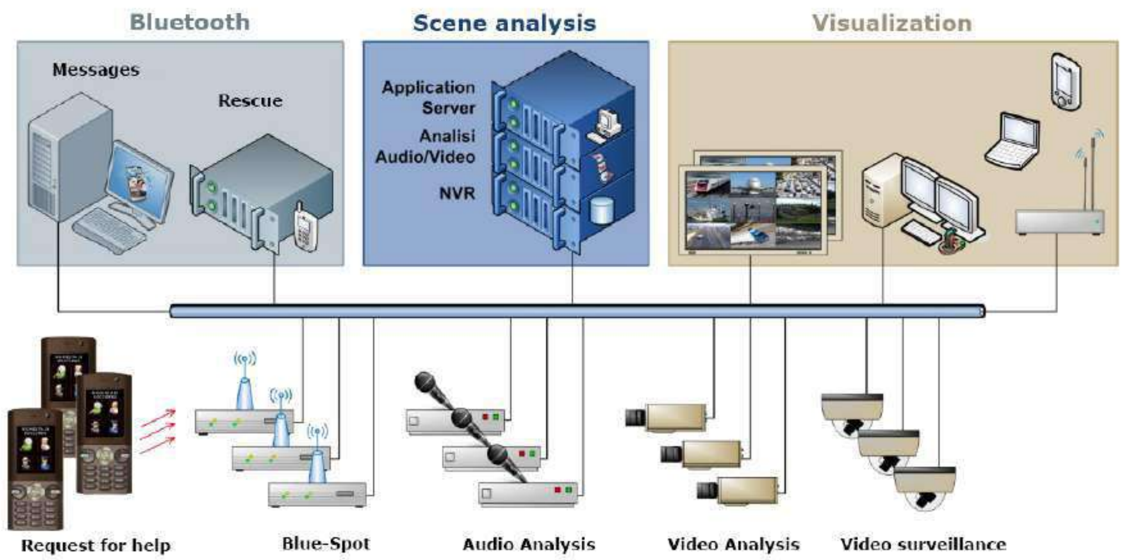

Figure 2: Varese, architecture of the system proposed for Repubblica square. Source: Municipality of Varese and Selex Elsag "Progetto sperimentale Sinecura di Sicurezza partecipata" (Experimental project Sinecura on Safety with the involvement of citizens) 2012

This pilot project was funded by the Finmeccanica holding with the aim of creating an experimental laboratory called "Dictum Factum" which is an example of how artificial intelligence can be used to safeguard an area such as Repubblica square. This place, due to mistakes in the urban planning process, was characterised by clear difficulties in ensuring security. This initiative aimed at combining connectivity via the web with sensors and civic participation to show the role technological components can play to guarantee security in specific urban quadrants.

This project did not have a follow-up phase because of political, economic and administration reasons and technological problems since it was not possible to use this system with all smartphone models available in that moment on the market.

5. The Living Lab of Liber Paradisus square and Fioravanti street in Bologna: 2013-2016

In 2013 the National Council for Research CNR published a call for tenders addressing Italian Municipal Authorities and called "Smart Cities" as well as "Energy from Renewable Sources and ICT for Energy Sustainability".

Figura 3: Bologna, view of Liber Paradisus square. In the middle of the picture we can see one of the smart posts installed. Photo by G.Sergi 2018

This call for tenders aimed at studying and testing a range of innovative solutions to make cities sustainable from an energy and environmental point of view.

Afterwards CNR started some tests according to the Living Lab model applied to the issue of Smart City in some Municipalities with different levels of population such as Agordo, Riccione and Siracusa.

The implementation difficulties pushed CNR together with the Municipality of Bologna to focus all available resources on a project "Smart Cities Test Plan" applied to Liber Paradisus square in Bologna which hosts an important building complex and a part of municipal offices. This complex was designed by the local firm Mario Cucinella Architects.

The square is located in the Bolognina quarter close to the High-Speed train station.

The lampposts placed between Liber Paradisius square and Fioravanti street were changed into smart terminals with several tasks: the implementation of some public wi-fi hotspots, the control over the use of parking places in Fioravanti street and security control for citizens through cameras.

This project ensured also the functioning of five touch screen totems in 2016 which provide citizens and tourists with information and services. These totems were placed along the route from Liber Paradius square to Rizzoli street in the city centre. Some expertises related to this project was used for EXPO in 2015 in Milan.

6. The Living Lab for the Campidoglio quarter in Turin: 2016-2017

In 2015 Municipal Authority of Turin decided to implement the first Turin Living Lab to verify the possibility to integrate a range of new technologies in the Campidoglio quarter and reach the goals set by the Municipality in terms of strategic and urban planning. The Turin Living Lab was useful to verify whether a semi-suburban quarter, in this case Campidoglio quarter, where 30,000 people live, could become a smart quarter.

Figure 4: Turin, the Campidoglio quarter. Source: Municipality of Turin, 2016

In January 2016 the Mayor Mr. Fassino presented the Turin Living Lab project for the Campidoglio quarter. The experimentation started in September 2016 and ended in March 2017.

This Living Lab refers to the Masterplan SMILE Smart Mobility Inclusion Energy implemented in 2013 for the city of Turin by the Smart City Foundation together with the Torino Wireless Foundation.

The Masterplan SMILE includes 45 ideas-projects which identify sectors where the Smart City vision can be implemented. These 45 ideas-projects refer to four fundamental sectors: mobility, inclusion, life and health, energy.

The Municipal Authority set three main objectives by implementing the Turin Living Lab for the Campidoglio quarter:

1. use the already acquired expertise in the Smart City sector and enrich them by implementing and testing new initiatives;
2. urge private companies working in the field of new technologies to test new products within real situations in Turin;
3. support professionals and innovative businesses capable of integrating themselves into the objectives of Turin Smart City.

The Campidoglio quarter was chosen because it is a complex urban quarter and therefore represents the suitable environment to test new technologies and show how these can contribute to the development of a consolidated urban quarter.
The Municipality of Turin considered a call for tender addressing the operators in Piedmont, Italy as well in some other countries (UK, Israel etc.) in the field of new technologies as a central element of the Living Lab.

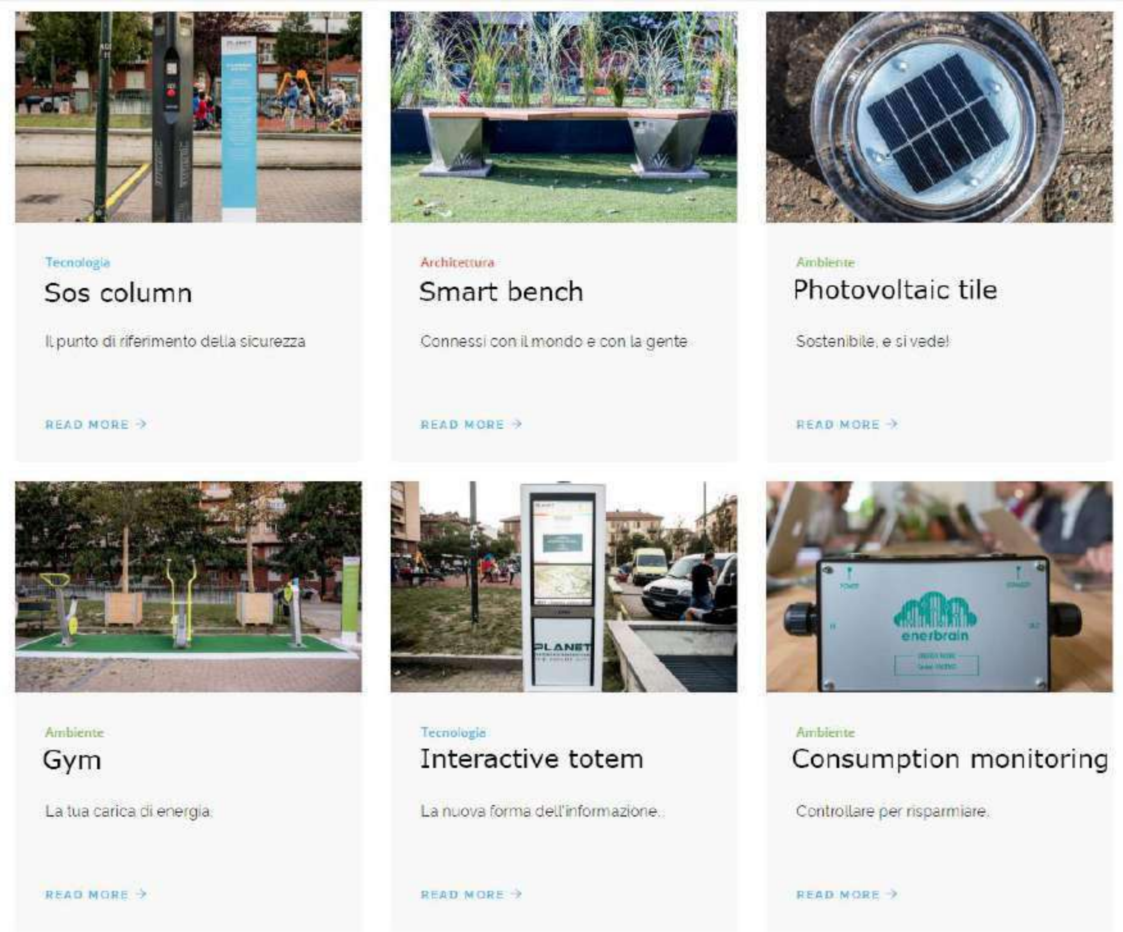

Figure 5: Turin, Risorgimento square in the Campidoglio quarter. Some of the technologies integrated into Risorgimento square as a smart square. Source: www.planetidea.it

As a result the Development, European Funds, Innovation and Smart City Department of the Municipality of Turin published in January 2016 a Notice for the search of parties interested in the project Turin Living Lab for the Campidoglio quarter. The call for tenders specified the Municipality's interest in selecting parties capable of developing technologically advanced products, testing them and using such participation to promote themselves.

Private and public parties were allowed to take part in the call for tenders in an associate form, too. After the call for tenders had been published, more than 50 experimentations were selected to be implemented between the Campidoglio quarter and Risorgimento square.

The smart square Risorgimento was opened in September 2016 using a surface of 5,300 square meters until March 2017.

Several companies took part in the Living Lab such as Tim, Vodafone and other small and medium-sized companies in the field of advanced technologies. The University of Turin and its IT department as well as some important professionals from Piedmont specialized in urban sustainable and smart transformations were part of the project.

The Living Lab created on Risorgimento square an interesting range of technologies which can contribute to change a semi-suburban area into a smart and inclusive quarter. The IT department of the University of Turin launched in 2016 a georeferenced social network called FirstLife to support citizens, economic operators, non-profit companies and so on.

Figure 6: Turin, Risorgimento square in the Campidoglio quarter. Parking area for sharing 5 electric cars built after the end of the Living Lab. Photo by G. Sergi, 2018

FirstLife is a civic social network developed to create, share and exchange information among all private and public parties involved in social, economic and recreational activities as well as in the management of local services, at different levels within the city and beyond. It is a platform based on an interactive map where contents regard activities and projects linked to these places and where users can interact by taking part in discussion, theme groups and events. The project was developed by the research group "Social Computing" which is part of the IT Department of the University of Turin and obtained important acknowledgements from the EU.

The project to set up Risorgimento square was implemented by Planet Idea srl, an engineering company founded in 2015 led by Giovanni Savio. Moreover, it was outlined in cooperation with Recs Architects, the engineering firm Francesco Tresso in Turin as concerns ecological sustainability, Daniele Alberti of the ICT and IOT team, the company SocialFare from Turin as concerns social innovation.

7. The Living Lab for the urban regeneration project of Gasparotto square in Padua, Railway Station quarter: 2014-2018

In 2016 the Unipolis Foundation, belonging to the Unipol group, published a call for tender “Culturability – Regenerating areas to be shared” to support innovative projects with a high social impact that can regenerate abandoned or underused areas. Five projects out of 522 presented projects were selected. Among these five projects, the project for Padua “LAB+: piazza Gasparotto Urban Living Lab” coordinated by Elena Ostanel researcher at IUAV.

This experience represented an interesting example of inclusive design aimed at social and urban regeneration of an area which was excluded from the most recent real estate development processes.

Figure 7: Padua, Gasparotto square, entrance from Popolo street. We can set both the entrance of the underground car park, the proposed urban garden of 380 square meters and the community theater. Photo, G. Sergi 2018

In Padua Gasparotto square is located within in the Railway Station quarter and close to the large area included in the real estate project called PP1, abandoned in 2005. The modern buildings which outline Gasparotto square are part of an urban area close to the railway station to host private and public offices.

The area belonging to the real estate project PP1 was an unbuilt area with a surface of 48,000 square meters. It is the largest abandoned area in this city. This area began its decay in 2005 when the PP1 project was abandoned by a group of local real estate companies. The events connected to this failure caused the closure of the building site and then worsened the state of deterioration of the whole PP1 area. Today this area is affected by petty crime.

For some years the buildings that face Gasparotto square have had vacancies on different floors. Over the past few years, the square has become a critical area characterized by social marginalization and illegal activities at night. After the closing time of offices, the area is no more crowded and dangerous to attend.

Since 2014 groups and associations have committed to recover this area which is on the one side attended by people who work here in this business district during the day and people living in this quarter, especially aged people, and on the other side groups of immigrants and people involved in petty crimes who use this area for illegal activities.

The Co-operative EST Educazione Società Territori was the first to settle down on the ground floor of the square and created a co-working area CO+ with seat on the ground floor of one of the buildings in Gasparotto square. EST has become the leader of some associations such as Gasparorto which deals with the creation of an urban garden and the Hub – Culture Food and Sport which promotes an urban regeneration process with the participation of citizens.

The EST co-operative supported the development of the urban regeneration project LAB+ whose promoters were CO+, Hub-Culture Food and Sport and the Association Parkour Wave.

"To achieve this objective, some actions for the reclamation of public spaces have been given an overall perspective: involvement of inhabitants through the social and community theater, creation of public art works, enlarging of the urban garden, a weekly organic farmer's market. The project aims at improving the quality of life of local inhabitants, by combining several fields such as public art, community theater, sport, urban agriculture to make the square a social and cultural hub for the community" extract from the website https://culturability.org, 2016.

There are ten partner organisations of the LAB+ project. The institutional partners are the Municipality of Padua, Banca Popolare Etica and the IUAV University of Venice.

The work carried out within this co-working project led to a regeneration project of the square which can't be defined as ordinary because it focused on some potential actions: 1) a project on urban gardens 2) a community theater 3) the reuse of nearly 10,000 vacant square meters which face Gasparotto square.

This project has the following critical aspects: 1) difficulties encountered by the Municipality of Padua in using 4,000 vacant square meters owned by the Municipality for social and health services both on the ground floor and on the floors above ground 2) the problem of petty crime which is difficult to deal with because of situations of degradation in the nearby and in the Railway Station quarter 3) difficulties in involving the local population comprising aged people and commuters 4) difficulties in developing sport and recreational activities, especially street sports and parkour.

We can mention the following positive aspects: 1) the establishment of a cultural club called Nadir which promotes several initiatives 2) a co-working space on the ground floor of Gasparotto square which attracts the interest of several young professionals 3) the success of urban gardens which led to the creation of an urban garden with a surface of 380 square meters. The urban regeneration process supported by the LAB+ project has also been promoted by the Municipal Administration which has recently taken office.

Evaluation of Built Greenway Network in Beijing Based on Big Data Analysis

(Evaluation of Built Greenway Network in Beijing Based on Big Data Analysis)

Li Tan, Beijing Forestry University, China

1. Abstract

As a multifunctional public space network deep into city, urban greenway network plays an essential role in the urban renewal process with the improvement of living environment and slow mode transportation, which can promote green lifestyle and reduce carbon emissions as an adaptive strategy responding to climate change in high-speed urbanization process. The purpose of the research is to evaluate the built greenways in Beijing based on the spatial analysis of the big data acquired from people's daily life to make a suggestion for promotion strategies.

Compared to traditional methods like questionnaire and interview, big data analysis can provide more objective information especially in large scale and complicated areas. 8 typical built greenways in different regions of Beijing was chosen to be studied in our research. The method used in our research is based on two types of big-data: location data from bike-sharing mobile applications like OFO Bike, and the point of interest data from Micro-blog. Firstly, spatial statistics tools is used to analysis the kernel density estimation of bike use in Beijing. The relativity between the spatial location of the greenway and the clustering feature of people's travel trajectory was gained from the research to evaluate the utilization rate of the greenway. Secondly, a method called NLPIR was used to extract the information related to the emotion and evaluation from the text data in blogs. Thirdly, the comprehensive ratings of different sections was gained through overlay analysis, from which the low scored sections can be visible in maps. Finally, a site investigation was used to revise the results and find out the reasons from 5 aspects including trace choice, resources connectivity, integrity, facility and social promotion. Strategies for improving the built greenways and suggestions for future urban green network construction were provided.

2. Introduction

2.1 Background

Urban greenway, as a multifunctional public space network deep into city, plays an essential role in the urban renewal process with the improvement of living environment and slow mode transportation, which can promote green lifestyle and reduce carbon emissions as an adaptive strategy responding to climate change in high-speed urbanization process. In recent years, mega cities in China have gradually built an urban greenway network, hoping to improve the urban ecological effectiveness. However, the complex land use and diverse public demands often make the use of greenways different from the planners' expectations and the already built network are not adapted to the changing and complicated environment. Because the greenway users are dispersed and the surrounding land use environment is complex and varied, traditional research methods are difficult to carry out. While the research and analysis of network big data can acquire, identify and analyze huge data volume, obtaining more accurate and objective results through deep mining and machine learning to make up for the shortage of traditional research methods.

2.2 Data Sources

The big data used mainly includes the spatial location of shared bicycles and the big data of Micro-blog texts. Since 2015, shared bicycles such as OFO and MOBIKE have become more and more popular in Beijing, and have become one of the important modes of travel for residents. Bike-sharing mobile applications are non-pile shared bicycle using platform in China. Users only need to enter the license plate number in the mobile phone app to get the password unlocking the bicycle, which can be used anytime and anywhere. The shared bicycle itself has its own real-time location information. Through the network big data crawling, researchers can obtain real-time bicycle spatial location information in a certain area. With the fast spread of non pile bike-sharing modes in China, an increasing number of citizens pay close attention to the greenway system and are calling for a healthy and safe travel environment at present.

Weibo is a Chinese microblog platform for sharing, disseminating and acquiring information based on user relationship. Users can set up a personal community through various clients such as WEB and WAP, update information with 140 words (including punctuation marks), and realize real-time sharing. Weibo has a large number of users in China, so its text data volume is huge, which is a good representative for research about people's post-use evaluation.

2.3 Research object

The government has announced eight completed greenway projects by 2018. This paper selects eight typical built greenways in Beijing as the research objects, whose names are shown in Table 1. For the convenience of description, the eight greenways are named after U1-U4 and C1-C4. ‘U’ represents urban greenway, which is in the urban area, connecting the parks, squares, recreation space and scenic spots in the city. ‘C’ represents country greenway located in the countryside area of the city. The spatial relationship with Beijing of the eight greenways is shown in Figure 1.

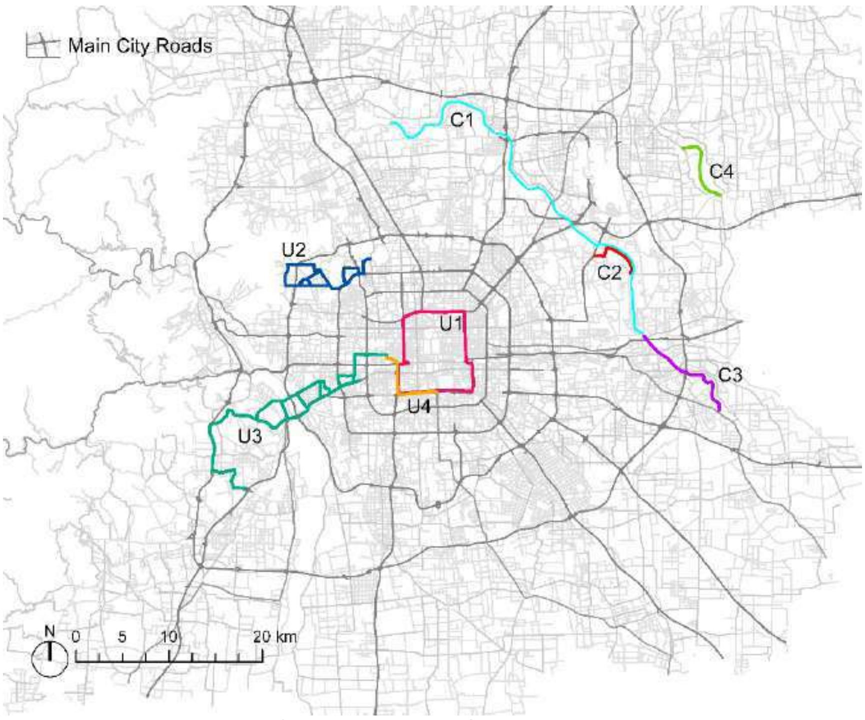

Figure 1: Site of the Built Greenways in Beijing

As of 2016, these greenways have completed the construction of the entire line. Among them, some greenways were completed in phases, and the completion dates of the whole line are shown in Table 1. The relevant research in this paper is based on the completely built greenways, and the relevant data are collected after the completion of the entire greenway.

As the responsible groups and construction plans of greenway construction in different regions are different, some greenways have different names but share overlapping line. In the selected greenway, there is partial overlap between U1 and U4, C1 and C2. Since the text analysis of this study is based on the search for greenway names, each greenway is still considered separately in order to obtain more data.

Number	Name of Greenway	Type	Built time	One-way length
U1	Greenway around the second ring city	Urban type	2014	35km
U2	The 'three hills and five gardens' region greenway	Urban type	2014	36.1km
U3	Garden expo garden greenway	Urban type	2014	64.5km
U4	Yingchengjiandu greenway	Urban type	2013	9.2km
C1	Wenyu river greenway	Country type	2015	78km
C2	East suburb forest park greenway	Country type	2013	7.7km
C3	Tongzhou north canal greenway	Country type	2016	15km
C4	Shunyi new town riverfront forest park greenway	Country type	2013	13km

Table1: Greenways in the Research

3. Methods

The research of this paper mainly includes three parts, the evaluation of greenway usage based on the spatial distribution analysis of shared bicycles, the evaluation of user emotion based on microblog text analysis and the overlay analysis and comprehensive evaluation of these two analysis results.

3.1 the evaluation of greenway usage based on the spatial distribution analysis of shared bicycles

The data used for analysis was derived from OFO shared bicycles. Data was extracted at 10:17 am on July 3, 2018, containing 630,000 shared bicycles real-time spatial location big data in Beijing (Figure 2).

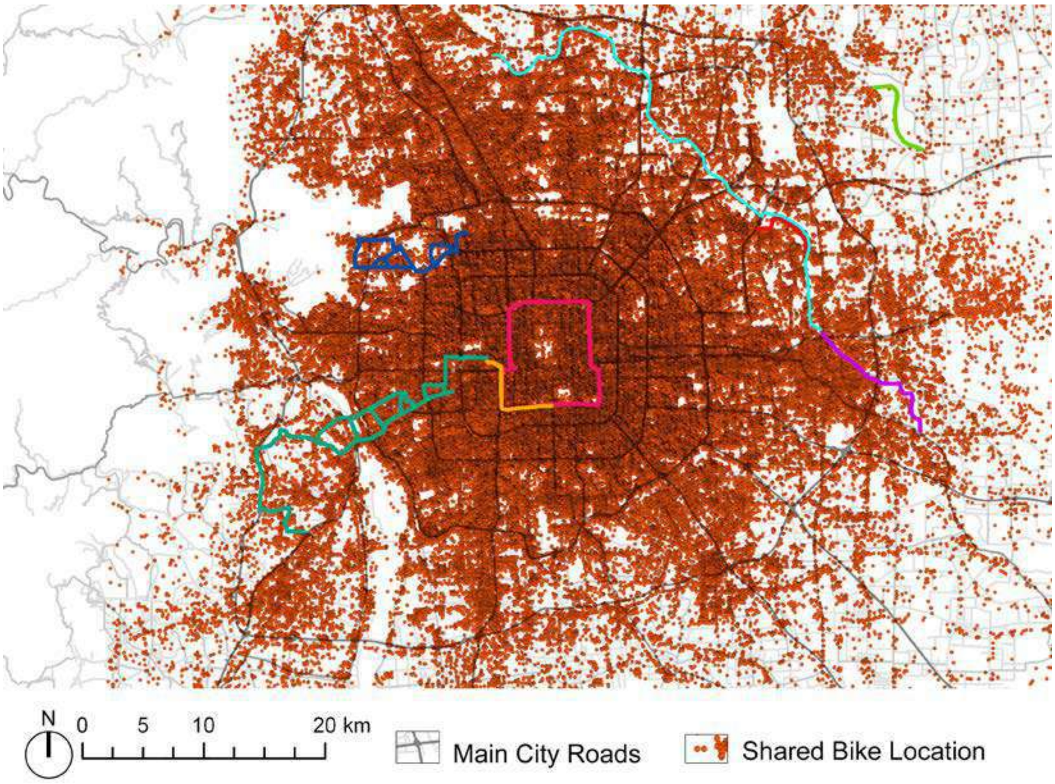

Figure 2: Shared Bicycles Real-time Spatial Location

Based on ArcGIS 10.2, the paper uses the Kernel Density Analysis (KDE) method to analyze the spatial position of shared bicycles and explore the hotspots along the greenway. Kernel density calculates the density of point features around each output raster cell. The kernel function is based on the quartic kernel function described in Silverman.

The analysis includes two dimensions: city scale and block scale. The city scale is the urban area of Beijing that contains all the greenways in order to explore the relationship between greenway's space distribution and kernel density. Figure 3 shows the kernel density of shared bicycles in Beijing. It can be seen that the density of shared bicycles is concentrated in the central urban area. There is a large difference in the kernel density between different greenways. Among them, the U1 and U4 greenways which are in the central city have the largest kernel density, which means that the potential utilization rate is higher than other greenways. The kernel density gradually reduced from city central to suburbs near U2 and U3 greenways. The usage rate of the C1~C5 greenway is relatively low. It is obvious that the level of greenway usage has an obvious relationship with its location in the city. In addition, other areas where nuclear density is concentrated review the high demand for slow-moving systems. These areas do not currently have a good greenway system and will become the important choice of greenway selection in the future.

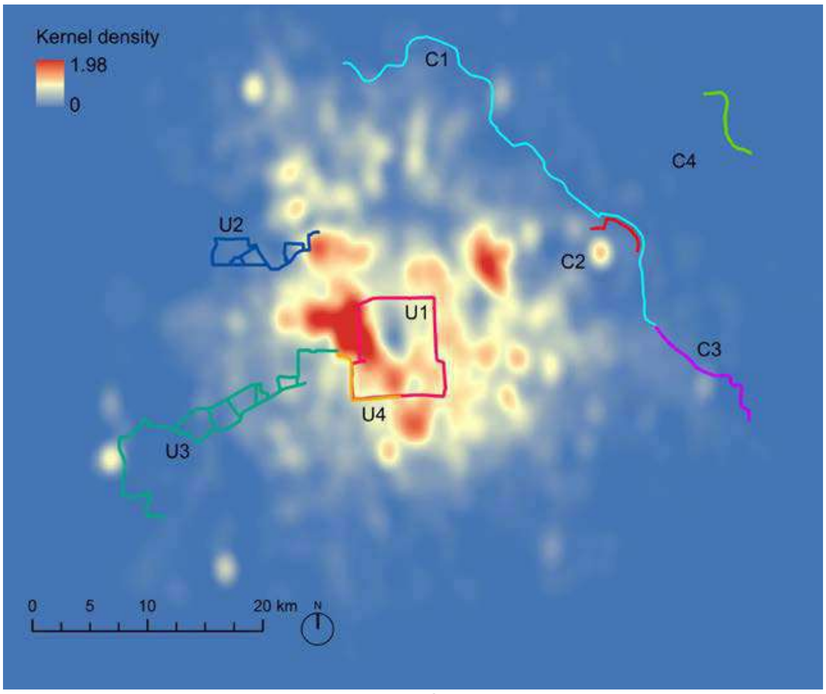

Figure 3: Kernel Density of Shared Bicycles in Beijing

At the block scale, it is mainly expected that the size of the kernel density reflects the usage rate of different sections of the greenway, thereby exploring potential and problem areas. In order to make the difference of kernel density in different sections more prominent, we firstly construct a 500 meters buffer in ArcGIS, and only calculate the kernel density inside the buffer. The kernel density distribution map of the 500m buffer of the eight greenways in Figure 4 is obtained. There are two possible reasons for the aggregation of nuclear density. One is that the use rate of the section is high, which is an important potential area of greenway construction. Another possibility is that there is a centralized parking space for the shared bicycles.

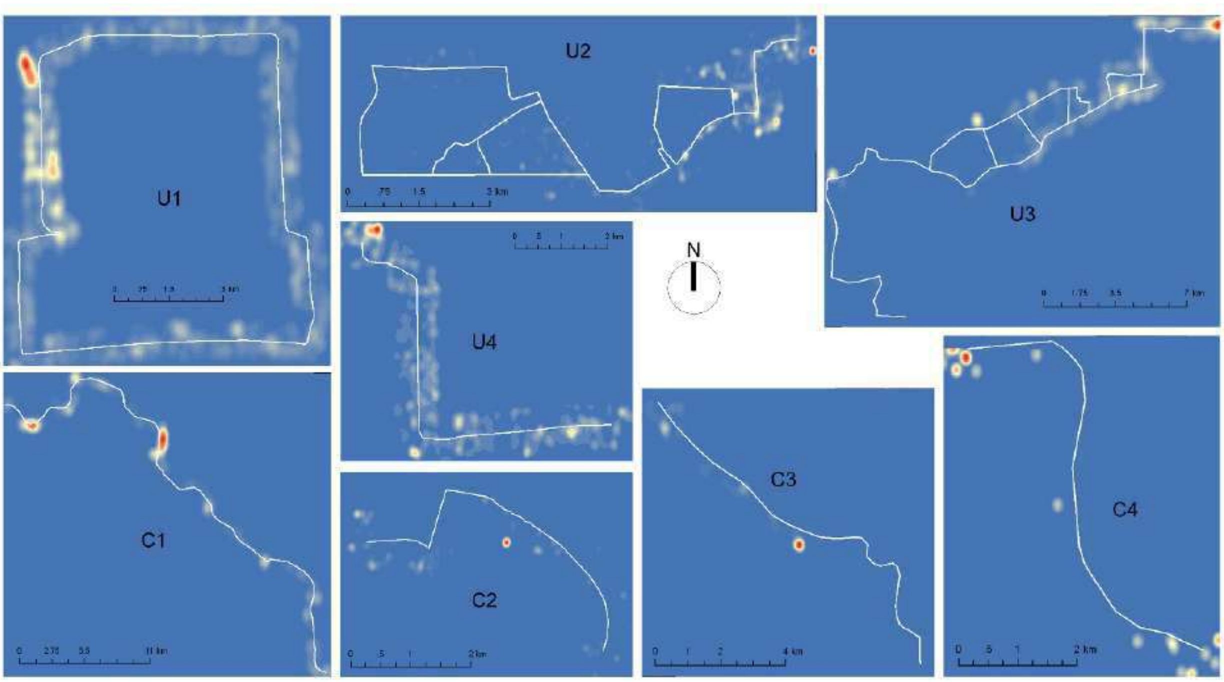

Figure 4: kernel density distribution map of the 500m buffer of the eight greenways

3.2 User's Emotional Evaluation Based on Weibo Text Analysis

The text used for analysis comes from 'Sina Weibo'. Micro-blog text with eight greenway names as related keywords was gained through big data crawling. This research has crawled 2019 related micro-blogs. In the relevant micro-blogs, some location and content are inconsistent with the research object and some are the promotion microblogs from the government and related institutions. After removing these microblogs, 310 microblogs are reserved for analysis, which includes 20,326 Chinese characters. The amount of text for each greenway is shown in Table 2. Among them, the data volumes of U3, C3, and C4 are relatively small, indicating that the surrounding residents are not highly aware of them. Due to the small amount of text, the evaluation of its objectivity is poor.

Number	Total quantity of related microblogs	Effective quantity of related microblogs	Quantity of propaganda microblogs	The quantity of valid text words
U1	551	84	415	5457
U2	434	50	325	2884
U3	184	4	60	207
U4	324	87	189	6012
C1	340	60	184	3964
C2	120	13	68	956
C3	51	8	24	686
C4	15	4	8	160

Table 2: Text Quantity of 8 Greenways

This paper adopts text emotion analysis technology based on deep neural network and word frequency statistics based on perfect double array TRIE tree.

Sentiment analysis mainly adopts two kinds of techniques: 1.The automatic identification and weight calculation of emotional words are iterate by using co-occurrence relationship and adopting the tactics of Bootstrapping and finally generate new emotional words and the weight. 2. Deep neural network for emotion discrimination: based on deep neural network, emotional words are expanded and calculated for synthesizing the final result. The whole analysis process was completed in NLPIR（Natural Language Processing & Information Retrieval） big data search and mining platform.

The results of emotional analysis are shown in Figure 5. The study divided the analysis results into positive emotions and negative emotions, positive emotions include happy and like while negative emotions include angry, sad, fear, nausea, and scare. The pie charts reflect the proportion of users' emotions in different greenways.

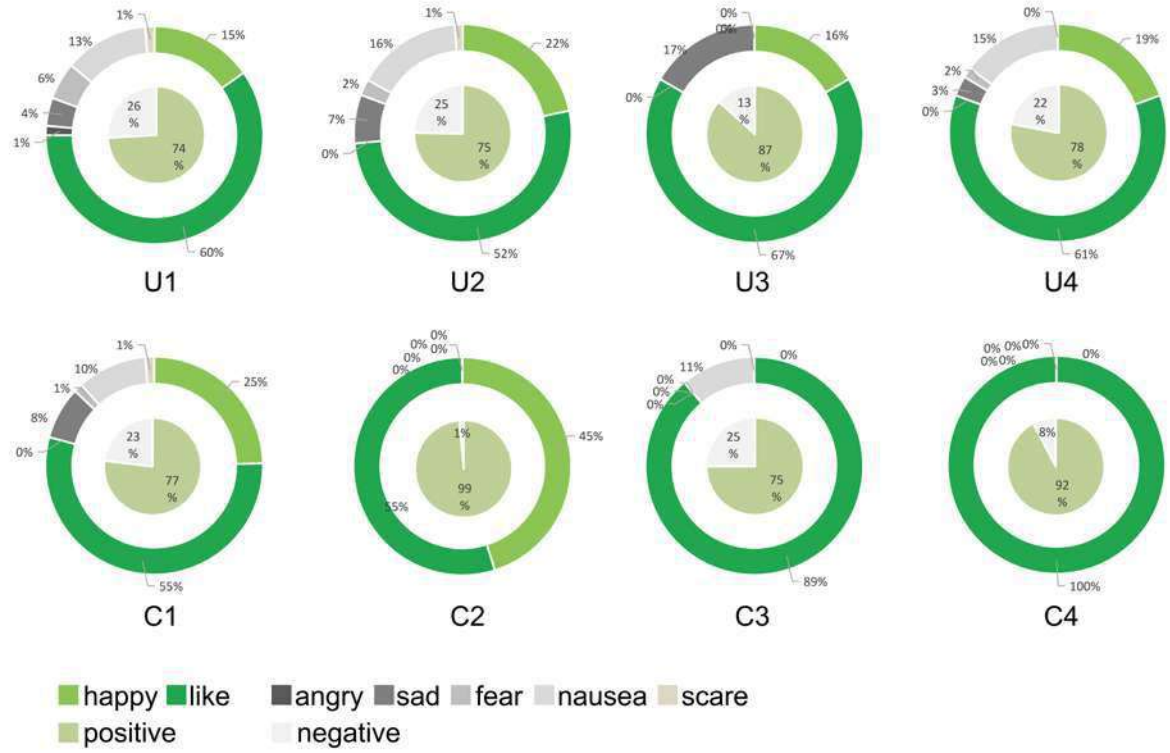

Figure 5: the Proportion of Users' Emotions in Different Greenways

The word frequency statistics based on the perfect double array TRIE tree are provided by the NLPIR platform, and its word frequency statistical algorithm is ten times more efficient than the conventional algorithm. The efficiency of the algorithm does not increase exponentially with the increase of the number of pending statistics, but generally grows sub-linearly.

This research extracts nouns, verbs and adjectives in the text, and counts the top 10 words with the highest frequency respectively. Among them, the statistical results of nouns reflect the attention paid to different nodes of the greenway, and the results can correspond to the spatial position of the greenway, as shown in Figure 6. Statistics about verbs reflect the types of activities people do on the greenway, and the top 3 types of activities are shown in the Table 3. The adjectives' statistical results evaluate the green lane mood reflects people reasons. Among them, the top 3 negative emotions in the evaluation are "crowded" , "dangerous" and "where", and top 3 positive emotions are "health", "happy" and "beautiful".

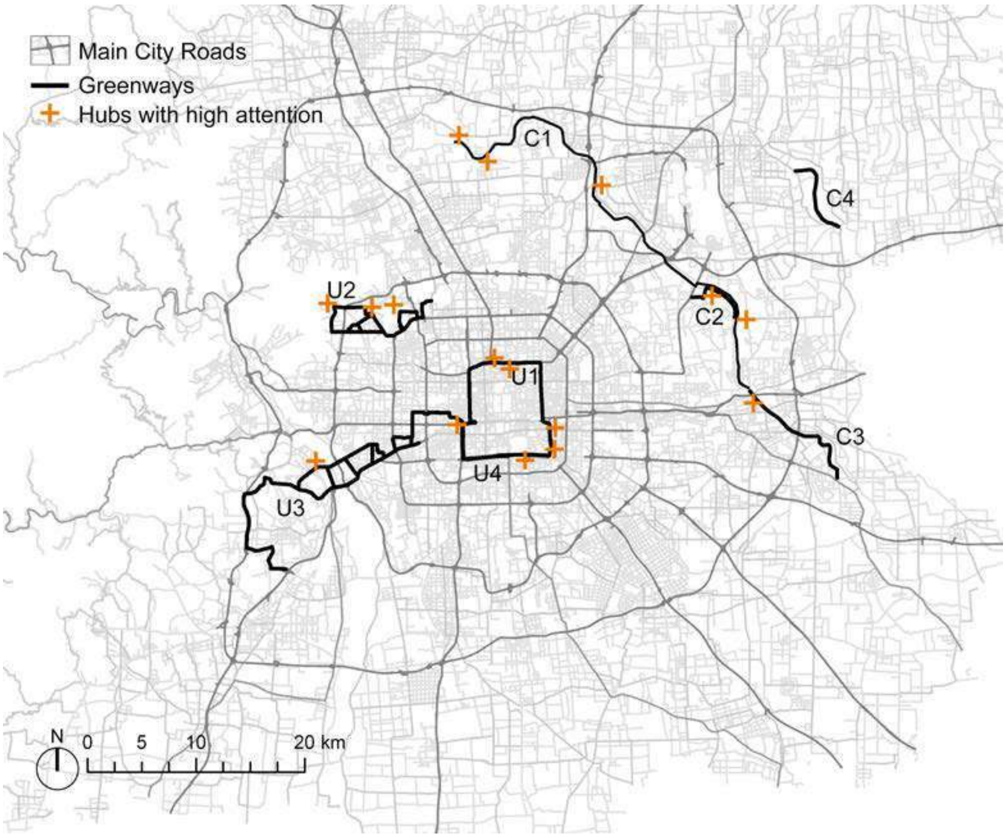

Figure 6: Hubs with High Attention

	U1	U2	U3	U4	C1	C2	C3	C4
1st	discovery	Walking	Travelling	Seeing	Bicycling	Bicycling	Accomplishment	Connecting
2nd	Passing-by	Running	Connecting	Trees shade the street.	Enjoyment	Open	relaxation	Morning exercise
3rd	relaxation	Experience	Souvenir	Exercise	Accomplishment	Accomplishment	Bicycling	Sharing

Table 3: Top 3 Types of Activities in Different Greenways

Through field research, we verify the usage of each greenway, which basically conforms to the results of text analysis. However, the C2, C4 and U3 greenway have many problems in infrastructure, continuity and identification system, which is quite different from the results of text analysis possibly due to the small amount of text.

3.3 Overlay analysis and comprehensive evaluation

This part is mainly to supplement and verify the two research methods. We overlay the kernel density distribution map of the 500m buffer of the eight greenways (Figure 4) with the greenway focus heat map of the text analysis section (Figure 6). The results are shown in Figure 7, which reflects the potential areas of these built greenways.

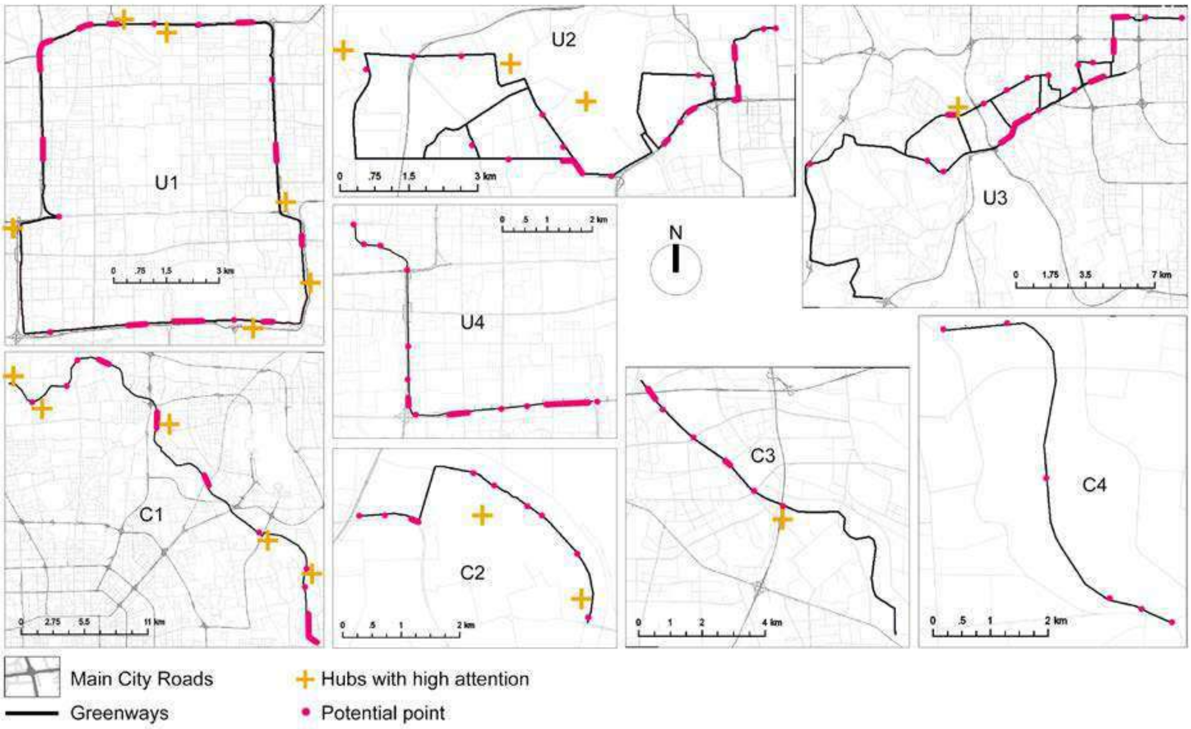

Figure 7: Potential Areas of the 8 Greenways

4. Conclusion

4.1 trace choice

According to the analysis of Beijing city shared bicycle kernel density (Figure 3), it can be seen that there are many areas in the city with large bicycle utilization rate, but there is still no greenway system. These areas are potential areas for future urban greenway system selection. By improving the riding environment through targeted green roads, it can provide people with a better slow-moving experience.

4.2 resources connectivity

The potential areas obtained by the superposition study (Figure 7) present important surrounding areas which have better landscape resources or a l arge number of people. However, in the actual survey, the design and planning of most of the potential areas are built like other areas, and the surrounding resources are also separated. It is recommended to improve the design quality of these potential sections in the future greenway construction, especially to connect the surrounding resource nodes, such as increasing the greenway branch line, better combining the resources with the greenway.

4.3 integrity

Through analysis and research and demonstration, we found that an important issue in Beijing's built greenways is the integrity of the greenway. Although the government has planned a continuous greenway system, in the actual construction process, many greenways will be affected by urban roads. There are many problems that greenways are cut off by urban roads or lack of land, only to occupy roadways or crosswalks. "crowded" , "dangerous" and "where" in emotional analysis often reflect such problems. It is suggested that in the future greenway construction and transformation process, these problem areas will be treated in a targeted manner by gradually adjusting land allocation and constructing a three-dimensional transportation system.

4.4 facility
According to the results of sentiment analysis, the problem of greenway facilities is concentrated on the recognition of greenways. It is suggested that through the improvement of paving and marking system, the recognizability of greenways can be increased, and people who are riding can better find greenways locations and directions for their travel.

4.5 social promotion
We found that although some green roads have the same construction time, the related terms have great differences in the microblog platform (such as U2 and U3). The statistical results show that there are also large differences in the number of publicity microblogs between the two. It can be s peculated that the government's online publicity also has a certain role in promoting people's use of greenways. It is recommended that the government and relevant agencies increase relevant social propaganda, and actively build and open up network platforms such as Weibo to provide a better foundation for future feedback research.

Integration of Green Infrastructure into Transportation Planning in African cities

Ifeoma F. UKONZE
Department of Urban and Regional Planning, University of Nigeria Nsukka, Enugu, Nigeria
Donald C. OKEKE
Department of Urban and Regional Planning, University of Nigeria Nsukka, Enugu, Nigeria
Obinna C. NNAMANI
Department of Estate Management, University of Nigeria Nsukka, Enugu, Nigeria

1. Abstract

Green infrastructure concept emerged as a solid tool in all areas of specialization in town planning development projects. Transportation planning is an important sector that has significant influence on effectiveness or functionality of all sectors of the environment. The concern lies on how countries can make development in this sector more sustainable and efficient. However, there exist a gap in literature for an integrated framework to aid engineering organization, the planners and the government in planning the start-up of new transport efficient projects in the context of greening and sustainability in African cities. This study attempts to identify existing framework that have been proposed by major cities in Africa that ensure green transportation projects and review frameworks used by developed countries. This review identifies several approaches that have been employed by developed nations and recommends a ready-to-use framework of sequenced tasks that will aid proper integration of green infrastructure in transportation development. This research also reviews GI. literature with a focus on transportation development and including methods and techniques adopted in these reviewed approaches in African cities.

Key words: Green Infrastructure, Transportation planning, Sustainability, Environment

2. Introduction

Most environmental professionals have started incorporating different ecological integrated concepts that supports design of liveable and sustainable environment. However, in the area of transportation planning, planners and policy makers seem to be lagging behind in providing such an ecological integrated concept (Beatly, 2010). Contemporary studies focuses on a unified approach to design of sustainable system that integrates all scales including the transportation sector ranging from molecular to global (Van Der Ryn and Cowen, 2007). Green infrastructure has been proposed by most professions as an approach to designing sustainable city systems in transportation planning in developed nations. Although, the principles and concepts underpinning are not and can be traced through the beginning of environmentalism, landscape architecture and planning in the 19th century Europe (Pankhurst, 2010). Then it was termed concepts as sustainable environment, liveable cities, smart growth, compact cities etc. However, the G.I concept is being paired with other mitigative tools that will aid in achieving a sustainable environment. Due to the cost implications associated with the provision of the infrastructure required for the implementation of sustainable (mitigative) tools, developing nations has been encouraged to first employ adaptive measures as G.I infrastructure (UNCCC, 2015). As this is an efficient way to solidify the resilience of cities to the effects of climate change and encouraging sustainable development.

In African cities most of the effects of climate change are as a result of mans uncontrolled and indiscriminate activities and this can be managed. The disparity between land use and mobility has been an issue in the implementation of a sustainable transportation infrastructure. The transportation sector contributes immensely to greenhouse gas emissions in the world and in major African countries like South Africa, transportation has grossly its own share in the total emission from 32% from 36 016 Gg CO2 eq in 2000 to 47 607 Gg CO2 eq in 2010 (Peters, 2017). As a result they have set targets in line with the Paris agreement at COP 21 to reduce the emissions by 34% in GHGs by 2020 and a 42% reduction by 2025 (Peters, 2017) with the formulation of the Green Transport Strategy. In Nigeria, steps are still underway but there is still a gap in a policy framework that supports green infrastructure in transportation planning. The draft transportation policy strategy has little or no framework that support integrating green planning. Generally, in transportation planning, this concept is relatively new as underlying factors supporting its implementation has a great deal of gray infrastructure. This is one of the reasons why most cities are still have not developed an integrative policy framework that supports green infrastructure approach

However, green infrastructure have been defined using the adaptive management approach and this has been designed primarily to support managers in dealing with highly connected systems like transportation (Wietske and Jeffrey, 2005). This approach is instrumental to developing economies as there are no massive funds required in its implementation. Therefore developing a new standard of measuring, or technique and analytical framework that will make integration easier for cities (Jeffrey & Geary, 2004) in the transportation sector with both developed and developing economies is very much required. This is due to disregard of the 'green' and concentrating on energy efficiency in public transportation infrastructure paying little attention to improving livability and urban happiness through expanding the dimensions of nature (Beatly, 2010).

The aim of this paper is to provide a comprehensive review of green infrastructure in transport planning as could be seen in African cities. It is noteworthy that a number of studies on green infrastructure over the last decade with little focus on the transportation sector. There also exists a gap on finding an integrating framework on green infrastructure to transportation development in African cities. This paper suggests steps that can be taken to address this gap. This paper builds on existing literature in developed countries. This is followed by a discussion of existing general practices approaches that could be employed in integrating the concept of green infrastructure in transportation planning. The research concludes on selecting an adaptable approach to the geography of African cities. On that note, the current challenges, on-going progress and sectors that need further research are outlined and discussed.

3. Methodology

The paper is a desk-based review of a number of articles focused on green infrastructure transportation development in African cities with emphasis on Nigeria and South Africa in order to identify salient issues in green transport infrastructure with relation to the concept and why integration into policies have proved challenging till date. This paper also reviews different conceptual framework for green infrastructure that has been designed by developed countries and that could be adapted into the Nigerian transportation sector. It further recommends a framework(s) or a guide to develop one to be adapted into cities in Africa in their transportation policies to ensure sustainability.

The review begins by defining green infrastructure and analyzing the cost and benefit of this approach to its counterpart, traditional infrastructure. It further reviews the concepts and theoretical framework supporting the green infrastructure generally and relating them to the transportation sector. The review concludes with a short summary of the lessons learnt.

4. Overview

a. Defining Green Infrastructure

The concept of green infrastructure has been defined by many authors and professionals but before attempting to define this, it is imperative to understand, an understanding of its counterpart, the traditional or gray infrastructure. Thus, gray infrastructure refers to the sub-structure system such as aqueducts, traditional road pavements, pipelines on which the development of a city depends (Mell, Roe & Davies, 2009). Whereas green infrastructure is a network of multi-functional green spaces, both new and existing, both rural and urban, which supports the natural and ecological processes and is integral to the health and quality of life of sustainable communities (TCPA, 2008) Simply put, green infrastructure can be said to be the concept of adapting traditional infrastructure respecting and paying attention to nature, ecology and its principles. The term 'green' may mean different things to different people. It can be grouped into two forms, green (nature, trees) and the engineered structural part such as bicycle parts, public transportation infrastructures using renewable energy sources, viaducts etc that are designed to be environmentally friendly (Benedict & McMahon, 2006).

Also, green infrastructure on transportation sector follows some outlines which includes low carbon infrastructure, climate resilient, transport infrastructure, public transportation systems, renewable energy, water conservation infrastructure with improved irrigation systems.

b. Cost Benefit Analysis of Green & Traditional Infrastructure

There has been reluctance by cities especially in Africa to attempt the integration of G.I into policies (Rohde and Muller, 2015). Due to the doubts on the positive implications on economic development. However, the question of the feasibility of green infrastructure as a good instrument for economic development is not debatable as it does not only save the environment, it helps achieve sustainable development and promote urban happiness. As could be seen in Gauteng city-region, South Africa and some other cities where G.I was used to address local transportation challenges in South Africa.

The European commission posited that the main feature of the Green Infrastructure Strategy is its integration into relevant policies through: ecosystem-based adaptation into climate change policies; nature-based solutions into research and innovation policies but the onus lies in providing an adaptable framework that will support such integration sustainably.

A recent study shows that the there is only an increase of between 0% and 7% construction costs per year (see table 1 below). The table further showed that in the transportation sector, the global increment cost of switching from traditional infrastructure projects to green infrastructure projects is would be between US$ 0 billion to US$ 400 billion per year between 2015 and 2020 which is insubstantial compared to the cost of rehabilitation and reconstruction projects for a city to recover after a climate change hazard. Also for Sub-Saharan Africa, North Africa and South Africa where the level of infrastructure is already low, even though measurement of such data is challenging due to lack of adequate research in that area. Also even with the inadequate data, it is seen that the additional cost of adapting infrastructure is minimal. World Bank (2010), noted that only cost between 5% and 7% more than would have otherwise have been spent, whilst maintenance costs would be 30% for traditional structures for climate resilient structures.

Table 1: Global Traditional vs. Green Infrastructure Costs 2015 - 2020

Sector	Traditional Infrastructure Cost (US$ Billion / year)	Green Infrastructure Cost (US$ Billion / year)
Power Generation	320	380
Electricity Distribution	270	260
Buildings	320	620
Industry	280	310
Water	772	772
Telecoms	646	646
Road	245	< 245
Transportation Vehicles	3,300	3,370
Rail	120	120
Airports	120	< 120
Ports	40	40
Oil & Gas Distribution	155	< 155
Total	*6,590*	*6,500 - 7000*

Source: OECD (2012)

Generally, it is important to rethink the way infrastructure provision and development are envisaged in African cities through green infrastructure. This is because it has the ability to deliver such services using a flexible planning approach that could be tailored to address pecific challenges unique to African cities (Culwick and Bobbins, 2015). Moreover, it can be said to require less capital budget and provide additional benefits compared with the use of sole traditional engineered infrastructure. In other words, the concept can aid in the enhancement of services delivery and minimizing disaster risks and protecting the environment. Due to the effects of climate change on the environment, African cities are in need of a more resilient approach to adapt to these effects. Also, with the contribution of the transportation sector, the encouragement of integrating green infrastructure is very important.

c. The State of Urban Sustainable Transport in African cities

Urban population has been rapidly growing and with the galloping urbanization therein, the growing demand for urban transport services, facilities has also been simultaneous. The existing transport facilities are inadequate to support the current population, let alone the future (Pirie, 2013). Previous study shows that the population of Abuja (Nigeria), Accra (Ghana), Kampala (Uganda), Johannesburg (South Africa), Dar es Salam (Tanzania), Kumasi, Nairobi (Kenya), etc., are predicted to double more between 2000 and 2025 and to triple by 2050 (InHabitat, 2010).

The inadequacy in transportation services and infrastructure has a major contribution on the slow growth of the economy as congestion slows down efficiency and economic growth (Piere, 2013). In Dakar, for instance, it is estimated that 1 million working hours are lost per day due to congestion (Kunieda and Ganthier, 2007). And with the population growth and the effects of climate change, major Africa cities will have their economies suffering more economic issues in the nearest future. The existing transport infrastructure is insufficient and inefficient as the low capacity in government hinders efficiency in service delivery, increasing the growth of private transport. Moreover the existing infrastructure are seen to be more socially exclusive, environmentally unfriendly and economic promoting (United cities and local governments, 2009). Generally, urban mobility is seen to be very low as it varies from 1.7 trips per person per day in Morogoro (Tanzania) to 1.9 in Dar es Salam, 2.2 in Kinshasa and Nairobi (Pirie, 2013). In this regard, due to the effects of low mobility on the economy, the normal response to this is to construct more road space, buy more vehicles. This is the frequent encouragement of the traditional infrastructure without much focus on the effects on the environment. This frequent response of government to the transport needs of people addresses the symptoms, abandoning the root causes of these issues. Over the years, focus has been always pointed at promoting traditional infrastructure through motorized mobility. However, gradually, a wake has been seen in most African cities as there is seen to be a shift to affordable, socially equitable accessibility using appropriate technology in line with the principle of sustainable development (Pirie, 2013).

Although this shift is gradual and limited to few cities, a challenge presents itself in filing the gap of providing a formidable framework that will aid the integration of this green infrastructure concept into transportation planning policies as an adaptive tool to the effects of climate change.

d. Green Infrastructure

Green Infrastructure emerged after various attempts to incorporate climate change issues into international political agenda in the 2000s brought energy (Irek and Thomas, 2008) and resource efficiency to the center of the discussion on sustainable development and city sustainability. With the population growth, urbanization and uncontrolled expansion of cities into urban sprawl, discussions have been ongoing in international communities in the search or new concepts and methods to define and measure city sustainability. The above mentioned further led to the development of the concept green infrastructure. From the 1990's other concepts such as sustainable city, green urbanism, liveable city and compact city among others were propounded. While most of them are still current, and are very much in the center of most debate, this term with regards to transport infrastructure due to its major contribution to climate change. Hence, it also borders on energy use and resource efficiency prompted this focus on 'green'. This is because it has a bearing on sustainability and eco-friendliness. In South Africa a framework for assessing and valuating green infrastructure was designed by Groot et al, (2012) to support the different strategies designed and also ensure successful integration of this concept into different sectors especially the transportation sector. This could also serve as bedrock for most cities in developing their own indigenous frameworks (figure 1).

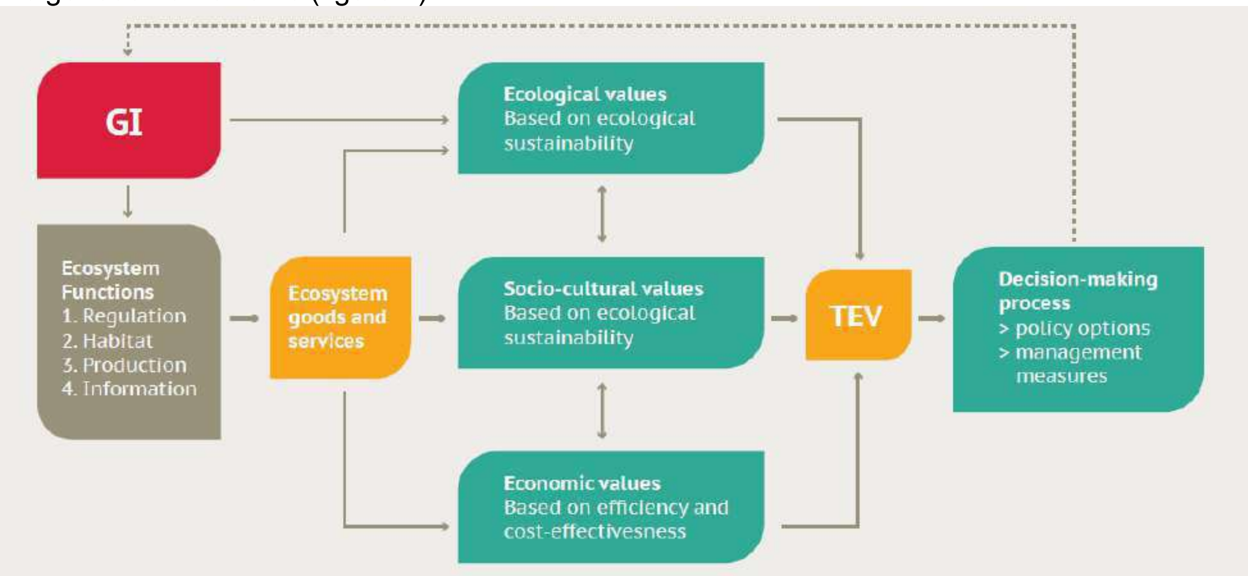

Figure 1: Framework for assessment and valuation of green infrastructure
Source: Based on De Groot et al. (2002:394).

5. Concepts and Approaches

a. Specific Frameworks

Major groups like professional associations and world leaders have realized that the current infrastructures and urban planning paradigms have been an hindrance to achieving sustainable urban development and living (Novotny et al, 2010). Even though the role of green infrastructure is well documented, it is difficult to integrate spatial planning approaches and green infrastructure planning in urban contexts let alone transportation planning. This is because land use decision making takes place within a broad framework driven by the demand for housing and other services. In South Africa for instance, as well as many African cities, green land uses generally are always competing against other urban land uses (Cilliers et al, 2011) and a proper understanding of the purpose of 'green' to our environment, has not been very relevant during planning decisions. Most sustainable projects and related researches deal with environmental processes at a regional scale which finds it difficult to be translated in a practical way to the local government level that has the task of implementing such projects (Cilliers and Cilliers, 2016). Globally green infrastructure in transportation development has limited conceptual framework which has made it challenging for its adaptation by most countries even in Africa. However, in the developed societies, many green concepts and approaches have been developed generally and will be further stated below

b. American Society of Landscape Architects (ASLA) Sustainable Sites Initiative Benchmarks and Performance Guidelines

This initiative is an interdisciplinary efforts established by landscape architects in the Lady Bird Johnson Wildflower Center at The University of Texas at Austin and the United States Botanic Garden to create voluntary national guidelines and performance benchmarks for sustainable land design, construction and maintenance practices (Cilliers and Cilliers, 2016). This Sustainable Sites Initiative was funded by the Meadows Foundation and Landscape Structures (ASLA, 2009). The framework is presented in nine topics as represented in Figure 2. This is to show the plan outline starting from the selecting of site to the monitoring and innovation. The framework showed a detailed presentation of how the sustainable land design is integrated.

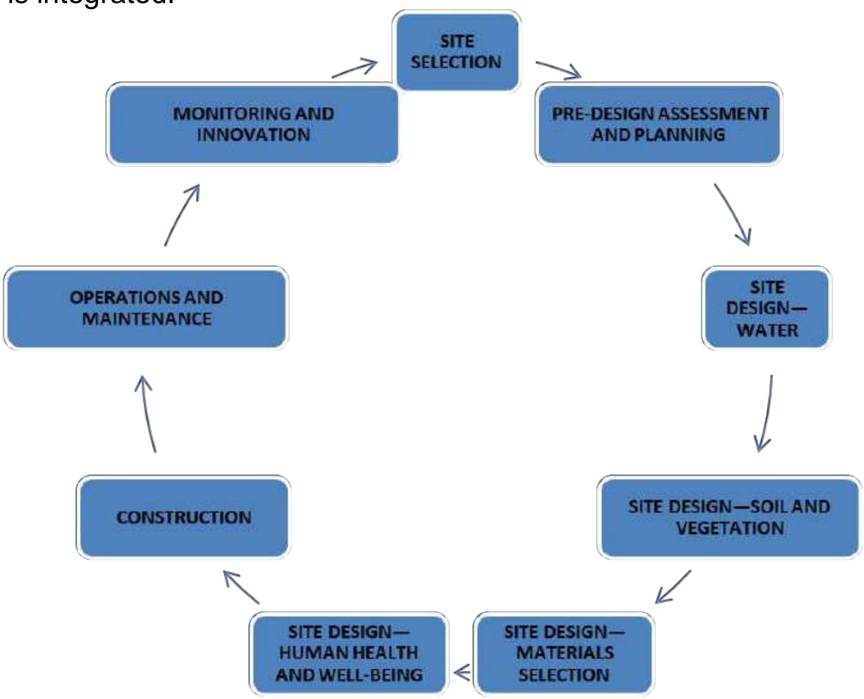

Figure 2: Sustainable Sites Initiative Framework
Source: ASLA, 2009 Benchmark and Performance Guidelines

This framework focused on achieving sustainable land design and landscaping functions which was limited to transportation development.

c. BREEAM

''BREEAM (building research establishment environmental assessment method) is a building certification system established in 1990. It is a method of environmental auditing, providing a set of standards for best practice in sustainable development for the design, construction, operation and environmental performance of buildings'' (Cilliers and Cilliers, 2016); The main criteria for calibration include measures affecting energy, water use, indoor environment, pollution, transport, materials, waste, ecology, and management processes (BREEAM,2012). In transportation, its aim was to ensure transport and movement strategies reduce the impact of the development upon the existing transport infrastructure and improve environmental and social sustainability through transport (BREEAM, 2012). In this framework, there was a breakdown of the assessment requirements and detailed activities but with limited considerations of how the local community and relevant stakeholders can take part in the different stages.

d. The LEED Concept

LEED is an internationally recognized green building certification system that provides third-party verification that a building or district was designed and built using strategies aimed at improving performance across all metrics (LEED 2012). It is preferred by urban development professionals in developed countries (Novotny et al, 2010). These metrics include energy savings, water efficiency, CO2 emissions reduction, improved indoor environmental quality, and stewardship of resources and sensitivity to their effects (USGBC). There are six categories of certification: (1) new construction; (2) commercial interiors; (3) core and shell; (4) existing buildings; (5) homes; and (6) neighborhood developments. In the US, the USGBC manages the certification program while the Canada Green Building Council (CaGBC) manages the program in Canada even though both organizations are independent (Beauchamp and Adamowski, 2013).

As LEED is mostly dedicated to buildings, the USGBC has developed the LEED for neighborhood development (LEED ND) rating system to guide and assess sustainable community development (Beauchamp and Adamowski, 2013). The 2009 LEED ND, for example, is a set of performance standards for certifying the planning and development of new neighborhoods. The intent is to promote healthful, durable, affordable, and environmentally sound practices in building design and construction. Prerequisites and credits in the rating system address five topics: smart location and linkage, neighborhood pattern and design, GI and buildings, innovation and design process, and regional priority credit. The system was created as a partnership between the USGBC, the Natural Resources Defense Council, and the Congress for the New Urbanism (CNU) and registration opened in April 2010 (Beauchamp and Adamowski, 2013).

The CNU is the leading organization promoting workable, mixed-use neighborhood development, sustainable communities, and healthier living conditions and is one of the major leaders of LEED. The CaGBC has developed the Canadian Alternative Compliance Paths (ACP) for the LEED ND 2009 rating system (Beauchamp and Adamowski, 2013).. The ACP are formally approved approaches that provide clarity and guidance for Canadian projects, addressing sections of the rating system that contain US-specific standards or wording (CaGBC, 2012). The approach herein was designed using a rating system where projects are accredited. Following the registration of such project, the design team begins to collect information and perform calculations to satisfy prerequisite and credit documentation requirements. The basic steps outlined in this approach includes site analysis and programming, preliminary planning and final design. However, transportation networks were fully incorporated during the preliminary planning and its interaction with land use before the final design. This approach is much more used in the United States of America (Sarte, 2010). However, the lop sides to this approach is that it focuses mainly on new development and cannot be adapted to brownfield development and initiating a project form these criteria remains very tedious. Despite all these, it could serve as a benchmark for similar societies to develop their own strategies and frameworks therein

e. US Environmental Protection Agency Green Approach; Municipal Handbook

The EPA has developed a *Municipal Handbook* (USEPA, 2012), a series of documents aimed at helping local officials implement GI in their communities. The documents cover specific terms to help municipalities introduce GI in the design of storm management facilities. (Beauchamp and Adamowski, 2013). One chapter identifies and discusses the most common funding options available to communities for funding green storm water infrastructure, storm water fees, and loan programs. Another chapter covers street design and various other topics are also discussed. Additionally, the EPA has developed the *Water Quality Scorecard* (USEPA, 2009). This approach does not address the local communities' integral participatory roles in green infrastructure development and has little focus on transportation sector.

f. The British Columbia Approach

In BC, the Rainwater Management and Green Infrastructure seminar was initiated by an inter-governmental partnership (IGP) on 11 June 2007. The Water Sustainability Action Plan for British Columbia provides a partnership umbrella for an array of on-the ground initiatives that promote a "water-centric" approach to community planning and development (Beauchamp and Adamowski, 2013). One of the tools developed under this umbrella is the water balance model for BC. Developed by an IGP (BC and Fisheries and Ocean Canada) as an extension of *Storm Water Planning: A Guidebook for British Columbia,* the water balance model enables users to visualize ways to implement GI solutions to achieve rainwater runoff source control at the site level. The Water Sustainability Action Plan for British Columbia is sponsored by the province of BC, and its elements are delivered through partnerships. Under the Action Plan umbrella, the Water Sustainability Committee of the BC Water and Waste Association is the managing partnership and is responsible for providing leadership, facilitation, and organizational services for program delivery (Beauchamp and Adamowski, 2013). Basic information is provided in a guidebook, refocusing the approach to sustainable ecosystem management. The use of the term "storm water" suggests there is a problem, whereas "rainwater" is seen as a resource (BCWWA, 2005). The past two decades has seen an evolution to an integrated approach.

The approach introduced the concept of performance targets to facilitate implementation of the integrated strategy for managing the complete rainfall spectrum (BCWWA, 2005). Rainfall capture means include measures such as rain gardens and infiltration soak ways, runoff controls (which delays overflow runoff by means of detention storage ponds), and flood mitigation (which reduces flooding by providing sufficient hydraulic capacity to "contain and convey") (BCWWA, 2005). Defining rainfall tiers simply enables a systematic approach to data processing and identification of rainfall patterns, distributions, and frequency. The integrated approach proposed (BCME, 2013) is presented in seven steps:
(1) Secure political interest and support;
(2) frame the watershed problems and opportunities through a land use working session, drainage working session, ecology working session, and interdisciplinary roundtable session;
(3) develop objectives and alternative scenarios through flood management scenario modeling and source control scenario modeling;
(4) collect meaningful data and refine scenarios according to concurrent rainfall and stream flow data, data on soils and groundwater, water quality data, and data on fish and their habitats;
(5) evaluate alternatives and develop component plans;
(6) develop an implementation program;

(7) refine through adaptive management.
BC's approach is one of the frameworks used for analysis and some of its proposals will serve as a platform or guide to developing a more efficient framework for green infrastructure.

g. Sustainable Infrastructure and Water Centric Sustainable Communities Approach

Contemporary studies have specifically examined the engineering of GI: in 2010, S. B. Sarté who conducted a research on 'Sustainable Infrastructure and Water Centric Sustainable Communities which was published by Novotny et al. (2010). Also Ahern (2010), who developed a six methodology water-centric approach to green planning. Sarté offers several forms of guidance for project planning, creating a unique approach for each project by combining different philosophy or development frameworks. Sarté identified 13 frameworks, the most popular being LEED and BREEAM which has been briefly discussed above. However four approaches were identified to analyze sustainable infrastructure and four existing frameworks to organize green projects were suggested as stated by (Beauchamp and Adamowski, 2013):

1. Framework 1: pillars of sustainability. This approach presents an analysis based on five elements: water, energy, materials, ecology and community. Analysis of the project is formatted in these terms and it is proposed to proceed with a development evolution of the design following five levels of progression.
2. Framework 2: the scale density framework. The approach is defined in four words: water, wastewater, energy, solid waste. The needs analysis is defined according to four levels: the city, the district, the block and the building. The organization becomes a pyramidal structure and presents an overall picture of the final proposal.
3. Framework 3: the transect. This approach defines territory into seven areas: T1 (natural), T2 (rural), T3 (suburban), T4 (general urban), T5 (urban center), T6 (urban core), and SD (special district). This approach is a form of territorial organization to establish a balance between each of the zones and to identify needs. The overall plan is determined based on a progression from one area to another by introducing measures of sustainable development.
4. Framework 4: the built form-ecology framework. This approach interconnects human actions with natural ecological systems. The method uses drivers to guide development. On the horizontal axis are biodiversity, water, air, land and energy. The vertical axis is divided into habitation/settlement, industry/resource extraction and recreation. The principle consists of establishing an equilibrium balancing all these elements according to the criteria in the appropriate box. All these approaches or developmental frameworks are elements of reflection appropriate to define a development project and to define a sustainable strategy.

However, none of these outlined frameworks define a formula to initiate a project and carry through to final detailed engineering.

Also, Ahern examined best practices for planning the urban environment in a sustainable manner. The proposal was on a water-centric approach to sustainable planning (Ahern, 2010). Ahern proposed this using a six step methodology: 1) ecosystem services (goals and assessments); 2) resilience factors; 3) resilience planning strategies; 4) developing scenarios; 5) urban resilience-sustainability planning; and 6) planning implementation–adaptation. (Beauchamp and Adamowski, 2013). However, this approach did not give a detailed description of how to achieve this, to the local institution level. It focused more on integrating the work of many professionals.

This study showed the various approaches and frameworks that have been developed for green planning and sustainable development but no framework has been developed with the

Green infrastructure in transportation development were more detailed in cities strategies which will be illustrated below

h. The Green Transport Strategy (GTS)

Due to the greenhouse gas emissions produced by the transport sector in South Africa and climate change issues, the department of transport in South Africa developed a strategy on how to reduce these emissions. This will contribute significantly to the national effort to reduce emissions as agreed to by the South African government at COP21 in Paris through the Nationally Determined Contribution (NDC). This will in turn reduce the environmental and human health impacts associated with the transport sector and result in a more resilient sector (Staatskoerant, 2017).

Following the Research undertaken by GIZ, SANEDI and a host of other research organizations on behalf of the South African government some conclusions that led to the establishment of the strategy arose. This focused on reducing the need to travel and avoiding unnecessary trips through walk able communities, integrated land use planning or transit oriented development and improving vehicle occupancy rates. Given that the road transport sub-sector is responsible for 86% of direct emissions from transport, shifting of passengers to public transport and freight to rail is a necessity (Staatskoerant, 2017). Finally, Biogas and solar powered electric mobility outstrip any other cleaner fossil fuel in terms of GHG reductions. In their strategy key measures to facilitate the modal shift from road to freight and private to public transport was identified. The strategy also stressed on the promotion of non-motorized transport and development of the associated infrastructure to support this plan

The GTS has identified and proposed key measures to facilitate the modal shift from road to freight and private to public transport. There also exists an important need to promote non-motorised transport and develop the associated infrastructure to support this. The strategy focused on 4 implementation themes and 8 strategic pillars (Table 2) and the implementation tools to support it was very comprehensive and the various stakeholder duties were outlined and addressed (Staatskoerant, 2017).

Table 2: Strategic Pillars of the Green Transport Strategy

Green Roads	1. Shift passengers from private to public transport, including rail 2. Shift freight transport from road to rail 3. Provide infrastructure to promote non-motorized transport
Green Rail	4. Extend the rail network to provide reliable, safe and affordable high-speed transport
Green transport technologies	5. Reduce the carbon footprint of fossil fuels 6. Promote alternative fuels such as compressed natural gas (CNG) or biogas, liquefied natural gas (LNG), fuel cell and liquid biofuels as transport fuels. 7. Promote electric and hybrid-electric vehicles 8. Explore the option of Fuel cell/ hydrogen technology
Green Fuel Economy Standards	9. Provide norms, standards and regulations that promote fuel

	economy in vehicles and improve emission standards of fuel in South Africa

Source: The Draft Green Transport Strategy, 2017

This strategy employs the use of measuring, reporting and verification (MRV) framework which is required to be developed by the person and team responsible for implementing each project on this strategy (Staatskoerant, 2017). This plan could be used as a platform for other African cities to adapt to their communities but focus was more on the engineered part of green infrastructure and little emphasis on the 'green' part of this concept. This neglect affects most strategies as it is assumed that it is an integral part without making it form a part of their strategy. Also at the local authority level, there was not a comprehensive breakdown regarding how they intend to be fully part of this strategy which when future frameworks are designed, that part should be addressed.

5. Conclusion

Most of the above listed frameworks were tailored specifically to satisfy the needs of designated professionals and public servants. Most of these frameworks focused on storm water control, landscaping, waste water etc. and the approaches to guide the design of these areas. But no designed framework on how to integrate green infrastructures into urban transportation planning when creating urban development. Also most of these concepts were focused on the engineered aspect of green infrastructure and little structure for the 'green' part of green infrastructure. The main thrust lies on individual countries to develop strategies and frameworks to support green infrastructure in their transportation planning design just as South Africa has done through mainstreaming as their draft green transport strategy. Nigeria is yet to develop a green transport strategy and their transport policy is yet to be reviewed as the 1993 transport policy is still in use and does not support the integration of green infrastructure. If this is neglected, transportation sector will continue to be a major contributor to greenhouse gas emissions and their contribution will keep increasing which is not good for the environment. Lagos state government has proposed an action plan for sustainable transport planning but has not been fully publicized for adaptation.
Borrowing a leaf from Cilliers, as done for planning green spaces in rural South Africa, there are areas that should be considered for a framework to border on. Hence this study recommends that to develop a framework for green infrastructure in transport development the following should be first considered,

a. Identifying the value of the green infrastructure proposed. This should be done within the local context, outlining the challenges and opportunities present in the specific areas and in Africa, the unique cultural needs of the people
b. Identify the framework to interlink both the traditional and green infrastructure in a sustainable manner. This is in order to defeat the fear that the later has come to remove the former totally from existence.
c. Identifying methods and beneficiaries of green infrastructure in those transportation sectors. This is one of the lacking issues in earlier frameworks. The beneficiaries for each transport infrastructure and mode should be identified and integrated fully in the design process.
d. Quantifying the value of green infrastructure design. This is very vital in the design process, and also in the decision making process. These issues will be quantified with regards to the indirect benefits which include the social values, environmental values, child and aged friendly transport networks and the direct benefits which include the economic values. This is to ensure that the projects are more sustainable.

Finally, this research shows that the proposal of green infrastructure in transportation design will meet the challenges of climate change and make the African environment more resilient to these effects. However, developing a framework based on these recommendations would form another topic of empirical study.

Abstract
Sponge city is a type of strategies to cope with stormwater management under the rapid urbanization in China. It intends to naturally improve water quality with infiltration while drawing lessons of Low Impact Development (LID) and Green Infrastructure (GI) from European and American Countries. Old districts in China now are faced with more obvious and urgent issues including excessively large of construction intensity, much population, insufficient area for implementation and old infrastructures, which call for the targeted approaches and methods to coordinate and conserve the original historic buildings and features. This paper will select Garden Street historic block , a representative historic block in Harbin, to determine its control goal of total annual runoff adapting to its problems and status quo. The space will be hierarchically managed and controlled and buffer zone is applied to avoid the foundation of historic buildings. Meanwhile, the green LID facilities are combined with Gray Infrastructure to design the invisible LID infrastructures, which are coordinated with the features of traditional blocks. The space of old district is optimized in a resilient manner to establish spatial system of stormwater management, which contributes to the theoretical exploration for sustainable and resilient development of old districts in China.

Sponge city; old districts; hierarchy management and control; Garden Street Historic Block; Harbin

1. Introduction

As urbanization speeds up in China, social economy booms rapidly with significant achievement of city construction. Although city numbers increases and city scales expand and development, the extremely strong development density also leads to the excessive hardening of the original natural underlying surface and alters the original city natural ecology background and hydrological characteristics and other issues (Zhang, 2015). City is challenged with frequent water logging, runoff pollution, heavy loss of rainwater resources, deterioration of ecological environment, loss of water culture and other issues. The traditional drainage model of city rainwater is hardly to follow and to cope with the more severe stormwater problems, China has drawn lessons from foreign counties worldwide and, in sight of our national conditions, further propose the rainwater solutions and strategies: sponge city. The core of sponge city is to realize the comprehensive objectives of pollution control, disaster prevention, utilization of rainwater resource and city ecological remediation. The coordination and control are applied during the entire process by multidisciplinary from mechanism construction, planning regulation and control, design and practice to construction operation and management. It aims to conserve and utilize city Greenland, waters and other spaces as well as prioritize to combine green infrastructure with Gray Infrastructure to jointly establish the resilient rainwater infrastructures and realize five aspects of rainfall runoff: infiltration, blocking, reservoir, purification, utilization and drainage.

The construction of sponge cities is in full swing in China. Its construction and research mostly focus on outskirts areas and new cities with less serious issues, not even mentioning the old districts with frequent water logging. As old districts afford much of the city population and more important functions, their stormwater problems are more server. The sponge city is therefore imperative in old districts. In sight of the excessive hardening of the original natural underlying surface, insufficient space for implementation of sponge city and more strict of features' management and control, this paper will attempt to put forward the targeted and resilient controlled indices and implementation strategies in space with the aim to improve the stormwater issues in old districts. At the same time, the author also has discussed the coordination between the construction of sponge city and the historic features of old districts as well as the heritage and continuation methods of local culture in China.

2. Difficulties for implementation and construction of Sponge City in old districts

2.1 Large construction density and insufficient implementation space

One of the main difficulties for implementation and construction of Sponge City in old districts in China lies in the insufficient space of implementation, resulting from high construction intensity, crowded environment and excessively hardening of underlying surface. Old districts are always located at the core area of the city and the area with the largest construction intensity. Therefore the commercial atmosphere from the excellent geographical location and history accelerates the population agglomeration and the growth of construction intensity, which thus hardens the underlying surface with infiltration and permeability.

As indicated from the research, the hardening ratio of underlying surface in old districts nationally could peak at 65% and the public green land area per capita is less than 5 m^2 and the common green rate usually is between 7%-12% (Li, et al., 2017). Compared with the regulated green land ratio for newly constructed communities, 30%, the area of green land is seriously in sufficient with unevenly distribution, leaving less public space for the construction of Sponge City. And all these are contrary to the connotation of Sponge City to reconstruct the stormwater facilities through the extensively and largely demolish the harden pavement or rigidly occupy the limited space resource. Ultimately, the spatial layout and features are destroyed in old districts, challenging the construction of Sponge City in old districts.

2.2 Old and obsolete drainage system and low bearing capacity of pipes' network

Urban drainage system of Harbin, initiated in 1904, witnessed the preliminary construction during tsarist Russia, Japan and pseudo-ruling periods, sped up in the later period of the founding of the People's Republic of China and was generally improved nationally after the reform and opening up. It has been over a century of history from the establishment of drainage system. Old districts are mostly dominated by the drainage of confluence of rainwater and sewage. However, the drainage facilities for these old districts are already overwhelmed with seriously insufficient drainage capacity of flooding due to their long construction periods and increasing construction and population density.

The initial drainage system, in old districts, basically set the runoff coefficient, ϕ, at 0.5, comparing with the actual runoff coefficient, 0.7. Part of the construction standard of pipes' network set the recurrence period at 0.5 years (Xue et al., 2011). The drainage efficient is much far from the national standards. The area with drainage system is 216.05 km^2, accounting up 66.36% of the planned area. According to national standard, the coverage of drainage pipes' network should be over 80% for the cities , equal to the same scale of Harbin. As regulated, the density of pipes' network for the system of confluence of rainwater and sewage should be 8 km/ km2. The density for Harbin City is only 5.68 km/km2. The service coverage of network is only 69%, hardly satisfying the standard, 95%, enforced by Ministry of Housing and Urban-Rural Development. In 2016,the total length of drainage pipes was 1,242 km in old district in Harbin and among about 49.6 km was constructed in 1940s or 1950s. 5.3% was constructed in 1960s. It's 217 km in 1970s, also the peaking point. appropriate one in third length of pipes has already far exceeded the 40-year lifespan, an national standard. The over-aged service is also one reason for urban rainwater issues and also endangers the stormwater safety. If the drainage system are reconstructed to satisfy the current flood control in old districts, it will not only be time-consuming and laborious, but also badly have influence on daily lives.

2.3 Management and control of historic features and huge reconstruction difficulties

Old district, formed during certain periods, has already developed and evolved for hundred of years to represent the original of a city. With abundant historic culture, old districts have generated their unique city features based on their characteristic material environment and civilization. They can't be regenerated and replaced. City features and buildings'culture in Harbin is extremely valuable in their conservation. Firstly, as a colonial city, Harbin is both the experiment site of modern construction for European sovereign countries and the platform for integration of Chinese and Western architectural styles. The unique buildings' features in old district were the results of collision between local building design and international trends, such as Art Nouveau, Russian style, Baroque, and eclecticism. Meanwhile, as rising from railway, the earlier buildings were basically constructed to service railway system and the architectural styles also have been strongly marked during the aided period by the former Soviet Union. In 1994, Harbin was approved as one of the third list of National Historic and Culturally-Significantly Cities by the State Council of China and its historic conservation blocks also was increased into 23 from 19 in old districts.

The reconstruction and renovation in old districts all should prioritize the conservation of historic features ahead of the development and construction. The Sponge City also should obeys the requirements of traditional features' management and control in old districts. The existing construction of Sponge City calls for large-scale reconstruction and design in its control methods. The construction of sunken lawn, permeable pavement, grass ditch, wet pong and rainwater detention tank will inevitably affect the features of old districts. How to coordinate the construction of Sponge City and traditional features is a huge challenge faced by Sponge City in old districts, especially under the strict features' control and management of historic blocks.

2.4 Low construction quality and limited construction conditions

The buildings are newly constructed, renovated and improved during each period historically. The temporal construction is divided into four ages: Qing Dynasty to the early Republic of China, the middle and late period of the Republic of China, 1950-1970 and 1980-now. The buildings from Qing Dynasty to the early Republic of China are the main bodies for most of old districts in our country with the oldest construction time. In the current designated buildings in old districts, the number or area of the buildings before early Republic of China accounts for about 50% of the total buildings. Within the old districts, the buildings are damaged naturally and artificial to some extent due to the long time after construction. Their quality are also weak because of the limited construction technology and technique and insufficient construction material when they were built. Most of the buildings in old districts in Harbin were built at the beginning of last century and therefore are faced with issues including roof leakage, structural aging and foundation damage due to frozen in winter.

The buildings and their surroundings are the important space for the implementation of Sponge City, which calls for the high quality of buildings or is greatly challenged otherwise. For instance, the structure and roof waterproof , for some less qualified buildings, hardly satisfy the construction of green roof and infiltration, blocking and technology might lead to the foundation erosion by rainwater.

3. Optimized implementation strategies of resilient space for Sponge City in old districts

3.1 Layout of three-dimensional sponge facilities

Different from the goals-oriented pattern of new districts for the construction of Sponge City, the old districts should integrate the controlled objectives and indicator system into the design requirements at the very begging of the planning and design. The built-up area is high in old districts, leaving less space for Sponge City. Therefore the construction of Sponge City should better orient in problems and the controlled rate of annual total runoff and storage capacity and other objectives are decomposed into the facility type and number for each plot, realizing three-dimensional layout with maximized utilization of each space *(Xue, et al., 2017; Xue, et al., 2015; Xue, et al., 2014)* (see Figure 1).

From the earlier field research, it's concluded that the green land space is less with fragmented distribution, depending on which some large sponges are decomposed into sponge cells to rationally use green land space system with landscape design. The roof greening is feasible for flat roof with good roof loads and waterproof conditions or the sloping roof with the angel less than 15%. The roof greenery should be carefully selected in historic blocks. Historic buildings and the less-qualified buildings could apply rainwater tank to collect the roof rainwater. The total underlying area of the roof in old districts possibly accounts up to 30%. if the rainwater runoff is well blocked and utilized on the roof, annual runoff could be reduced by one third. The permeable pavement is applied in squares and road space as much as possible with permeable design for ground parking in old districts. The less-qualified buildings should be avoided rationally for implementation. By utilizing the cracking space in old districts, we intends to carry out the controlled objectives, construct resilient and three-dimensional spatial system of Sponge City to further achieve the development requirements of Sponge City: natural reservoir, natural infiltration and natural purification.

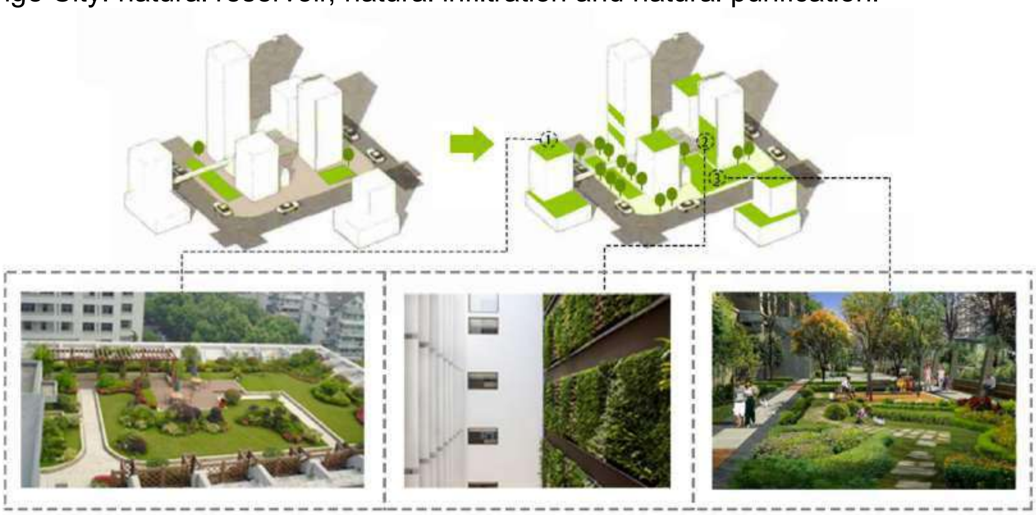

Figure 1: Layout of three-dimensional sponge facilities in old districts
Figure sources: drawn by author.

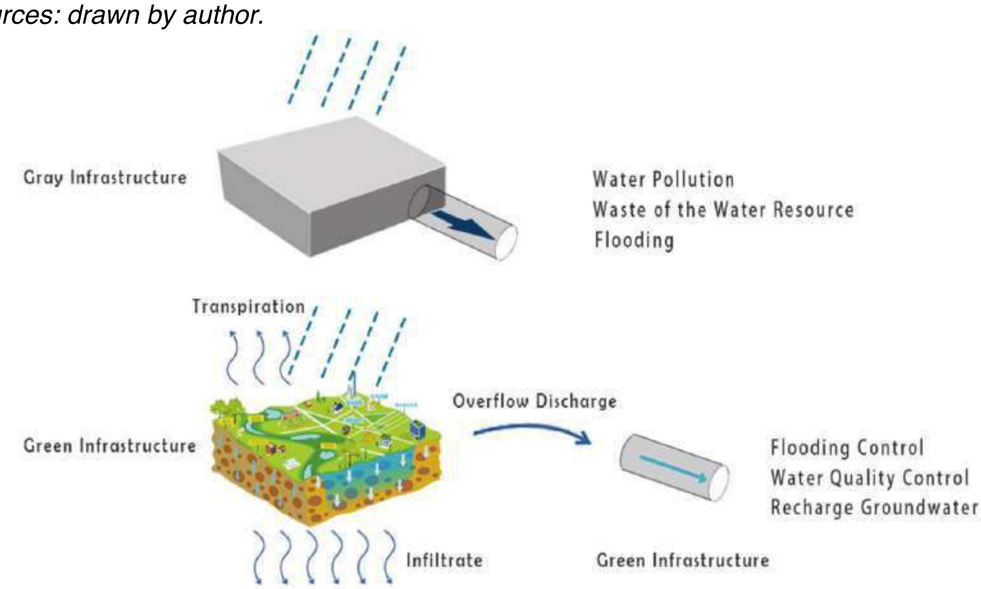

Figure 2: Combination of Gray and Green rainwater drainage pattern
Figure sources: drawn by author

3.2 Combination of Gray Infrastructures and green infrastructures

The flooding is more serious in old districts with obsolete Gray Infrastructures and less bearing capacity, leading to the definite flooding when it rains. Gray Infrastructure, as a way of fast drainage, will waste water seriously , in particular when the underground water level decreases year by year. Additionally, the bearing capacity of drainage, set at the early period of construction, only cope with low intensity rainwater (Yan et al., 2013). Meanwhile, the green land is less in old districts and the construction space for green infrastructures is also less. It’s hardly to solve the stormwater issues just depending on green infrastructure. The difficulties also lie in the reconstruction the old district whose original permeable area is not large. In conclusion, the stormwater in old districts must apply the combination of Gray and green, underground and ground and origin and ending point with rational economy (Zhang, et al., 2012). When the rainfall intensity is high and the green infrastructures are already saturated or there is no time for absorption, the Gray Infrastructures will discharge the extra rainwater .The combination of green and Gray and rapid and slow have realized the effective drainage of sponge in old districts(see Figure 2).

	No.	**Area （ha）**
Old districts	322	298.68
Harbin City	923	2312.84
Percentage	34.89	10.62

Table 1: Urban water environment layer during the period of city siting
Table sources: drawn by author.

Green Infrastructures layout of Sponge City almost depends on public area, especially that the green land space network serves as its implementation carrier. Based on green land pattern, city green land space can be divided into spot green land, parcel green land, belt green land and wedge-shaped green land. ArcGIS is applied to analyze the green land in old districts and the areas are selected within the fourth ring of Harbin, namely the wide-recognized Harbin City, as the comparative research area. From data comparison through NDVI (see Table 1), it’s clear to compare the characteristics of green land space for old districts. Two in thirds of single green land area is less than 0.5h with fragmented layout (see Figure 3). Spot green land , as the most one in old districts, should serve as the source controlling facilities to absorb rainwater, which can be used as the support space for sunken green land , simple bioretention ponds and rainwater wetland and others. Belt green land can be used as transport space on halfway and transport rainwater connecting with spot green land, which can be used as the support space for transporting grass ditches, dry/wet grass ditches and plant buffer zone and others. Parcel and wedge-shaped green land, as the less large green land space in old districts, function as ending treatment and rainwater management and control, which can be used as the support space for infiltration ponds, wet ponds and large rainwater wetlands with concentrated disposal.

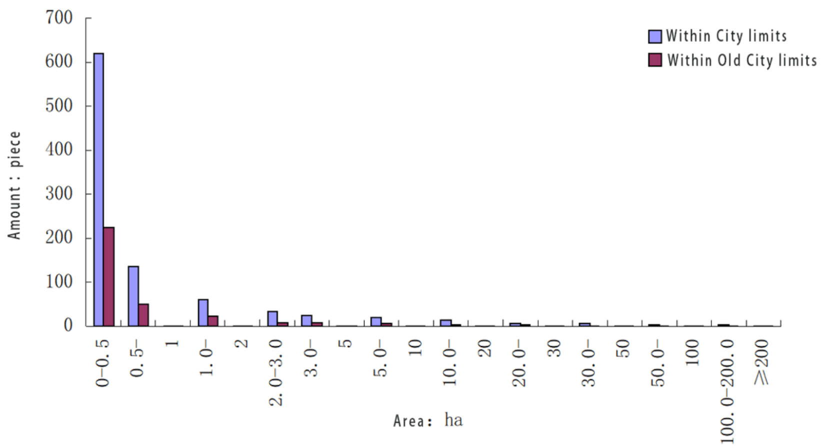

Figure 3: Area statistics of each type of green land
Figure sources: drawn by author

3.3 Quantitative design and hierarchy management and control of space

In old districts, the runoff pollution and controlled total runoff is relatively higher than that in new districts. The construction of Sponge City in old districts sets the total runoff and runoff pollution as the controlled objectives. The design of facilities within should be quantitative according to the volumetric method.

The construction number of sponge facilities is quantitative based on the above results. Meanwhile, limited under Sponge City in old districts, it's particular important to quantitatively and hierarchically plan and design the space. Different rainfalls are designed to generate varied rainwater absorbing and reservoir space with hierarchical management and control. The spaces are divided into rainfall density every 0.5 year, 3 years and 5 years. Difference space is launched under different rainfall intensities (see Figure 4). without the threat of rainfall, the sponge space functions as landscape and urban use.

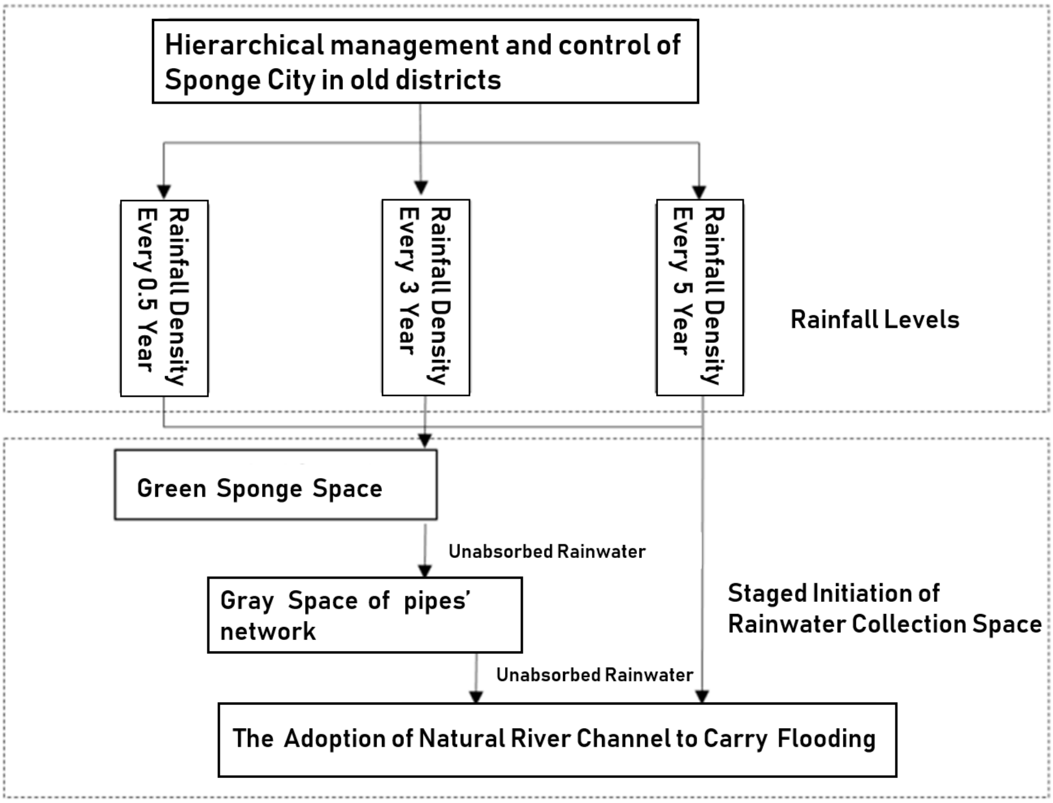

Figure 4 : Illustration of hierarchical management and control of Sponge City
Figure sources: drawn by author.

3.4 City features' coordination based on status quo

Old districts have witnessed city development and mitigation and its features should be planned and designed as coordinated elements whenever in any plannings and designs. The construction of old districts should not affect city landscape features, especially the construction of Sponge City in historic conservation areas should also be based on the features of historic blocks. The construction of Sponge City in old districts should be resilient according to the status quo. The sponge measures are selected with minimized influence as well as technology facilities. The appropriate local reconstruction of Sponge City facilities is possible combined with the features of old districts.

The features conservation coordinated areas are divided hierarchically. The purple line range for historic blocks and historic buildings serves as the 1st level feature conservation area, where the construction of Sponge City should strictly adheres to the conservation of historic features. The single sponge facility is strictly constrained with large influence on city features with coordination and conservation of the landscape elements within the range of purple line; the historic block or one block scale surrounding the single building serves as the 2nd level feature conservation area, where the sponge facilities with less influence are selected. If the selected facilities has large influence on features for rainwater construction, the appropriate resilient landscaping reconstruction could be conducted with the guarantee of implementation function of single facility; the view range of historic blocks serves as the 3rd level feature conservation area, where the requirement for the selection of sponge facilities is low and the historic landscape feature can be coordinated with certain ornamental value.

4. Practice of Sponge City in Garden Street Historic Blocks in Harbin

4.1 Status quo

Garden Street Historic Block was initiated in 1899 in Harbin new city planning. new city plan considered railway administration as the main body during the construction period of Chinese Eastern Railway by Tsarist Russia. The most advanced Howard Garden City was introduced at that time. Garden Street Historic Block , as the residential community for Russian senior railway staffs, represents high-level Russian style of architectural blocks in early times and also the only existing area in Harbin which maintains the basic appearance during the period of business with foreign countries. The spatial layout of Garden Street Historic Street was was originally organized in groups. Single residence was set up in surrounding style with wide internal public space within the blocks, integrating with the greenery including elms in the blocks. Buildings' layout was relatively loose and every residence had its own independent courtyard with high greenery rate and completed landscape, becoming the representative of garden residential blocks at that time. However, since 1950s, due to the lack of management and maintenance , unified planning of large-scale construction, free construction, house and warehouses expansion inside the block, the blocks' texture has been badly damaged and the green area is constantly encroached with the increasingly serious of underlying surface (see Figure 5). This also has led to the emergence of stormwater in Garden Street as well as the severe water logging issues. The construction of Sponge City is imperative.

Figure 5: Texture changes of Garden Street Historic Block
Figure sources: drawn by author.

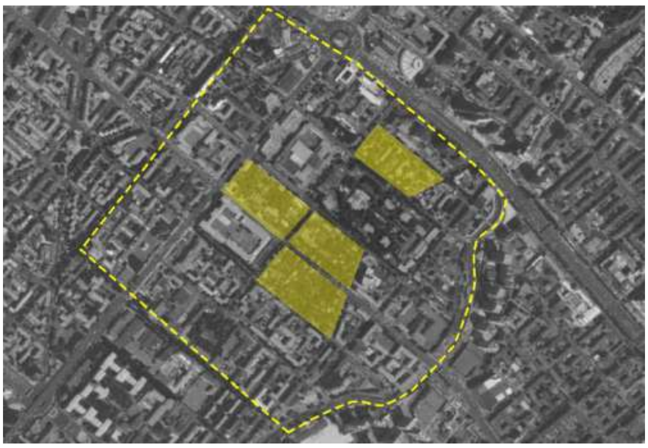

Figure 6 : The selected research range and the range of Garden Street Historic Block
Figure sources: drawn by author.

According to the zoning of water collection area, the practice of Sponge City usually set the area of 1-2 km^2 as a zoning of water collection area. In this practice, to better control the features of historic blocks and sponge construction, Garden Street Historic Block is set as the center to expand one block outward. As shown in Figure 6, the yellow area is the historic conservation blocks. The selected research range is yellow dotted area with the area of 1.13 km^2.

4.2 Construction principles

4.2.1 Conservation principles of elms

A large number of elms were planted in four blocks in the early stage of the construction. According to the survey, there are 258 elms, including 13 with a breast diameter of l00cm, over 100 with a breast diameter of 66cm and 188 with the breast diameter over 50cm. The conservation of elms with hundred years of history should be prioritized over the construction of Sponge City. The conservation hierarchy is determined to further divide the conservation range and clarify the prohibited area of construction for facilities of Sponge City. The elms with the breast diameter over 100 cm are designated as the 1st level of conservation, which should be strictly avoided by the construction of Sponge City. Within the vertical projection of the canopy and its 5.0 m outward, the construction sponge should not damage the topsoil and change the surface elevation; the elms with the breast diameter of 66 cm are designated as the 2nd level of conservation. Within the the vertical projection of the canopy and its 2.0 m outward, the sponge facilities are strictly forbidden which could soak the elms' root such as bioretention ponds and rainwater garden. The elms with the breast diameter over 50 cm are designated as the 3rd level of conservation. Within the vertical projection of the canopy and its 1.0 m outward, the construction demands are relatively flexible and the construction of the sponge facility requires the anti-soak design of the root.

4.2.2 Principles of features' coordination

The coordination between the construction of Sponge City and historic features is the first principle to abide by the construction of historic blocks in old districts. The historic features are well conserved in Garden Street Block. The sponge facilities with the minimized influence will be selected in sight of the coordination and conservation. The source control facilities should be coupled with the traditional green land in Garden Street. The spot green land is depended on to take the scattered layout with damage to its spot historic distribution pattern. Meanwhile, the sponge facilities are reconstructed according to the status quo to adapt the scale and layout of LID space to that of historic blocks. Additionally, the material, texture and color of rainwater collection facilities also should be coordinated with the surrounding historic buildings. The plants should obey the context and landscape styles of the edge of traditional architectural style to continue the historic atmosphere. The concealed principle is adopted to reduce the influence on historic features and optimize the reservoir and purification of rainwater.

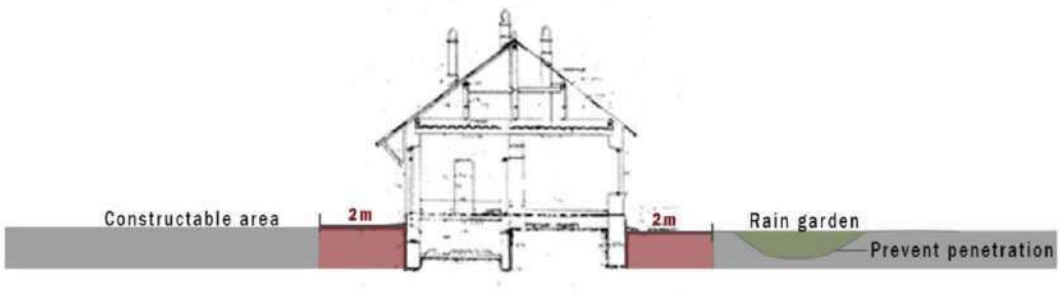

Figure 7 : Illustration of avoiding Historic architectural foundation in Garden Street Historic Block
Figure sources: drawn by author.

4.2.3 Principles of avoiding buildings' foundation

The quality of each building should be surveyed as well as the foundation situation for the construction of Sponge City in Garden Street Historic Block. The foundation, structure and roof condition are determined. And then during the construction of Sponge City, the architectural foundation should be avoided by 2 m , according to the conservation regulations of historic buildings. The sponge facilities, involving the rainwater penetration, such as rainwater garden and sunken green land, require the water-proof on part of their foundations nearby the architectural foundation(see Figure 7).

4.2.4 Resilient design principles

A lot of factors need to be coordinated for the design of Sponge City in Garden Street Historic Blocks, which has more difficulties comparing with the construction of new city. Being at the preliminary stage of development, the construction of some sponge facilities still simply draws the lessons from the United States for implementation. And many facilities and methods still lack local absorption and utilization, causing the difficult implementation of Sponge City in old districts, especially the historic blocks with more difficulties, such as Garden Street Historic Block (Xue, et al., 2012). The design of Sponge City here must uphold the resilient principle and make resilient exploration into sponge facilities and construction methods according to the status quo with the aim to successfully solve the contradictions between increasingly serious stormwater issues and blocks' features.

Single facility	**Influence on features**	**Landscape value**	**disposal**	**involved landscape elements**
permeable pavement	weak	weak	scattered	Pavement
green roof	Strong	Strong	scattered	Plants, vegetation and garden structures
sunken green land	Strong	Strong	scattered	topography, plants
bioretention pond	weak	Medium	scattered	topography, plants
infiltration pond	weak	Medium	Relatively concentrated	topography, plants and water
infiltration well	weak	weak	Relatively concentrated	—
wet pond	Medium	Medium	Relatively concentrated	topography, plants and water
rainwater wetland	Medium	Strong	scattered/Relatively concentrated	topography, plants, water and structures
Reservoir tank	Medium	Medium	Relatively concentrated	—
Adjusting tank	Medium	weak	Relatively concentrated	topography, plants and garden structures
grass ditch	weak	Medium	scattered	plants
filtration pipes/ditches	Medium	weak	scattered	—
vegetation buffer zone	weak	Medium	scattered	topography, plants
rainwater flow facilities	weak	—	Relatively concentrated	—

Table 2: Comparison and selection of sponge facilities in historic blocks

Table sources: drawn by author.

4.3 Facilities' comparison, selection and quantification

4.3.1 Facilities' comparison and selection

Sponge facilities usually function as the supply of underground water, reservoir and utilization,

peaking runoff reduction and rainwater purification with multiple-objectives of total runoff amount, runoff peak and pollution. When selecting the sponge facilities in historic blocks, the economics and applicability of water collection area and facilities' function should be combined along with their influence on features, landscape and space disposal, generating flexible selection ways of sponge facilities and their combination system.
Within the 1st feature conservation areas, the combination of sponge facilities is implemented, which include permeable pavement, bioretention pond, infiltration pond, grass ditch, vegetation buffer zone and rainwater flow facilities. Within the 2nd feature conservation area, the added facilities cover filtration well, wet pond, adjusting tank, filtration ditch and rainwater wetland. Within the 3rd feature conservation area, green roof is added surrounding the well-qualified buildings and the sunken green land is also available.
4.3.2 Quantitative facilities
The quantitative facilities adopt the volume method. ArcGIS is used to supervise the classification of underlying surface, which is divided into green land, roof and road. The proportion for each type is concluded (see Table 3).

Types of underlying surface	Runoff coefficient	Mean value of runoff coefficient	Proportion
Buildings' roof	0.85~0.95	0.90	0.565
Roads' pavement	0.55~0.65	0.60	0.168
Green land	0.10~0.20	0.15	0.267

Table3: Comparison and selection of sponge facilities in historic blocks
Table sources: drawn by author.

The specific calculations can be referred to that in Technical Guidelines for the Construction of Sponge City issued by the Ministry of Housing and Urban-Rural Development. Calculated as follows. The calculation formula is shown as follows.
$V=10H\varphi F$
Where: V - design pondage volume, m^3;
H - design rainfall, mm;
Φ——runoff coefficient of integrated rainfall , calculated according to the weighted average of the runoff coefficient of the underlying surface of the study area;
F——the collection area, hm^2;
The pondage volume, V, is concluded at 19,639.65m^3 according to the rainfall density every 0.5 years in Garden Street Historic Blocks; it's 28,990.12 m^3 according to the rainfall density every 3 years and 31,652.25m^3 every 5 years. Then the implementation space is hierarchically designed based on the above results.

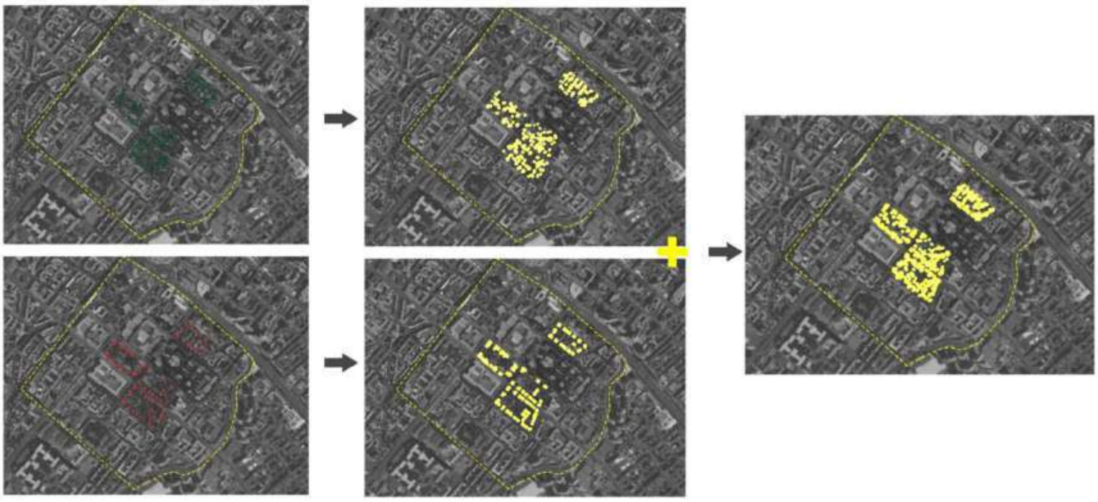

Figure 8 : illustration of non-construction area in Garden Street Historic Blocks
Figure sources: drawn by author.

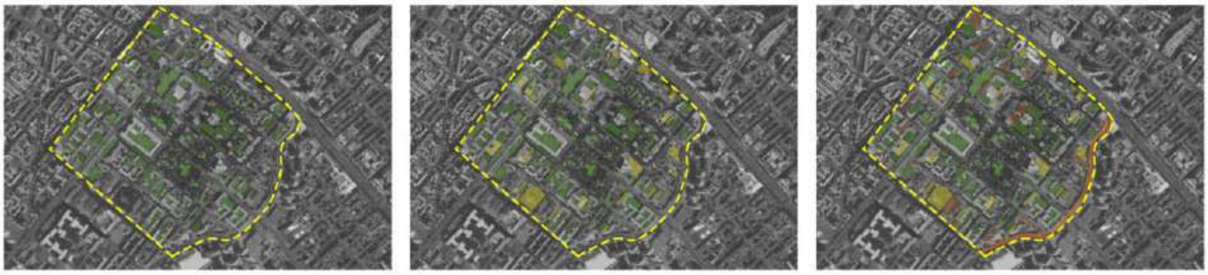
4.4 Design strategies of implementation space

4.4.1 Determine the construction range

According to the construction principles of Sponge City and the field research, the location of historic buildings and conserved elms are determined with the conservation range of buildings and elms within historic blocks. The Sponge City is strictly forbidden within 2 m away from the historical buildings' foundation. Elms are avoided according to their conservation levels. The avoiding space of historic buildings and the non-construction space of elms are overlapped and matched to determine the ultimate construction management and controlled range of historic blocks. As shown in Figure 8, the yellow area is the non-construction range , which should be strictly avoided in the construction of Sponge City in historic blocks.

4.4.2 Resilient hierarchical management and control

Volume method is used to quantitative the construction of sponge facilities with the resilient layout in space. In sight of different rainfall density every 0.5 years, 3 years and 5 years, the three-dimensional sponge facilities are set up in scattered manner in the construction-available range (see Figure 9). The hierarchical management and control of sponge space depends on the rainfall density. For 0.5 year, the green sponge space with the pondage volume of 19,639.65m^3 is turned on to collect and reserve the rainwater; for 3 years, the yellow sponge facilities' space is additionally used besides the green space with the sponge facilities' pondage volume of 28,990.12m^3 collect and transfer the rainwater. Meanwhile, the grey rainwater pipes' network is used to rapidly discharge the rainwater which can't be collected timely to prevent city water logging. For 5 years, the orange sponge space is added with the sponge facilities' pondage volume of 31,652.25m^3 collect the rainwater, mitigating the speed of flowing into low-lying areas. The gray rainwater pipes' network dominates with its rapid drainage. The flooding space of river channel is used to discharge the rainwater which can't be absorbed by the design plot along with the gray pipes' network space.



a Space for rainfall every 0.5 years b Space for rainfall every 3 years c Space for rainfall every 5 years

Figure 9 : illustration of hierarchical management and control for historic space of Garden Street

Figure sources: drawn by author.

5. Conclusion

Oriented in problems, this paper has deeply analyzed the implementation difficulties of Sponge City in old districts and put forward the targeted and resilient optimized strategies for the construction of Sponge City with the quantitative design of the implementation of Sponge City; Garden Street Historic Block in Harbin is taken to explore the old districts with insufficient implementation space and more serious stormwater issues with the possible three-dimensional space design in each small space. To coordinate with the historic features in old districts, the hierarchical management and control ways are put forward in sight of different rainfall densities; ultimately this paper aims to offer the reliable foundation for the future research and construction of Sponge City in old districts.

Study on Vegetation in Haidian District of Beijing Based on Heat Island Effect

Zhong Yujia, Beijing Forestry University, Beijing 100083, China

Abstract: With the development of the city, the city's underlying surface has been heavily eroded by gray infrastructure such as buildings and roads. The degree of vegetation coverage has dropped, the heat island problem has intensified which weakened the quality of urban residents' life.

The study chose Haidian District of Beijing as the research object, using four different periods Landsat remote sensing images from 2000 to 2018 as the basic data, extracting vegetation information and inverting surface temperature, and summing up the spatial-temporal evolution of surface temperature and vegetation coverage in Haidian District. Mesh analysis method was used to study the correlation between land surface temperature and vegetation coverage. On this basis, 20 plots were selected to analyze the cooling effect, in order to study the relationship between greenspace elements, including morphology, area and so on.

Finally, by studying the data combined with the law of cooling effect of green space, we found that the cooling effect of green space can be improved by controlling the green area, perimeter, shape coefficient and community structure. Based on this, we will guide Haidian District to design, renovate and expand urban green space and build a highly efficient ecological green network.

Key words: Surface temperature ; Vegetation coverage ; Spatio-temporal evolution ; Correlation

With the development of the city, the underlying surface of the city has changed. The gray infrastructure such as buildings and roads have eroded the green space in the city, the vegetation coverage has decreased, the ecological landscape function has been lost, and the heat island problem has gradually increased. The hot and dull temperature has caused the urban residents' outdoor living quality to decline.

The urban heat island effect is a very important topic in the study of urban landscapes. In the traditional study of the heat island effect, the method of meteorological site measurement is often used to reflect the ground temperature of a specific area, but this method has great randomness and incompleteness. After the 1970s, the acquisition of satellite data made it possible to use remote sensing methods to study the spatial pattern of surface temperature and heat islands.Since then, with the advancement of remote sensing technology, high-resolution satellite heat data has been widely used to detect mesoscale or large-scale surface temperature, which can effectively depict the spatial pattern of urban thermal environment. The sources of these satellite heat data are mainly AVHRR, MODIS, Landsat TM / ETM + and ASTER images. With the change of surface land use status by human activities, the surface heat island effect also has spatial continuity changes. This change can be observed based on the time series of satellite thermal data to understand the temporal and spatial processes of land use and heat island effects and the correlation between the two. The use of time-series remote sensing images is more likely to produce more detailed and persuasive results than studies based on remote sensing images for a specific period of time.The focus of this paper is based on Landsat remote sensing imagery, summarizing the temporal and spatial evolution of surface temperature and vegetation coverage in Haidian District. On this basis, 20 plots were selected to analyze the cooling effect, and the relationship between the green form and area and the range and amplitude of green space cooling was studied.

1. Research area

The research area of this paper is Haidian District, Beijing. Haidian District is located in the southwest of Beijing, covering an area of 430.8 square kilometers. The boundary line is about 146.2 kilometers long, about 30 kilometers long from north to south, and 29 kilometers wide from east to west, accounting for 2.6% of the total area of Beijing. The regional geographic coordinates are between 39° 53′ -40° 09′ north latitude and 116° 03′ - 116° 23′ east longitude. The resident population is 3.593 million.

Haidian District is located in the northern edge of the North China Plain and is part of the ancient Yongding River alluvial. It has a mountain plain, the terrain is high in the west and low in the east, and the west is a mountain above 100 meters above sea level. The area is about 66 square kilometers, accounting for about 15% of the total area. The eastern and southern parts are about 50 meters above sea level, with an area of about 360 square meters. Kilometers, accounting for about 85% of the total area.

Haidian District is located in a warm temperate semi-humid semi-arid continental monsoon climate zone with four distinct seasons. It is hot and rainy in summer and cold and dry in winter. The annual average temperature is 12.5 ℃, the average temperature in January is -4.4 ℃, the extreme minimum temperature is -21.7 ℃, the aver age temperature in July is 25.8 ℃, and the highest temperature is 41.6 ℃. The specific scope of the study area is as follows (Figure 1).

Figure 1: Research area

2. Heat Island Effect and Spatial and Temporal Evolution of Urban Green Space

2.1 Research methods and data sources

The basic data selected in this paper is derived from four remote sensing images of the Landsat ETM satellite. The imaging time is July 28, 2003, September 11, 2008, September 25, 2013, September 28, 2017. The numbers are all 123, the line number is 32, and the spatial resolution of the satellite imagery is 30m*30m. After acquiring the satellite image, the thermal infrared remote sensing image data is subjected to atmospheric correction and thermal radiation calibration by ENVI5.1 software, and then the remote sensing image with each band data is used to calculate the surface temperature and vegetation coverage. The corresponding data was processed by ArcGIS 10.2 software, and the correlation between surface temperature and vegetation coverage was compared and calculated.

2.2 Calculation method

2.2.1 Vegetation coverage calculation

In order to calculate vegetation coverage, the normalized vegetation index needs to be calculated first. The expression is:

$$NDVI=(NIR-R)/(NIR+R) \quad (1)$$

For landsat7 satellite remote sensing images, NIR is the luminance value of the TM4 band (near-infrared band, identifying water-related geological structures), and R is the brightness value of the TM3 band (red band, distinguishing plant species and coverage).

Based on the results of the normalized vegetation index calculation, the vegetation coverage is calculated, and the expression is:

$$F_V = (NDVI - NDVI_S) / (NDVI_V - NDVI_S) \quad (2)$$

In the formula, $NDVIv=0.7$ and $NDVIs=0$; when the NDVI of a pixel is greater than 0.7, its FV is 1; when NDVI is less than 0, its FV is 0.

2.2.2 Surface temperature calculation

In order to calculate the surface temperature, it is first necessary to calculate the surface specific emissivity. Among them, the specific emissivity of the water body is 0.995, and the specific emissivity of vegetation and buildings is calculated by the expression:

$$\varepsilon_{green}=0.9625 + 0.0614\, F_V - 0.0461\, F_V^2 \quad (3)$$

$$\varepsilon_{building}=0.9589 + 0.086\, F_V - 0.0671\, F_V^2 \quad (4)$$

In the above formula, εgreen represents the specific emissivity of the vegetation, and εbuilding represents the specific emissivity of the building, and the surface specific emissivity is obtained by inversion calculation.

Based on the results of the surface emissivity, the radiance of the black body in the thermal infrared band is calculated. The expression is:

$$B(T_S) = [L\lambda - L\uparrow - \tau\cdot(1-\varepsilon)L\downarrow]/\tau\cdot\varepsilon \quad (5)$$

Where ε is the surface specific emissivity, B(TS) is the thermal radiance of the black body derived from Planck's law, and τ is the transmittance of the atmosphere in the thermal infrared band.

After obtaining the radiance of the black body in the thermal infrared band at a temperature of TS, the true surface temperature is obtained according to the inverse function of the Planck formula. The expression is:

$$T_S = K2/\ln(K1/ B(T_S)+ 1) \quad (6)$$

For Landset7 remote sensing images, take K1 = 666.09 and K2 = 1282.71K. The calculated TS is the true surface temperature value in degrees Celsius.

2.3 Results and analysis

2.3.1 Surface temperature evolution characteristics

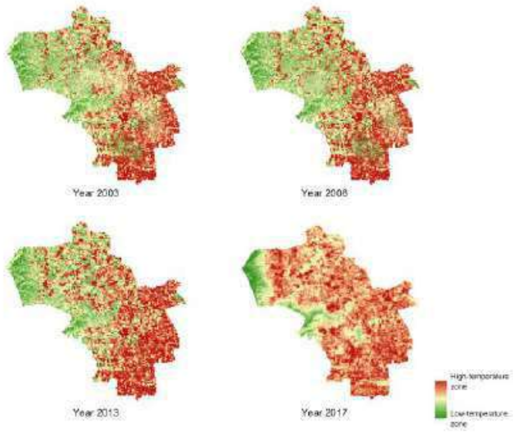

Figure 2.3.1 Temporal and spatial evolution of surface temperature in the study area from 2003 to 2017

2.3.2 Vegetation coverage evolution characteristics

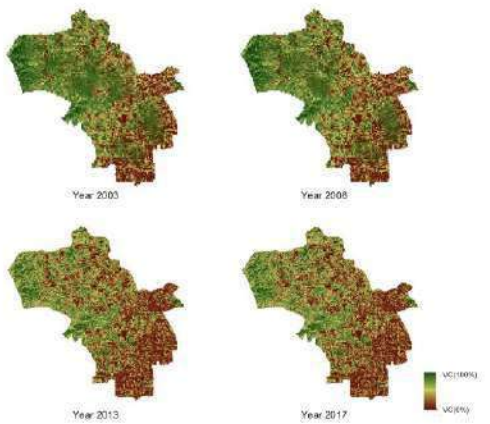

Figure 2.3.2 Time-space evolution map of vegetation coverage in the study area from 2003 to 2017

2.3.3 Study on Correlation between Surface Temperature and Vegetation Coverage

In this paper, the research area is analyzed in detail by grid analysis method, and the surface temperature and vegetation coverage information are extracted comprehensively to calculate the correlation between the two. The spatial resolution of Landsat satellite imagery is 30m*30m. ArcGIS 10.2 software is used to average the grids in each grid to express the surface temperature and vegetation coverage information in the grid. The correlation between surface temperature and vegetation coverage was studied with a single grid as the statistical unit, and the regression analysis results between the surface temperature and vegetation coverage in the four periods from 2003 to 2017 were obtained.

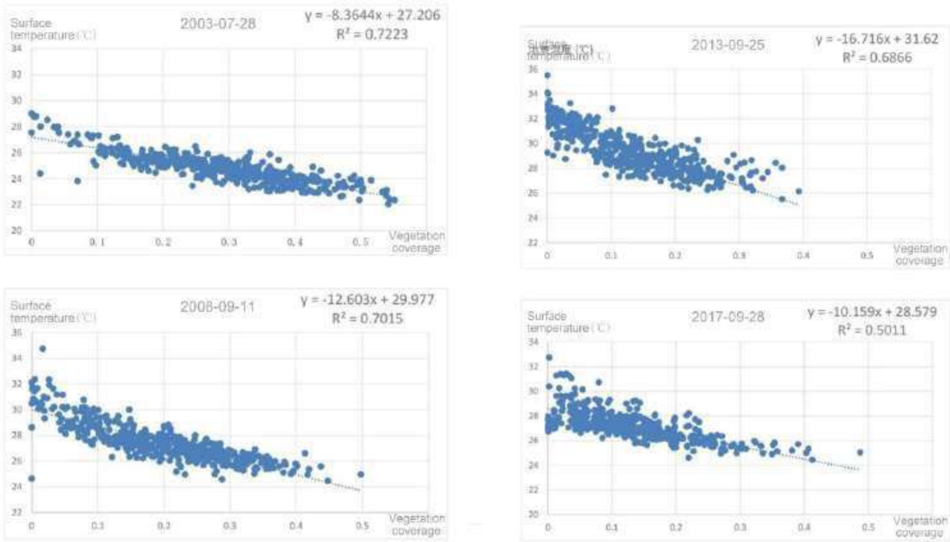

Figure 2.3.3 Analysis of regression relationship between vegetation coverage and surface temperature in the study area from 2003 to 2017

From the regression analysis results, there is a significant negative correlation between surface temperature and vegetation coverage. In 2003, 2008, 2013, the coefficient of determination (R2) of the regression equation for 2017 was 0.72, 0.70, 0.69, and 0.50, respectively, indicating a strong correlation between the two. From the slope of the regression equation, the slopes of the regression equations of 2003, 2008, 2013, and 2017 are divided into -8.3644, - 12.603, -16.716, -10.159, and the absolute range is 8.3644 to 16.716. This indicates that for every 0.1 increase in vegetation coverage index in Haidian District of Beijing, the surface temperature can be reduced by 0.84 ℃ to 1.67 ℃.

3. Study on Green Form and Cooling Effect

Summer green space cooling is the result of a combination of direct and indirect effects. In addition to the direct cooling effect of the green space, the green area reaching a certain area is a natural ventilation corridor in the city. And due to the direct cooling effect of the green space, local temperature difference will be generated to form natural ventilation. The ventilation of urban green space is much larger than that of construction land. Natural wind will take away most of the heat and play an indirect cooling effect on the green space. The cooling range will be affected by the green area's own area and greening configuration.

3.1 Research method data source

In the study area, 20 plots were selected and distributed as evenly as possible. The green space covers various green land types such as park green space and affiliated green land, and the green land has various shapes. Based on the remote sensing image of 2017, Acr GIS10.2 software was used to set buffers for selected urban green space samples, and the average temperature in each green space and its buffer zones was extracted. The difference was used to study.

The difference in surface temperature will increase to some extent as the distance from the green space boundary increases. When a certain distance is reached, the surface temperature difference tends to be gentle or gradually decreasing as the distance from the green space boundary increases. That is to say, within a certain range, the surface temperature increases with the distance from the green space. After reaching a certain distance, the surface temperature tends to be gentle or decreasing with increasing distance from the green space. The surface temperature difference curve is plotted with the distance variation law. The summer urban green space cooling curve is shown in Figure 3.2.2.

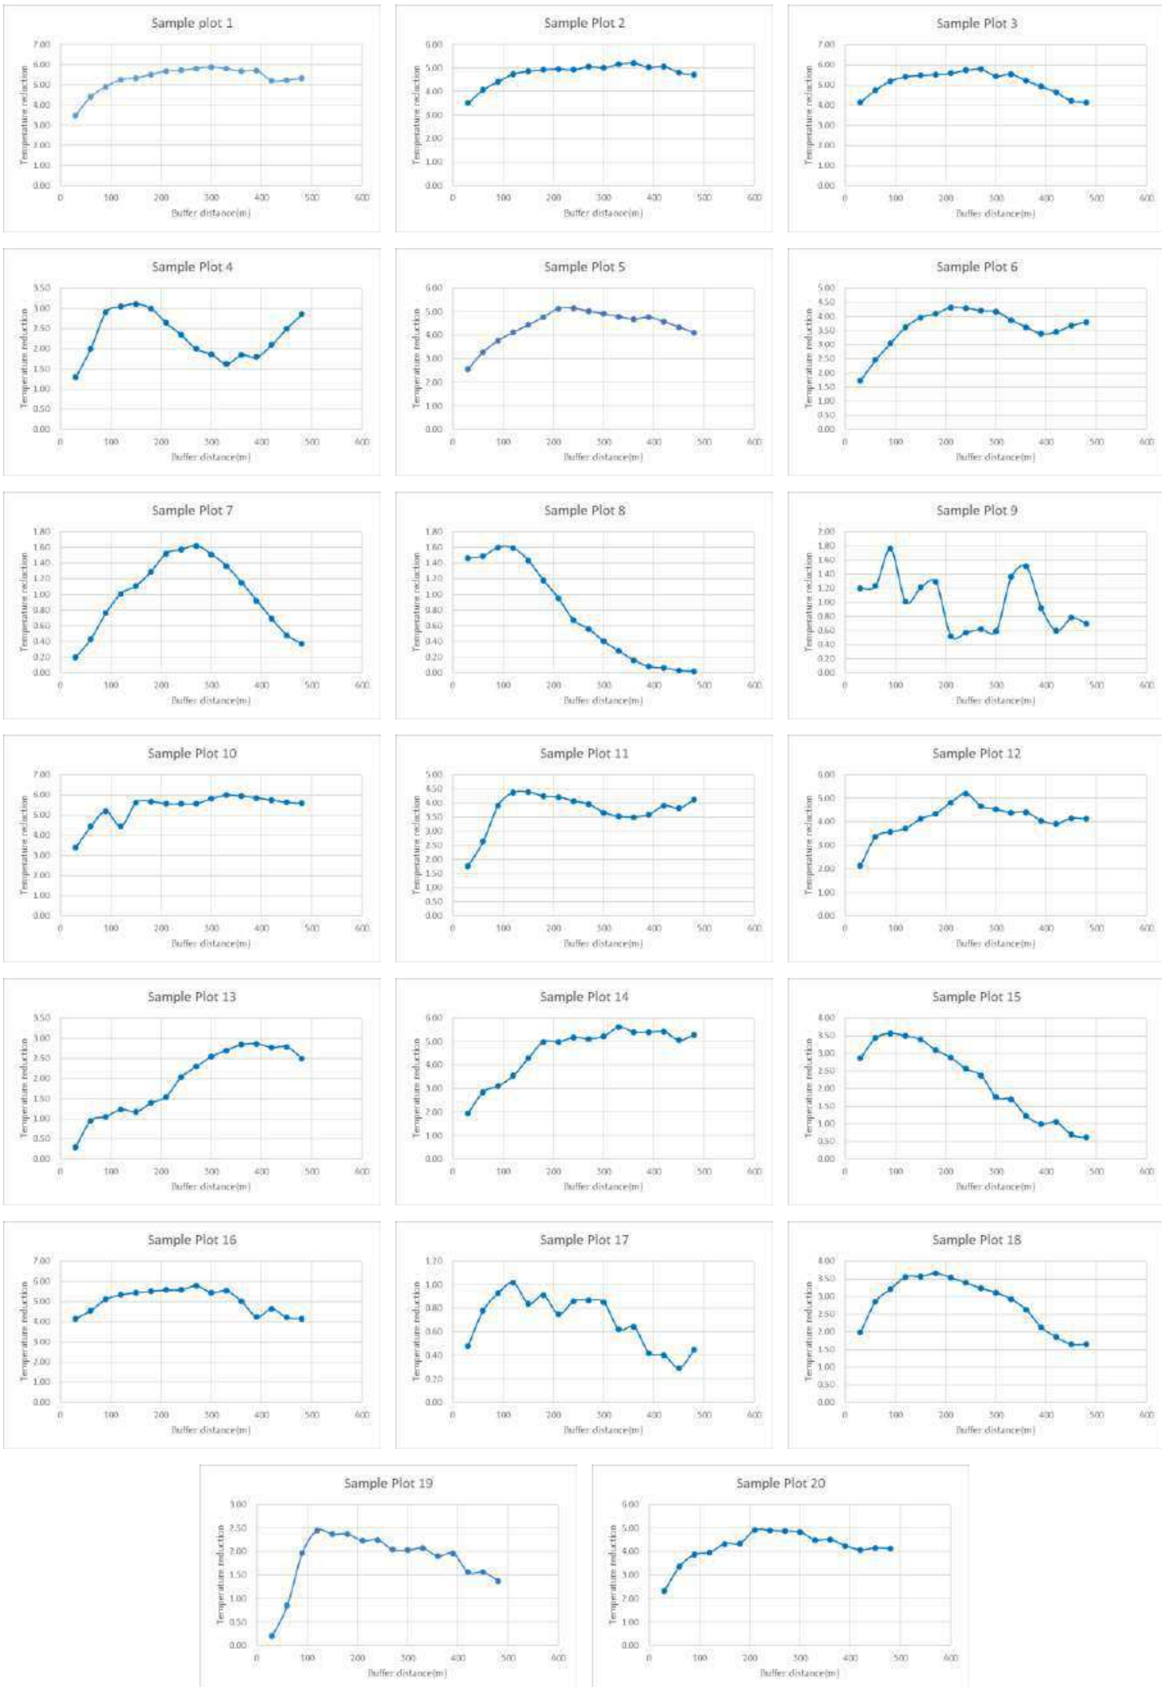

Figure 3.2.2 Urban Greenland Cooling Curve

The green ground cooling curve more intuitively reflects the change trend of the surface temperature change in each green space buffer. Basically, the cooling curve of green space in each city shows a trend of decreasing after rising first.

In order to facilitate the study of green form parameters and cooling effects, three indicators were extracted according to the urban green space cooling curve to carry out quantitative calculation: cooling range, cooling range and maximum temperature difference statistics table, as shown in Figure 3.2.3.

Explain the three indicators. Cooling range: The buffer boundary distance indicated by the inflection point of the urban green space cooling curve can be regarded as the cooling range of summer urban green space. Cooling range: the difference between the average surface temperature inside the green space and the average surface temperature in the buffer zone within 30m outside the boundary. The maximum temperature difference between the inside and outside of the green space: that is, the maximum temperature change inside and outside the green space is the maximum temperature difference obtained by subtracting the lowest surface temperature value inside the green space from the highest surface temperature in the 30m buffer zone outside the green space.

Figure 3.2.3 Statistical Table of Cooling Range, Cooling Range and Maximum Temperature Difference of Urban Green Space

Number of green space	Name of green space	Green area (ha)	Green space perimeter (m)	Green space shape coefficient	Buffer distance (m)	Temperature drop range (℃)	Maximum cooling difference (℃)

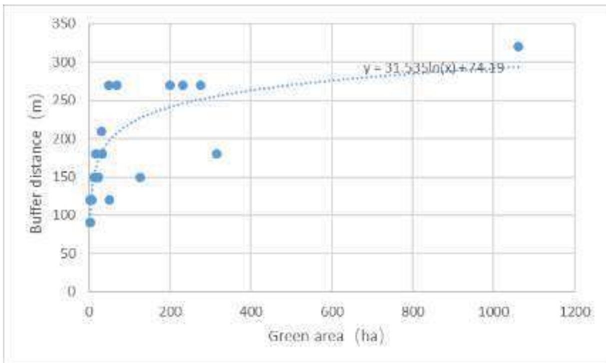
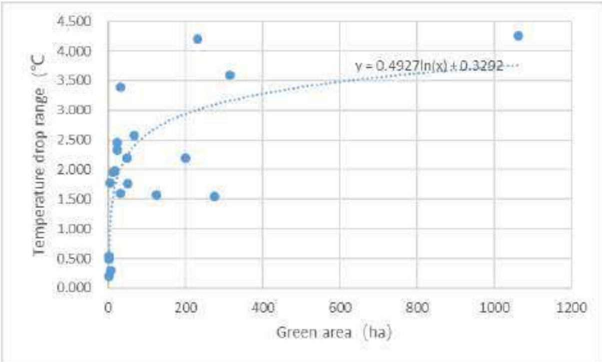
3.3 Results and analysis

3.3.1 Correlation analysis of green area on cooling effect

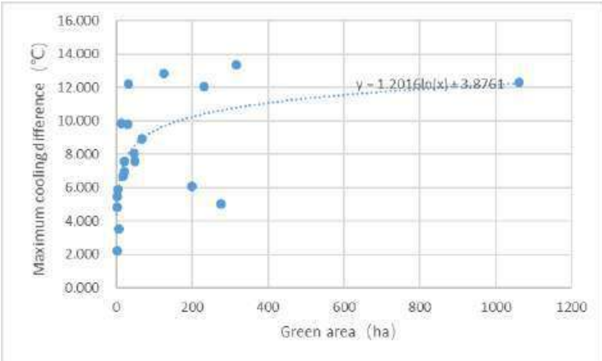
Based on the statistics of the urban green space area and the cooling range of the green space and the cooling range of the green space, the regression analysis is carried out on the green area and its cooling range, cooling range and maximum temperature difference respectively. The results are shown in Figure 3.3.1.



(1) Correlation analysis of green area and its cooling range



(2) Analysis of the correlation between green area and its cooling range



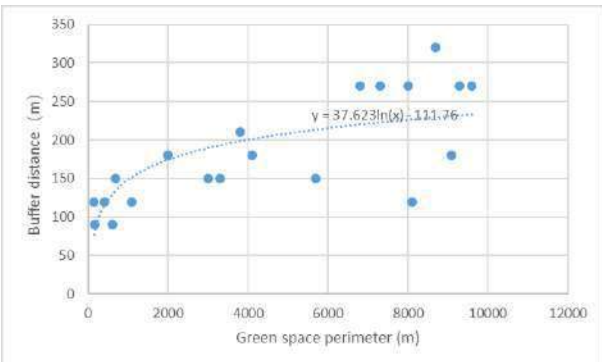
(3) Correlation analysis of the maximum difference between green area and its cooling

Figure 3.3.1 Correlation analysis of green area on cooling effect

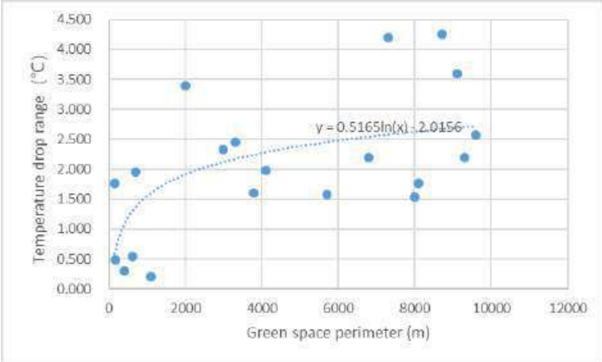
Regression analysis was performed on the above area correlation analysis and the equations were fitted. The relevant equations are y=31.535ln(x)+74.19, y=0.4927ln(x)+0.3292, y=1.2016ln(x)+3.8761. The area of green space and its cooling range, cooling range and maximum temperature change inside and outside the green space are logarithmically related. Within a certain range, these three indicators increase with the increase of the area, but the rising ratio gradually decreases with the increase of the area. According to the analysis of the research data, it can be found that when the green area is increased to about 23 hectares, it is most economical to increase the cooling effect.

3.3.2 Correlation analysis of the effect of green space perimeter on cooling effect

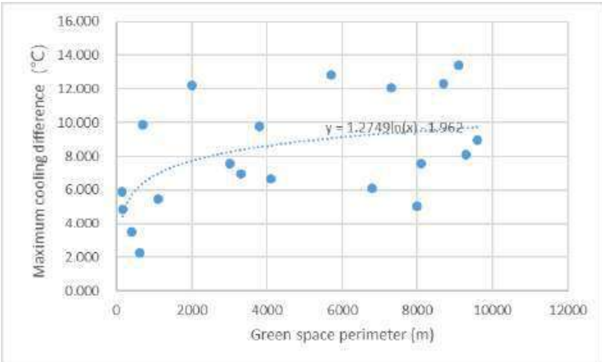
Based on the statistics of the urban green space perimeter and the green space cooling range and the green space cooling range, the regression analysis of the green space perimeter and its summer cooling range, cooling amplitude and maximum temperature difference are performed respectively. The results are shown in Figure 3.3.2. Show.



(1) Correlation analysis between the perimeter of green space and its cooling range



(2) Correlation analysis between the perimeter of green space and its cooling range



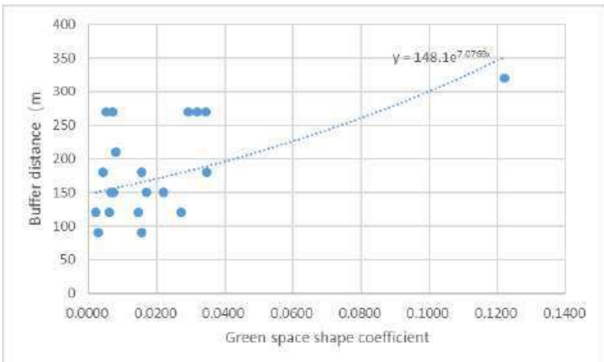
(3) Correlation analysis of the maximum difference between the perimeter of green space and its cooling

Figure 3.3.2 Correlation analysis of the effect of green space perimeter on cooling effect

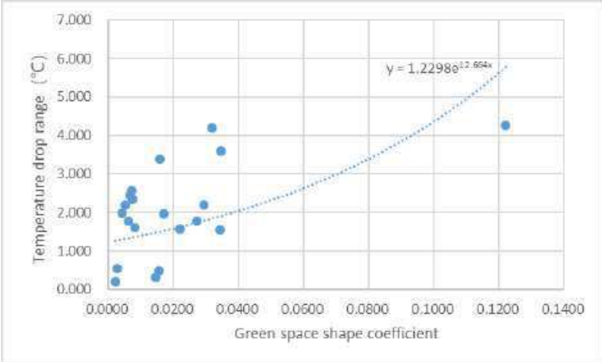
Regression analysis was performed on the above correlation analysis of the circumference and the equation was fitted. The relevant equations are y=37.623ln(x)-111.76, y=0.5165ln(x)-2.0156, y=1.2749ln(x)-1.962. The perimeter of the green space is logarithmically related to the range of cooling, the magnitude of cooling, and the maximum temperature change inside and outside the green space. Within a certain range, these three indicators increase with the increase of the area, but the rising ratio gradually decreases with the increase of the area. The analysis found that it is most economical to increase the perimeter of the greenbelt within 4800m.

3.3.3 Correlation analysis of green space shape index on cooling effect

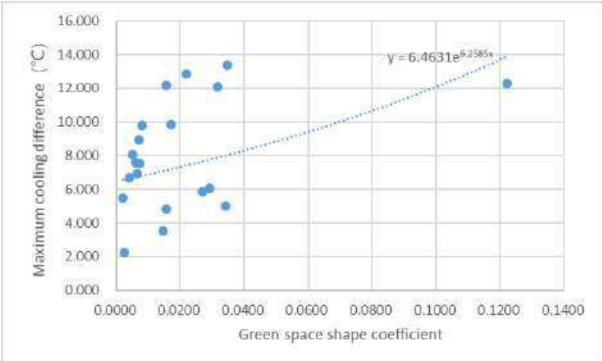
Based on the statistics of the urban green space shape index and the cooling range of green space and the cooling range of green space, the regression analysis of the green space shape index and its summer cooling range, cooling temperature and maximum temperature difference are carried out. The results are shown in Figure 3.3.3. Show.



(1) Correlation analysis of green space shape index and its cooling range



(2) Correlation analysis between green space shape index and its cooling range



(3) Correlation analysis between the shape index of green space and the maximum difference of temperature drop

Figure 3.3.3 Correlation analysis of green space shape index on cooling effect

Regression analysis was performed on the above correlation analysis of the circumference and the equation was fitted. The shape factor is the green area divided by the green perimeter. Therefore, the larger the shape factor, the more regular the green shape is. It can be seen from the curve in the figure that as the shape factor increases, the range of green space cooling, the temperature drop range and the maximum temperature difference are also gradually increasing. That is, the more regular the green field is, the better the cooling effect of the green space is.

6 Conclusion

6.1 Research conclusions

This paper uses the data contained in Landsat ETM remote sensing images from 2003 to 2017 to extract and map the temporal and spatial evolution of surface temperature and vegetation coverage in Haidian District, Beijing, and study the correlation between the two variables of surface temperature and vegetation coverage. It was found that the rapid development of the city and the substantial increase in the land used for construction in the past 15 years led to an overall decline in vegetation coverage and an overall enhancement of the heat island effect. In addition, studies have shown a significant negative correlation between surface temperature and vegetation coverage. Vegetation coverage increased by 10%, the average surface temperature can be reduced by 0.84℃ ~ 1.67 ℃, the average urban temperature is reduced by more than 1℃ in summer, and the local area can be reduced by more than 5 ℃, significantly improving the outdoor experience of urban residents.

At the same time, through the study of 20 plots selected in the study area, the green area and perimeter are significantly logarithmically related to the summer cooling range, cooling range, and the maximum temperature difference of the green space. It is most economical to increase the green space by appropriately increasing the green area within 23ha or increasing the green space perimeter within 4800m. The more regular the urban green space is, the better the cooling effect will be.

6.2 Recommendations and measures

The following suggestions are proposed for the green space planning of Haidian District:

(1) Through the optimization of industrial functions, intensive use of land, ecological restoration of wasteland and bare land, rational planning of park green space layout, and increase urban green space.

(2) To make full use of urban space to develop greening, use the techniques of roof greening and vertical greening to improve the coverage of green space. For the area where heat emission is concentrated, the city's “cold island” can be constructed through the combination of green space, water body and ventilation corridor to alleviate the heat island effect.

(3) When adding or renovating green space, combined with the actual situation to control the green area, shape and other factors, appropriately increase the urban green area or perimeter, control the green space form more regular, and improve its efficiency in reducing ground temperature.

Symbiosis with Rivers: The Management of Flood Respond to Climate Changes from the Perspective of Landscape Planning

Menghan ZHANG, Beijing Forestry University, China

Extreme weather caused by climate changes, especially heavy rains and flooding, have repeatedly plagued urban areas. Thus, we should find a solution to disasters based on the idea of resilience by establishing a place that can adapt to the temporal dynamics. In order to ingeniously handle the management of flood as well as symbiosis with rivers, detailed strategies from the perspective of landscape planning are provided through our projects or studies.

1. Background: The Changes of River System and Waterfront Environment in Guangzhou

Owing to historic reasons and special circumstance of modern China, the evolution of river management in Guangzhou is unique compared to most cities. As a well-known oriental sea port and the starting point of the “Marine Silk Road”, Guangzhou was born because of its location on Pearl River System. The tributaries of Pearl River named "Chong", which were densely distributed throughout the city, represent the most characteristic kind of rivers in Guangzhou, forming the backbone of the city's water system.[1] With a small amount of water, they were natural waterways directly connected to major rivers. In the urban area, there are 238 rivers with a total length of 913 km, which merge into Liuxi River, Baihe River and Pearl River.[2] And they employed an important influence on regulating water levels because of being affected by tides.[3]

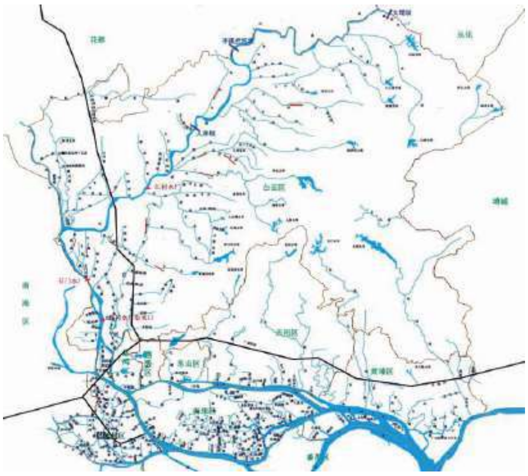

Figure 1: "Chong" and other water system (quoted from Planning of water system in Guangzhou)

1.1 The Period of Rivers' Cultural Development

Throughout the its long history, these rivers, as well as their environment, have been closely connected with people's daily lives, because they shoulder not only the city's task of flood management, irrigation and shipping transportation, but also the back lanes of residents' lives, such as taking water, washing, daily traveling and even recreational activities. Thus, instead of a merely beautiful natural landscape, the urban riverfront is a unique cultural landscape, which has shaped the urban spatial pattern of style for more than 2,000 years. For example, East Hao Chong, once a moat in the Ming and Qing Dynasties, has gradually formed a commercial center along the river at the end of the feudal society, supporting the development of business. [4]

1.2 The Period of Rivers' Traffic Decadence

However, in the 1910s, with the modern urban city-building movement, Guangzhou began to demolish the ancient city walls, constructed a great variety of municipal roads, which eventually became the main transportation system.[2] As a result, the traffic function of the rivers began to degenerate even gradually disappeared, signing an evident trend of transport declining, nevertheless, they did not lose their main function as the drainage channels. The development of the city was slow and orderly, [3] and the rivers, with high quality of purity, at that time still played an important role in the urban ecosystem and residents' lives.

1.3 The Period of 'Over-engineering' Rivers

After the 1950s, with the rapid development of the city's economy and the population growth, because of the disordered construction and management of the surrounding areas along rivers, the intensive buildings altered the original natural bank form of the river, weakening their capacity of flood discharge. Consequently, the riverfront repeatedly experienced guilt during rainy season. In order to solve the problems, Guangzhou reformed the urban drainage system from natural embankments to upright rigid embankments under the guidance of the idea of flood control at that time. There is no doubt that destruction of river system seems to be inevitable in the process of rapid urbanization. Moreover, Massive rivers were 'over-engineering', especially when Guangzhou in an all-round way started to unify the open channels into underground channels with city roads on its cover. Those open channels with slate were changed to underground channels with reinforced concrete box culverts, as we can see in Xiguan Chong and Yudai Hao. [2] What caused more serious problem is that the pollution of industrial and domestic sewage discharged into rivers was increasing, so the rivers in the central city become black and odorous as sewage pipes for the city.

1.4 The Period of 'Disappearing Rivers'

After the 1970s, especially the beginning of the Reform and Opening-up in 1979, Guangzhou entered a new period of booming development and its urban area has expanded dramatically. Thus the urban landscape has undergone major changes in the rapid increase in population, traffic jams, and the emergence of viaducts. However, the deterioration of the riverfront water environment was still intensifying. The environmental problems and traffic pressure brought about by the abnormal development of the urban construction have caused more rivers to lose their original ecological functions and landscape environment. As a result, many rivers in the city have gradually disappeared such as West Hao Chong, Yudai Hao, Lizhi Wan and many other rivers have been replaced by underground culverts. Only the effluvial East Hao Chong flows on the ground with the high-rise buildings around, with scarce slate road left over from history. The original bustling life scene disappeared and the river have almost been forgotten by the world. [3] There is no longer the scene of 'clear creek and green space' everywhere and Guangzhou lost its 'Water City' feature. What's more, the quality of rivers are becoming increasingly polluted and blocked. In 2016, the rivers that did not reach the standard of water quality accounted for 88.79% of the total. Consequently, urban water systems can hardly cope with environmental problems such as floods, intensified by the climate change.

Since the 21st century, more and more people have improved the awareness of the rivers' importance to the urban ecology and living environment.[5] However, the contradictions between gray infrastructure and green infrastructure are particularly prominent. There are two core problems of the rivers' status: the decline of the urban water system and the decline of urban space. The former, caused by being covered, has resulted in serious water pollution and weak capacity of flood management. The latter, plenty of negative activities such as illegal possession and garbage dumping, has led to the monotonous urban space without regional features and vitality. Thus it is against this background that we have started this large-scale project of comprehensive renovation of rivers.

Figure 2 "Chong": From the unique cultural landscape to the underground 'over-engineering' channel

2. Objectives: The Concept Based on the Idea of Resilience

Taking Guangzhou's intrinsic and unique features of urban river network conditions into consideration, this project seeks to find a solution based on the idea of resilience by establishing ever-changing urban renewal places that is symbiotic with rivers. The city's adaptation to disasters should reflect the temporal dynamics. The traditional engineering measures dealing with flood only with a single function of defense, or simplex ecological remediation, resulting in waste of urban space and resources.
Our plan is proposed to improve the construction and development of the cities built downstream along the river by solving the problems both under covers and on urban surface. The water flow plays a role of transporting sludge to the confluence or estuary considering time effect. A system aiming to transform sludge into humus is constructed underground, which will also provide opportunities for the renaissance of urban green space. After uncovering, various possibilities were re-introduced into the city and the waterfront areas became the basis for activating the urban space once decayed. Except for protecting cities from flooding it also has the function of revitalizing the public space and improving the eco-environment. Moreover, it is also an optimal strategy of balance between the tense land use and the protection of natural ecology.

3. Methods: Three Main Stages and Ecological Technology

Through on-site investigation and cases study, an exploration aiming to bring the covered river to light again through landscape strategies is proposed through in three main phases:

Figure 3 The Mode of Three Main Stages

3.1 Stage Ⅰ: Restoration Plan Both on the Urban Surface and Underground

In the first stage, in order to form the foundation of ecological and cultural river restoration, reconstruction is divided into two parts: the treatment plan on the urban surface and underground. On the one hand, underground excavation is conducted locally to form a stagnation space, where sludge is transported to by the process of river's automatic force. Then biogas power generation is used to convert concentrated sludge into humus. On the other hand, at the beginning of the restoration of the river, we ought to find waste space and potential areas on the ground to build some pocket parks. And electricity generated by that process of biogas could partly supply public infrastructure. The sludge transformation system is constructed underground since oxygen is exposed through openings of equipment on the ground, which will also provide opportunities for the construction of green space and the renaissance of urban public space. After uncovering, the purified sediment can be used directly for the construction of the revetment, as the foundation of the new waterfront space composition. So there is no doubt that it is an efficient way to restoring ecosystem of the rivers.

3.2 Stage Ⅱ: Uncovering and Diverse Treatment of Revetments

In the second stage when the regional sludge water system has basically been constructed, the large amount of sludge under the cover plate would gradually transform into soil containing humus, which will become the foundation of the new waterfront space composition after opening the cover plate. Obviously, the river will become visible, evoking the public environmental awareness. In particular, it is necessary to consider the status and adopt targeted methods to reconstruct revetments for different levels of urban density.
While uncovering sufficient space for the urban ecosystem, the comprehensive rectification of riverfront must first adopt diverse treatment of revetments according to the specific conditions of different rivers, making the river line richer in both morphology and function.[6] Because the revetment of river is not only a defensive line to ensure the safety of watershed, but also an important component of the waterfront landscape and spatial utilization. Modern ecological technologies are used to design different riverbeds and revetments including semi-permeable fabric-formed concrete channels, tubular mesh fabric growing containers and gabions in limited estuary water level change areas, different ways to form a high ecological potential green infrastructure that has flexible functions of flood control, as well as meets the needs of various animals and plants. For example, in the downtown area, where the space is relatively confined with over-engineering revetment, semi-permeable fabric-formed concrete channels and multi-level platforms with tubular mesh fabric growing containers are set up in order to meet the flood control requirements.[8] Only by this way could we weaken the rigid coastline to form an interesting waterfront with various needs such as hydrophilicity and recreation. In different circumstance, there is wide range for ecological restoration of the river, especially on the outer edge of city. For the treatment of such river banks, the design mostly uses natural grading treatment with natural materials such as rubble, wooden piles and gabions to stabilize slopes, and sometimes it also includes tubular mesh fabric growing containers to form a flexible ecosystem with functions of flood control.

3.3 Stage Ⅲ: Reactivating urban space with Diverse Possibilities and Technology of Water Purification

In the third stage, in the case that single landscape could be easily eroded by the construction of other lands, aggregation and transformation is necessary in the contemporary context rather than tearing apart river and city. The new functions replaced the original monotonous blocks, giving the blocks diverse possibilities, consequently the old city's space being reactivated. Meanwhile, humanistic landscape on river bank of architectural culture heritage protection and leisure space construction are involved in integration method.
There are three representative types of revival spaces. Cultural rivers, as the first type, are mostly located in the old urban area of the city with an attractive style of historic neighborhood, surrounded by a great variety of historical and cultural resources. There are massive scenic spots such as Morning Tea Market, River Museum, Outdoor Café, Street Corner Garden and so on. The second type called rejuvenated rivers, located in the developing part of urban area, have a lot of opportunities for the development of commerce and entertainment industries. The industrial transformation and activation of public space will make it the central area of future urban vitality, as we can see in City Terrace, Waterside Theatre, Water Steps and Bridge Park. Because of being located in urban fringe areas and important ecological nodes, the third type named ecological rivers have plenty of room and flexible space. Through Silt Garden, Rainwater Pond, Suburban Wetlands and Popular Science Park, in the future, they will become important regional eco-corridors or ecological parks.

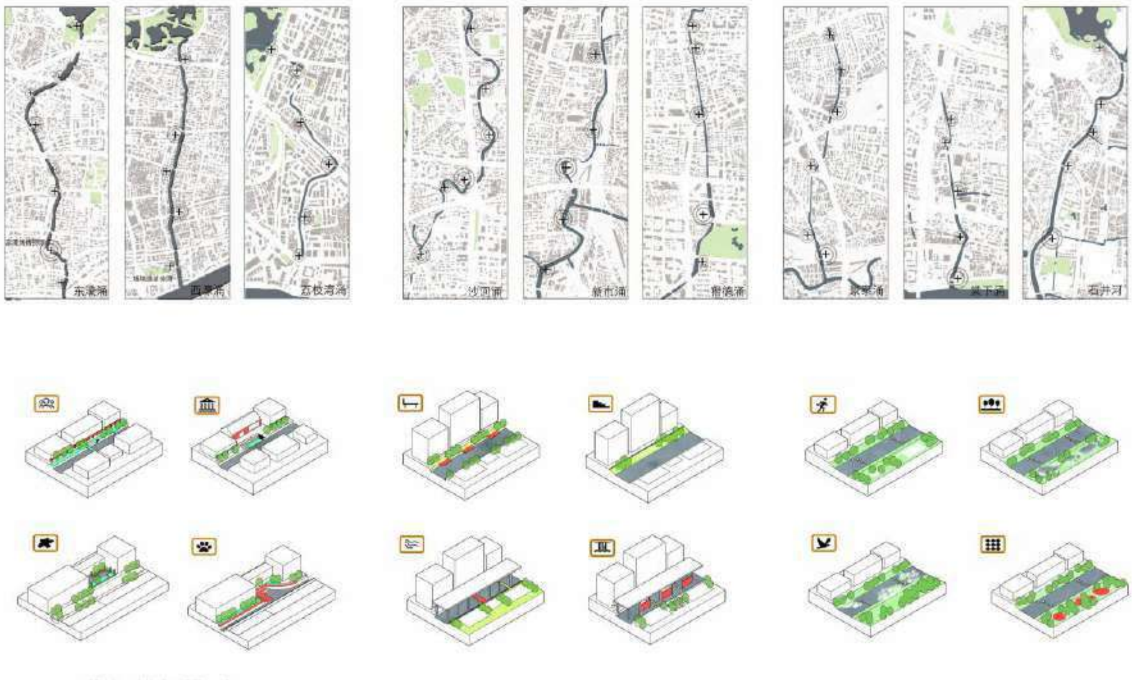

Figure 4 Three Representative Types of Revival Space

Water purification in the river is another important, long-term ecological mechanism for the comprehensive renovation. Plant purification is a common method: combining the requirements of the landscape, a combination of aquatic plants with highly effective purification is planted in the river fluvial to achieve the effect of adsorbing and degrading river water pollutants and purifying sewage. Since many rivers in the city are tidal rivers, the water level varies greatly with the tide of the Pearl River. In order to solve the impact of water level changes on wetland plants, ecological floating beds have been widely used for planting aquatic plants. The ecological floating bed is free to rise and fall as the water level changes, and it can respond well to tidal changes.[7] Moreover, aquatic plants, semi wet plants and damp-tolerant terrestrial plants preserve the natural environment and waterfront habitat as much as possible.[2] Through the purification of water quality, the rivers in the central urban area have changed from stagnant water to live water, and the river water environment has been improved.

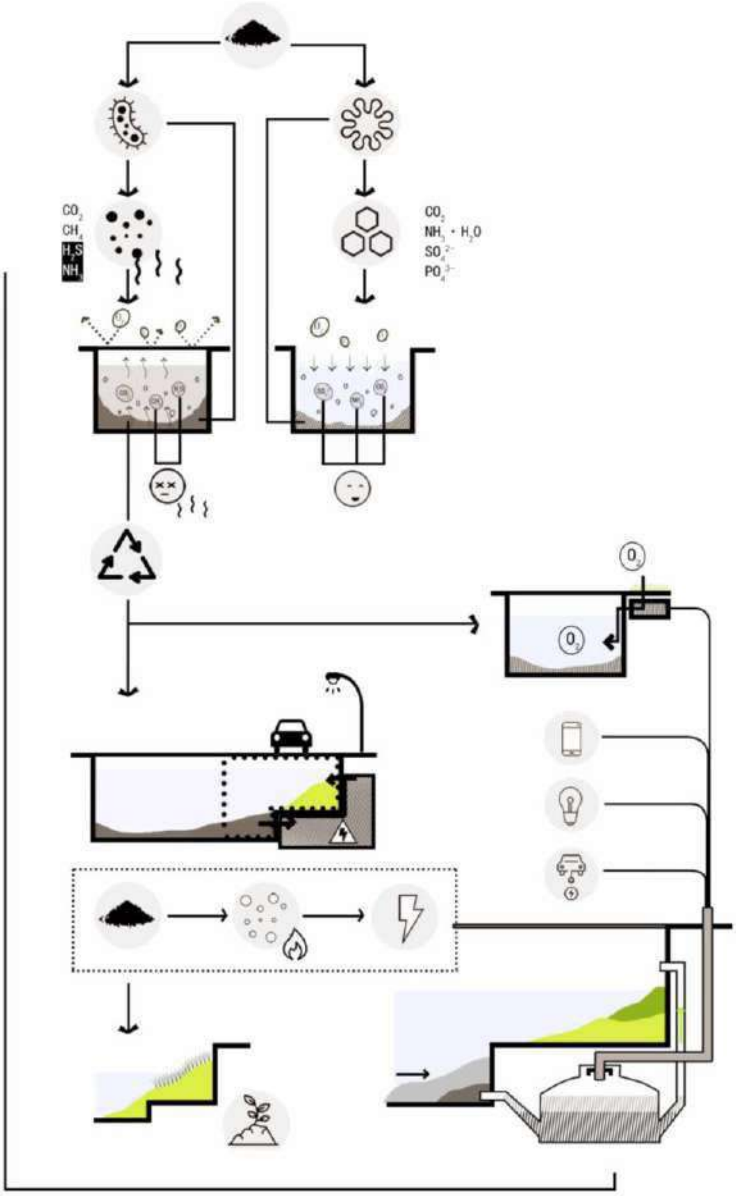

Figure 5 The Technic Mechanism of Ecological Restoration

4. Methods: Regional Renewal Strategy in a Large Scale

In a large-scale planning, the regional update strategy is also conducted through three main phases: taking Guangzhou's unique terrain and surrounding mountains into consideration, in the first phase, while starting ecological restoration of mountains, the sewer network is constructed as the foundation of all other process of ecological restoration.

Most of the rivers in central Guangzhou have lost their navigational functions, however, they are still the city's 'blue line' in the psychological of the public.[2] So in the second phase, we clearly defined the control area of rivers and the band-shaped green space reserved for the rivers. The control area of rivers could not only act as the natural site for the construction of the urban ped-bike system, but also guide the public to intimate contact with the waters, establishing dialogues and exchanges between the 'blue line' space and the greenway system.

In the third phase, various possibilities were re-introduced into the city and the waterfront areas became the basis for activating the urban space once decayed. Ultimately, the riverfront environment can serve city life in a more extensive scope. In return, river network regeneration can benefit from the urban space revival.

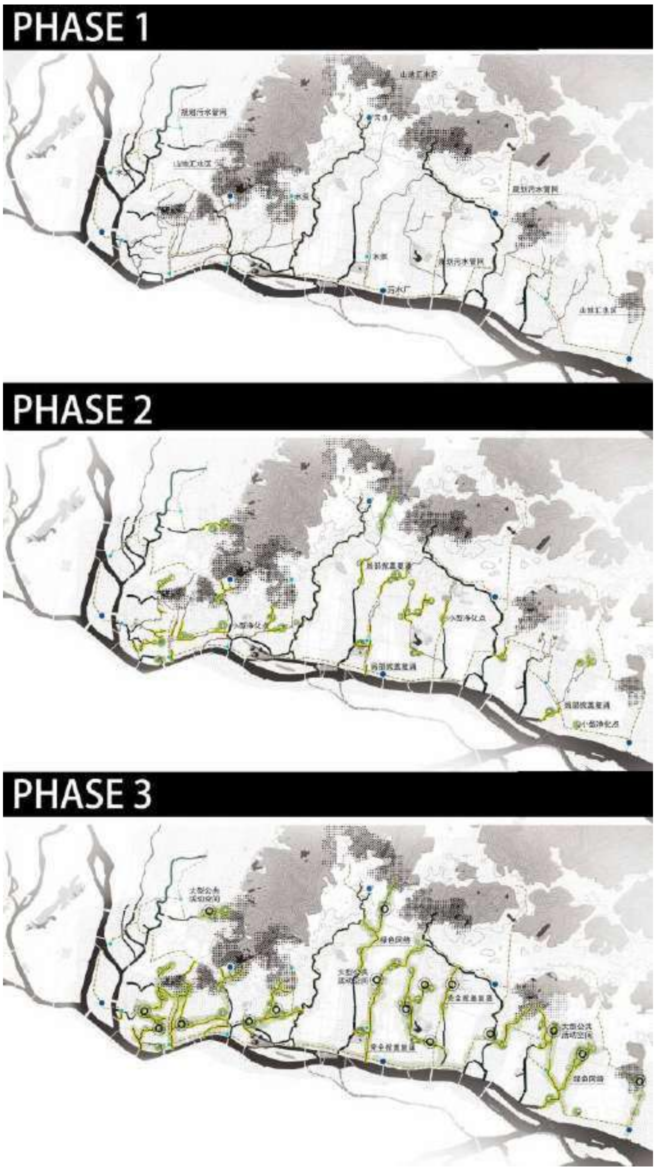

Figure 6 Regional Renewal Strategy

5. Results: Unique Space to Rebuild Close Relationship Between Waterfront Environment and Urban Life

Once as a real 'water city' being born in water and living in water, the river network in Guangzhou is widely distributed everywhere just like lanes, so the rivers are original place where the residents have live for thousand years, which employ an indispensable influence on their life-styles, however, after decades of urban development, the rivers have become no longer relevant to everyday life in urban city. The rivers are not only an important component of the urban ecological environment, but also a stage for the urban life. So the improvement of the riverfront environment is not only a simple ecological restoration or scenic construction of rivers, but also a repairing process of the relationship between city and river.

Taking social concern of riverfront improvement into consideration, urban riverfront remediation should fully measure the functional orientation, cultural inheritance, and life style of the surrounding urban area, so that it will become a space truly correspond to Guangzhou's flavor, carrying local life-styles. For example, if the houses along the riverbanks of East Hao Chong, once a moat in Guangzhou with a long history, were almost demolished during the renovation, the living space pattern of this area, which was rich in old Guangzhou, will disappear. In terms of the protection of urban life forms, the complete construction is often irreversibly destructive. While preserving selective part of the residential area and it will be transformed into an integral part of the riverfront green space. The existing neighborhood and unique urban life will continue, which should be a better choice to create more vitality with the temperament of Guangzhou.[3] Eventually, far from reverse to river as it used to be, the vitality of the waterfront environment will redirect the urban life facing the river, rebuilding the close relationship between waterfront environment and urban life. It is bright future prospect to contrive a beautiful vision of harmonious co-existence between people and river through the phased rejuvenation strategy of ecological restoration, exhumation and spatial integration.

Figure 7 Diverse Space to Rebuild Close Relationship Between Waterfront and Urban Life

6. Enlightenment of Constructing Green Infrastructure Based on Ecological Restoration of Rivers in Guangzhou

As we can see in restoration of rivers in Guangzhou, there is no doubt that the implementation of green infrastructure in the process of rapid urbanization is bound to encounter unimaginable difficulties, but it also contains unprecedented opportunities. I would like to conclude the enlightenment of constructing green infrastructure.

In urban construction, we must strictly protect existing key natural ecological areas that have not been destroyed through forward-looking planning. Next, we must seize the opportunity of urban development to explore a series of potential urban space construction and restoration of natural functions through creative means.[9] In particular, it is necessary to consider the combination with the urban status and adopt more targeted strategies and methods to reconstruct green infrastructure for natural, semi-natural, productive areas, suburban expansion areas, low-density and high-density urban core areas.

Moreover, the updated space with renewal of urban area could constitute green infrastructure with internal connectivity and systematic natural ecological functions, which would be compatible with the spatial and functional characteristics of modern cities. It is not merely a natural space, but also an efficient ecological framework for ensuring sustainable social and economic development, and an optimal strategy of balance between the tense land use and the protection of natural ecology. Some single landscape strategies can easily make the land eroded by the construction of other land. Instead, a compound urban strategy should be adopted to focus on the vitality and development potential of the multi-functional space, clearly defining a mixed proportion of land uses.

In addition, the green infrastructure in the urban environment must be protected by artificial means to make it more efficient,[9] reduce its existing vulnerability, and rely on the continuous development of advanced technologies and engineering facilities to enhance the functional efficiency of the green infrastructure.

The last but not the least, the construction of green infrastructure needs to solve the problem of short-sightedness, which only exists in the immediate future, which prevails in the process of rapid urbanization. It fully recognizes that its ecological role is played gradually, but its functional effect is long-lasting and low-cost. It will be a long-term development strategy and long-term ecological mechanism for the “green modern city” in the future.

Evaluation of public space vitality of based-scenic villages in subtropical climate region：*A case study of Guanhu Village in Shenzhen*

Longduoqi A, Harbin Institute of Technology(Shenzhen), China
Hang Ma, Harbin Institute of Technology(Shenzhen), China
Biao Yang, Harbin Institute of Technology(Shenzhen), China

Abstract：

With the rise of short-term tourism, more and more urban residents go to scenic spots around the city for short-term holidays. It brings new vitality and opportunities to villages around the city, and also brings some issues. Tourists instead of villagers became the main user of space. It leads to the function of the original public space could not meet the new demand anymore. And a large number of new illegal building disrupted tourists' activities in the village public space. These two phenomena lead to the serious problem of public space vitality. At present, there are many studies on the optimization strategy of village space, but there is no quantitative research on the public space vitality of villages. Establishing a method to evaluate the public space vitality (PSV) of based-scenic villages in subtropical region based on tourists' preferences is the purpose of this study is to. First of all, Analytic hierarchy process (AHP) was used to determine the influence factors and factors weight of public space vitality (PSV), basing on which the evaluation system of PSV is established. Secondly, analytic hierarchy process was applied to Guanhu Village, a typical subtropical village with sea view in Shenzhen.Then, important-performance analysis was conducted to diagnose the strengths and weaknesses of PSV of Guanhu Village. Findings suggest those high score for both important and performance , such as Number & layout of entrance, Function type of building and Density of leisure facility are tourists' key evaluation factors of PSV. This paper extends previous research on based-scenic village, and offers insights into the theoretical investigation and practical development of PSV of based-scenic village in subtropical climate region.

Keywords: *Subtropical Climate Region; Based-scenic village; Public space vitality; Analytic hierarchy process (AHP); Importance-performance analysis (IPA); China*

1. Introduction

With the rapid development of urban economy and social change, urbanization in China has grown year-by-year and reached an urbanization rate of more than 50% in 2010. Nowadays in China, many rapid-growth cities suffer from various urban problems, such as environmental pollution, space exhaustion and traffic jams. According to the research of two psychotherapists, Buzzell and Chalquist (2010), urban residents need to find a place, where they can reconnect themselves with nature and natural cycles of human life, to slow down their lives and experience different culture. Based on the Chinese residents' improvement of the living standard and changes of consumption ideas, more and more people are willing to travel to the scenic spots near the city on short-term holidays to relieve pressure and relax themselves. Because of its rich tourism resources and the position advantage, the scenic spots and villages near cities have become the first choice for urban residents to travel in the short term.

The concept of based-scenic villages was first proposed in "the administrative measures of famous west lake scenic villages in Hangzhou". It defined the based-scenic village as a tourist village located within or around the scenic area. Such villages have a strong dependence on scenic spots and share tourist sources with them. Based-scenic village and scenic spots complement each other in terms of tourism resources and tourism products. The based-scenic villages play an important role in the improvement of tourism service function and environmental quality of nearby scenic spots. In terms of industry, these villages have expanded the traditional agricultural industrial chain, developed their own tourism resources. Affected by the radiation spillover effect of the scenic area, the village has completed the transformation of tourism. In terms of social structure, and the lifestyle of traditional agricultural activities has been disintegrated. The population composition of villages is becoming more and more complex, and it is in the state of mixed local villagers, other investors and tourists. From the perspective of management model, most villages still retain the economic model of collective ownership. Land ownership and administrative management mainly rely on the village collective and it also restricted by the management mechanism of scenic spots. From the perspective of spatial characteristics, these villages often retain the original village texture and local traditional landscape characteristics. The agricultural function of the original space has transform into function of tourism service. The original public space in the village died out, while the new public space appeared.

With the continuous development of the based-scenic village, more and more studies have been put forward. Most researches tend to put forward specific development strategies, and ignore the space problems which arises in the process of traditional village turns into based-scenic village. It also ignores the special characteristics of based-scenic village in different regions and climate conditions. The optimization strategy of based-scenic village lacks strong theoretical support. Therefore, it is necessary to establish a feasible quantification method which can be used as a measurement standard for the public space vitality of based-scenic village. This study selected a based-scenic village in subtropical climate region as the research object, fully taking into account the demand and the comfortable experience of tourists in the region. The activities of the tourists is the source of public space vitality.

According to the previous relevant studies, this study establish the evaluation system of the PSV of based-scenic village. This evaluation system is based on the integration of Analytic Hierarchy Process (AHP) and Importance-Performance Analysis (IPA).AHP identifies layers of evaluation criteria related to attributes of PSV, whereas IPA further measures the gap between importance consideration and performance aspect that in turn affects the vitality level of public space. Precisely, this study has two-fold objectives: (1) to investigate and quantify PSV of based-scenic village, and (2) to advance the theoretical framework of PSV research in the context of the development of suburban tourism in subtropical areas. Through the inclusion of an empirical study in the case of Guanhu Village in Shenzhen, the findings will give useful implications for the improvement and reconstruction of PSV when the tourism authorities plan to transform the traditional villages into tourism destinations.

This research can shed lights on the theoretical investigation of PSV on the whole by introducing a quantitative evaluation system of public space attributes. This study can analyze and utilize the advantages and disadvantages of the development of the based-scenic villages. Guanhu Village is a fully-established based-scenic village where tourists have become its primary place consumers. The original villagers have moved away from the village, and tourists have become the main activity groups here. Therefore, this study focuses on tourists and does not discuss the original villagers.

2. Literature Review

2.1 Study on adaptation in subtropical Region

Most studies on public space planning in subtropical areas focus on people's comfortable sensation. The space users in subtropical areas mainly feel thermal comfort in public space. The temperature of public space will affect the behavior and psychological feelings of space users. In hot seasons, people usually have a strong preference for cool temperature and weak sunshine. Seeking shade of trees is the first choice for users to adjust their behavior（Lin T P，2009）. Studies have shown that in hot environments, the shadow provided by trees can effectively reduce the surface temperature of the shaded area. Therefore, the effective application of green plants can improve people's space experience in subtropical areas（Shashua-Bar et al.，2009；Drake M & Guaralda M,2013）. While trees can provide shade and reduce short-wave radiation. However, too many trees can reduce wind speeds, which is another important factor for people's comfort in subtropical public space（Yoshida et al., 2006; Gromke et al., 2008）. Tree shade and wind speed are two important indexes for preliminary evaluation of space thermal comfort. It is best to have shade and good ventilation. Therefore, there is a trade-off between planning measures to reduce solar radiation and improve wind speed（Hsieh C M et al. 2016）. In addition to environmental factors, the feelings of space users are related to the natural nature of the environment, the psychological expectation of users and the purpose of behavior. People are usually more tolerant of more natural environments. In different seasons and space, people's expect and comfortable sensation are different. Studies have shown that people with specific travel goals are more tolerant of public space and better adapted to the environment（Nikolopoulou M, Steemers K, 2003）.

2.2 Based-scenic village

The based-scenic village is a tourist village which is developed by the tourist source of the scenic spot and the unique tourist resources in the countryside. This kind of villages have strong dependence on scenic spots, and share with tourists in scenic spots, complementary resources and products, which has an important impact on the improvement of scenic function and environmental quality(Hu, 2013). From the perspective of social characteristics, village style characteristics and industrial mode, the dual attributes of landscape in the village with the "scenic spot" and "village", is located in the scenic area within the tourism is the main industry in the village, while retaining the rural style, collective ownership economy and land ownership, but the villagers to farming the way of life has collapsed (Zhou, 2016; Hou, 2007). Compared with the general rural settlements, the characteristics of scenic village are not only located inside the scenic area, but also have the characteristics: the use of their own natural cultural resources to develop tourism industry, the village land resources are generally scarce, the rapid population flow of villages (Zhang, 2013). Using the method of multiple regression analysis, starting from the characteristics of the development of scenic areas and villages, it proposed an internal force scenic-based tourism village and the center view of coupling development in difference potential, catalytic potential, management potential and more stable potential, and on this basis, in-depth to explore ways to view the development of coupled Village (Yang, etc. 2011).

2.3 PSV of based-scenic village

Urban vitality is composed of economic, social and cultural vitality (Jiang, 2007). The vitality of urban public space is the ability of all kinds of landscapes to attract, diversiform and continue to carry on activities for a long time (Zhang & Xiao, 2016). There are many aspects of evaluation of vitality, which are reflected in urban open space (Yao, 2012; Wang, 2012), campus public space (Zheng, etc. 2016), neighborhood vitality (Dong, 2015; Zhu, 2016), street vitality (Jiang, 2012; Gou, 2011), and less evaluation of village public space vitality. Some scholars appraise the village public space based on the satisfaction of farmers (Li, 2014; Wang & Zhang, 2016). Some scholars evaluate public space from the perspective of tourist satisfaction (Zhao, 2013; Chi, 2016). However, the evaluation of the vitality of based-scenic villages is less.

Considering the above previous methodological ideas of PSV assessment in different parts of China, this paper firstly uses AHP as the fundamental and multi-attributed approach to frame and measure the in Guanhu Village’s PSV from a touristic perspective, and then applies IPA to diagnose the strengths and weaknesses of the PSV based on the ratings and weightings of each attribute on site. AHP was introduced by Saaty (1980) as an approach to allocate the relative importance of evaluation items based on weights of criteria (Hsu & Tsai, 2009). IPA was introduced by Martilla and James (1977), who initiated this method in marketing analysis and planning. They suggested two dimensions, importance and performance, to prioritize the actions or improvements to be considered by decision makers in various fields of service quality and customer management (Duke & Persia, 1996; Arbore & Busacca, 2013). This method has been widely adopted in research areas such as airport and airline services (Mikulić & Prebežac, 2011), tourism policy and development (Evans & Chon, 1989; Coghlan, 2012; Li, 2012; Lai & Hitchcock, 2015; Sever, 2015), hotel operation (Chu & Tat, 2000; Pan, 2015), and so forth. One research methodological gap in the previous studies was the dearth of tourist perspective in the tourist resource assessment. Most of the assessment exercises were conducted by panels of experts and this study therefore makes an attempt to consider tourists' satisfaction with the PSV resources as the key component of the evaluation system.

Following the idea of combining IPA with other useful analytical tools (Lai & Hitchcock, 2015; Sever, 2015), this research investigates tourists' perceptions of the levels of "importance" and "performance" of the AHP-framed PSV attributes, and further diagnoses the strengths and problems of PSV in Guanhu Village.

3. Methodology

3.1 Identifying evaluation items of PSV

Based on the existing evaluation system of public space vitality, this paper finds that many scholars discussing the PSV from two aspects, representational elements and constitutive elements. They believe that the behavior and activities of space users, as the Visual representation playing a similar important role on the evaluation of PSV like the factors of material environment. The environmental factors of public space are usually divided into macroscopic, mesoscopic and microscopic aspects, corresponding to the traffic accessibility, the interface features, and the internal environment of the public space. Besides, service facilities and maintenance management factors in public space are also important primary indicators of PSV. Summary, this paper divides the evaluation index of PSV into 7 primary indicators: users, activities, traffic accessibility, surface, internal environment, service facilities and maintenance management. According to the existing 17 paper researching on evaluation of PSV, we found 40 frequency secondary index. The User has 4 secondary index, Activity has 3, Traffic accessibility has 6 index, surface has 6, internal environment has 12, service facilities has 6, and management maintenance has 3 index. These index have the particularity of their research, and the different quantitative and qualitative methods of PSV lead to the same indicators has the different definition. Besides, this research have to consider the particularity of the PSV of based-scenic villages in subtropical climate region. So it is necessary to screening the index.

The PSV of based-scenic village is different from the general urban public space. It has the typical characteristic of public space village, and different from traditional villages. Affected by tourism development, the form, function, activities and users of village public space have all changed. From the perspective of tourism development, the based-scenic village affected by the around scenic areas, and the life style of agriculture has changed. Original villagers had moved away, and tourists living in nearby cities crowed into the village through external transportation. Therefore, the accessibility of space and external traffic, the degree of close connection with scenic spots and the variety of tourism activities available become the key to attract tourists. These will affect the number and last time of tourists in the public space, which is an important indicator of the vitality of the public space. In addition, the needs of tourists in the village public space are different from those of villagers, who have three needs: food, shelter and travel. Then, the corresponding indicators such as tourism service facilities and functional types also need to be included in the set of indicators. From the perspective of tourists' short-term residence, in order to better meet tourists' demand in public space for living in, it is necessary to take into account the evaluation indicators such as tourists' night activities and leisure activities, such as public infrastructure, night lighting and transportation facilities within villages. Besides, the night activity facilities also can improve the PSV at night. From the perspective of the location and regional characteristics of the climate zone, the based-scenic village affected by the nearby scenic spots and the climate region, formed special regional characteristic. This paper choose the based-scenic village around seaside as the example. The coastal resources, the home stay facility culture and coastal activities are also the key points to be evaluated. Besides, in the subtropical climate region, it is usually hot and rainy in summer and mild and rainy in winter. Tourists usually have higher requirements on shading facilities and ventilation in public space

In conclusion, 34 indicators were selected to form the final set of evaluation indicators (Table 1).

Criterion layer(6)	**Sub-criterion layer(34)**
User (B_1)	Number of user (C_1)
	Type of user (C_2)
	Density of user (C_3)
	Duration on site (C_4)
Activity (B_2)	Type of activity (C_5)
	Frequency of activity (C_6)
Traffic accessibility (B_3)	Distance between public space and beach(C_7)
	Distance between public space and parking(C_8)
	Number & layout of entrance(C_9)
	Number of public transport station (C_{10})
Surface (B_4)	Function type of building (C_{11})
	Density of shopping (C_{12})
	Proportion of assessable building(C_{13})
	Degree of space enclosure(C_{14})
	Characteristic of building surface(C_{15})
	Elevation of boundary(C_{16})

	Size of space(C_{17})
	Depth-width ratio of space section(C_{18})
	Safe of traffic(C_{19})
Internal environment (B_5)	Surface roughness (C_{20})
	Occupation rate of pavement by vehicle (C_{21})
Internal environment (B_5)	Sunshade ratio (C_{22})
	Green ratio (C_{23})
	Wind speed (C_{24})
	Character of landscape element (C_{25})
	Density of leisure facility(C_{26})
	Sign of road(C_{27})
	Density of light facility(C_{28})
Service facility (B_6)	Density of dustbin (C_{29})
	Number of public toilet (C_{30})
	Density of obstacle-free facility (C_{31})
	Density of activity facility (C_{32})
Management & maintenance (B_7)	Frequency of cleaning (C_{33})
	Maintenance of facility (C_{34})

Table 1: Framework of the system for evaluating tourist satisfaction with PSV

3.2 Study site

The second stage is the analysis of the study site, Guanhu Village, by observation. Guanhu Village is a tiny coastal village covering a land area of 22 hectares located on Dapeng peninsula in Shenzhen (Figure 1). Guanhu Village is located in Dapeng peninsula of shenzhen city, belonging to Kuichong street of Dapeng new district. Guanhu Village is located on the north side of Guanhuchong beach, west side of Wangyuling park, east side of Dongjiang Column Memorial park. Along the main roads in the village about 1000 m west of Guanhu Village we can go to Shayuchong Village. Guanhu Village has good tourism resources. Due to its location in the urban fringe (approximately 58 km away from the city center) and its characteristics (different from most urbanized villages in China), Guanhu is considered a tourist village rather than rural village in this study. Most of villagers have moved from the village, and only 50 registered resident population and merchant managers of nearly 110 are living in the village now. During the last decade, the main income source of the villagers came from an industrial building lease to the Dapeng Cooperation Company.

In 2011, the Shenzhen Municipal Government designated Dapeng as a new district of Shenzhen. After that, some sorts of investment on the coastal tourism development of in Dapeng district emerged, while the idea of creating touristic homestay accommodation inspired the change of this coastal fishing village to a tourism destination. Since 2014, some farmer houses were converted into homestay accommodation for tourists by the villagers spontaneously. In 2016, the annual tourist arrival has gradually reached 80,000. Although they face up with the problems lacking of funds, without the financial support from the government, every villagers fully take part in public participation. The "bottom-up" renewal mode could be valuable reference for the surrounding undeveloped villages.

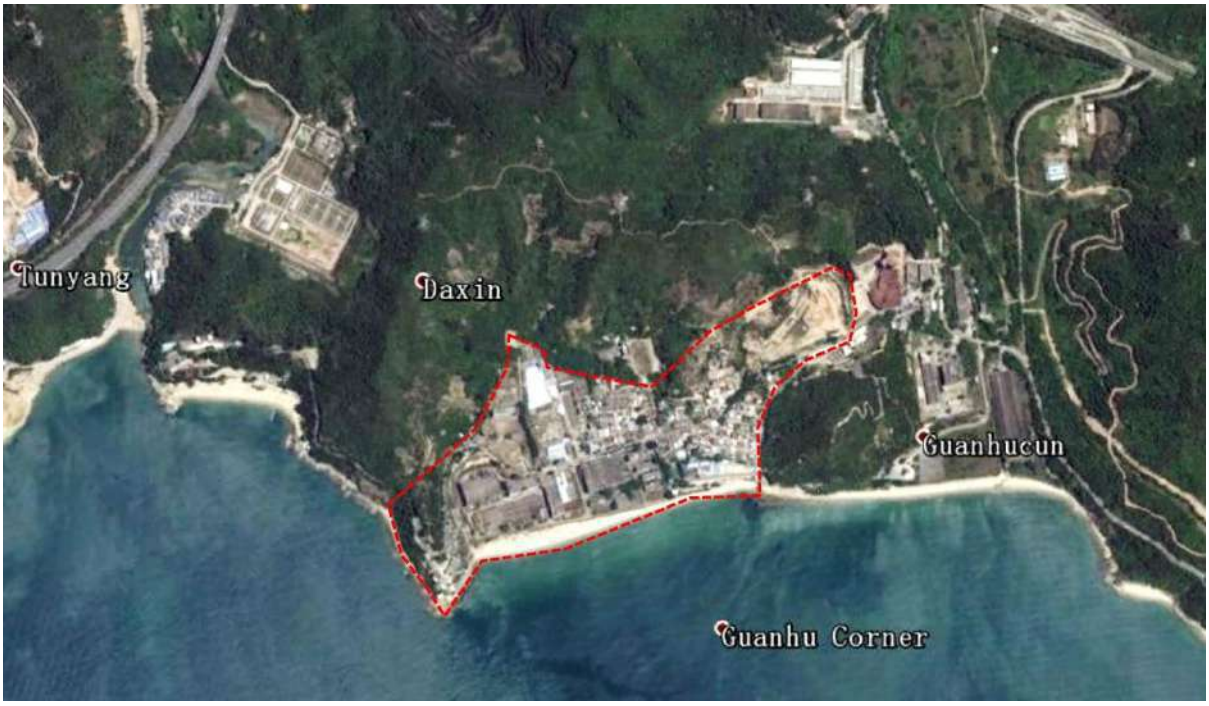

Figure 1: Aerial photo showing the location of Guanhu Village

Guanhu Village was chosen as the study site mainly because of three reasons. Firstly, Guanhu Village is a typical self-organized tourism village in Dapeng district. According to the Industrial Space Layout Planning in Shenzhen (2011-2010), Dapeng district was positioned as the characteristic tourism area based on its unique coastal landscape, valuable history and rich ecological environment. Official statistics indicated that tourist arrival in 2013 reached 3 million, and was expected to surpass 8 million in 2020 (Shenzhen statistics Bureau, 2014). Due to the limited government resources, the self-organizing development model of villages is the main development pattern and also advocated by the academic community. Secondly, compared to other tourism villages in Dapeng, Guanhu Village has a larger village scale and made an outstanding progress in terms of tourism industry development. Guanhu Village has a variety of public space and the space problem is also obvious. Thirdly, the village has a good basement for tourists. Most tourists for Guanhu come from Shenzhen city, Guangzhou Province or other parts of Pearl River Delta region. As these tourists have had a high revisit rate, they have a good understanding of the Guanhu Village and its PSV, and may thus provide a reliable source of perception and information about the satisfaction with the site.

3.3 Data collection

The last stage of the research method is related to the process of data collection. An administrated questionnaire-based survey was designed for this study. This questionnaire in

Chinese consisted of three parts. Parts 1 is the user background survey. Through basic information to the user, the user's gender, age, income, the identity, source, tourism purpose, such as dynamic evaluation results analysis for subsequent village public space and space optimization strategy provides the basis. The second part of the questionnaire asks users to rate public Spaces based on questions. Translating qualitative indicators requiring subjective evaluation into easy-to-understand questions, and collecting the results of public space based on tourists' experience. The third part of the questionnaire is the measurement results list of each quantitative index. Through field investigation, quantitative indicators such as the number of users, residence time, size, height and width ratio of sections, and the number of facilities of each public space are calculated to prepare for the next step of evaluation. All the quantitative and qualitative indicators involved in the questionnaire based on 34 evaluation indicators in the evaluation system.

A total of 350 questionnaires were distributed in Guanhu Village among a convenience sample of tourists during March (100 questionnaires in low season) and May 2016 (250 questionnaires in peak season). The entire survey was conducted by ten trained interviewers at different public spaces of the village. After an introduction of the study purpose, the voluntary nature and the confidentiality, an agreed participant would complete a self-administered questionnaire and each session took about 10 to 15 minutes. The interviewers would provide clarifications to the questions upon request. The quality of collected responses was checked by the interviewers separately. A returned questionnaire was deemed invalid when any respondent provided multiple answers to single-choice questions, or when a substantial portion of questions was left unanswered.

The resultant judgment matrices had to be combined with the ratings provided by tourists in the main survey, in attempt to attain the final satisfaction scores for evaluation of PSV. Finally, in the tourist main survey, a total 100 questionnaires were collected in low season with 96 valid responses included. Another 250 questionnaires for peak season were collected, including 243 valid responses. The effective response rates of the two parts of the survey are thus 96% and 97.2% respectively.

Table 2 shows the socio-demographic profile and the visitation characteristics of the two respondents groups respectively. Both low and peak season samples have a balanced gender distribution (the percentages of either male or female respondents do not exceed 60% in each). However, the proportion of male tourists is higher (59%) during low season when they often prefer participating in one-day leisure travel. Female tourists have a higher proportion (52%) during peak season as observed popular water sport activities like surfing and swimming among them. The majority of the sample has an age range of between 18 and 45 years (about 63% in low season to 64% in high season). During peak season, the proportion of elderly and children increased due to the pleasant weather, while many tourists age from 31 to 45 like travelling during the off-season, because their highly income level and relatively freely work time. Both groups have an even distribution of annual personal income though almost 50% earned more than RMB150000 per year. Regarding visitation, tourists from Shenzhen dominate the place of origin (about 67%). They mainly reach the village either by public transport or driving, both about 85.8% of the total.

Variable		**Low season**		**Peak season**	
		Frequency	**Percentage (%)**	**Frequency**	**Percentage (%)**
Gender	Male	56	58.3	115	47.3
	Female	40	41.7	128	52.7
	Total	96	100.0	243	100.0
Age	Below 18	0	0.0	9	3.7
	18-30	22	22.9	84	34.6
	31-45	40	41.7	72	29.6
	46-60	9	9.4	63	25.9
	Over 60	25	26	15	6.2
	Total	96	100.0	243	100.0
Personal annual income (RMB)	Below 80000	0	0.0	62	25.5
	80001-150000	29	30.2	86	35.4
	150001-300000	58	60.4	84	34.6
	300001-1000000	7	7.3	6	2.5
	Over 1000000	2	2.1	5	2.0
	Total	96	100.0	243	100.0
Place of origin	From Shenzhen	77	80.2	150	61.7
	Guangdong Province except Shenzhen	19	19.8	86	35.4
	From other province	0	0.0	7	2.9
	Total	96	100.0	243	100.0
Mode of transportation	Public transport (except taxi)	7	7.3	11	4.5

	Tour bus	0	0.0	28	11.5
	Bicycle	2	2.1	4	1.7
	Total	96	100.0	243	100.0

Table 1: Socio-demographics of the respondents (n=339)

4. Results

4.1 Results of AHP

Before the main tourist survey, the weighting set of PSV attributes was determined by fifty experts in tourism and local rural development who included 42 professors of tourism planning and 8 officers of urban planning and rural renewal. These experts rated the level of importance of the PSV items using a 1-to-9 scaled pair-wise comparison method. After eliminating one invalid case, the remaining 47 valid responses were used for the analysis.

A consistency test was further conducted to check the rationality of the weights, and the result shows that CR=0.073, which is below the critical value of 0.1 (Satty, 1980). Thus the judgment matrix has satisfactory consistency, indicating that the final weight set obtained by AHP in Appendix 2 is reasonable. Following the same procedure, the weight sets of the secondary evaluation items were also calculated, as shown in Appendix 3. The consistency test of these second-level weights are also below the value of 0.1. Based on the weighting judgement matrices, the resultant weights of the evaluation criteria of the Jiaochangwei's PSTV are shown in Table 3.

First-level factor	Weight	Second-level factor	Weight
B_1 User	0.153	C_1 Number of user	0.467
		C_2 Type of user	0.095
		C_3 Density of user	0.277
		C_4 Duration on site	0.161
B_2 Activity	0.247	C_5 Type of activity	0.333
		C_6 Frequency of activity	0.667
B_3 Traffic accessibility	0.393	C_7 Distance between public space and beach	0.586
		C_8 Distance between public space and parking	0.115
		C_9 Number & layout of entrance	0.242
		C_{10} Number of public transport station	0.057
B_4 Surface	0.083	C_{11} Function type of building	0.445
		C_{12} Density of shopping	0.158
		C_{13} Proportion of assessable building	0.234
		C_{14} Degree of space enclosure	0.034
		C_{15} Characteristic of building surface	0.084
		C_{16} Elevation of boundary	0.045

B_5 Internal environment	0.037	C_{17} Size of space	0.046
		C_{18} Depth-width ratio of space section	0.065
		C_{19} Safe of traffic	0.323
		C_{20} Surface roughness	0.031
		C_{21} Occupation rate of pavement by vehicle	0.220
		C_{22} Sunshade ratio	0.153
		C_{23} Green ratio	0.027
		C_{24} wind speed	0.117
		C_{25}Character of landscape element	0.018
B_6 Service facility	0.064	C_{26} Density of leisure facility	0.400
		C_{27} Sign of road	0.029
		C_{28} Density of light facility	0.248
		C_{29} Density of dustbin	0.054
		C_{30} Number of public toilet	0.130
		C_{31} Density of obstacle-free facility	0.054
		C_{32} Density of activity facility	0.085
B_7 Management & maintenance	0.023	C_{33} Frequency of cleaning	0.667
		C_{34} Maintenance of facility	0.333

Table 3: Weights of the evaluation criteria

The weighting criteria and scores in Table 3 form the basis of the satisfaction evaluation. Because of the different standards of different index, it is necessary to order a new unified evaluation standard. In order to analyze more accurately the evaluation criteria, the Likert scale method used in the questionnaire was further re-scaled and converted to an evaluation standard shown in Table 4 so that the ratings can be used for AHP evaluation.

Tourist satisfaction evaluation	Average score
E1 (excellent)	$X_j > 4.5$
E2 (good)	$3.5 < X_j \leq 4.5$

E3 (moderate)	2.5<Xn≤ 3.5
E4 (fair)	$1.5 < X_j \leq 2.5$
E5 (poor)	$X_j \leq 1.5$

Table 4: Tourists' satisfaction evaluation standard

4.2 Results of PSV

12 public spaces in Guanhu Village were selected to investigate each sample on the basis of the index set of the evaluation system. The evaluation indexes of this evaluation system are divided into two categories: quantitative and qualitative. Quantitative indicators can be obtained by measuring and counting the results. Such as the quantitative indicators of traffic accessibility, interface, internal environment, service facilities and maintenance management in the index, such as size, width, height and density of the facility scale measurement tools to get 12 samples of exact data space. There may be small errors in the measurement process, which does not affect the evaluation. In addition, the indexes as the user and the activity are affected by different measurement times which can easily produce large errors. So randomly selected 15 minutes including 8:00-10:00, 10:00-12:00, 12:00-14:00, 14:00-16:00, 16:00-18:00, 18:00-20:00, total of 6 periods of working day and weekend to statistics the all two level indicators of users and activity levels in twelve spatial samples. The average data measured in each time period is selected as the final data to eliminate the error caused by the difference of population activity in different time periods. The results of the three qualitative indicators of the target concentration need to be evaluated with the help of the tourist questionnaire. The questionnaire can be distributed randomly in the 6 research period. When the questionnaire is issued, the collection of spatial data should be considered in a balanced way, and to ensure that there are a certain number of effective questionnaires in each space.

Through field survey and questionnaire collection, obtain the each index data of the space vitality evaluation sample of Guanhu Village. Because of the large difference in the unit of each index, five points should be used to unify each index. Through horizontal comparison, choose the best spatial evaluation data of the 12 spatial samples under the same index as 5 points, and the other samples are scored according to the corresponding ratios. Finally, the index scores of 12 spatial samples were obtained according to formula (1) and got the final result.

$$U_i = \sum_{i=1}^{n} R_i * W_i \qquad (1)$$

where Ui is the evaluation result of vitality; Ri is the result of second-level factors; Wi is the weight of second-level factors in the target layer.

According to the above formula, the final result of the evaluation of the vitality of 12 public space samples in Guanhu Village is obtained. According to the evaluation semantics, all the samples are divided into four categories.

Evaluation of PSV	Public space	Result
excellent > 4.5	-	-
3.5 <good vitality≤ 4.5	X_4 (shopping street)	3.70
2.5 <moderate vitality≤ 3.5	X_5 (Hulong Yixiang)	3.45
	M_1 (beach)	3.38
	M_2 (center square)	3.08
	M_4 (seaside square)	3.02
	X_2 (the western street close to ancient tree square)	2.82
1.5 <fair vitality≤ 2.5	M_3 (ancient tree square)	2.32
	M_5 (Basketball Court)	2.05
	X_6 (Hulong Jiuxiang)	1.84
	X_1 (inward streets)	1.84
	X_3 (streets in old village)	1.68
Poor vitality≤1.5	D_1(Torri and the surrounding)	1.42

Table 5:Results of PSV

4.3 Results of IPA

According to the vitality evaluation scores of 12 public space samples, there is no space got Score above 4.5, belonging to the excellent public space. In the 3.5-4.5 score range, only has one spatial sample,X4 (shopping street),X5 (Hulong Yixiang), M1 (beach) and 5 samples belong to the moderate vitality space of 2.5-3.5, while the rest belong to the poor vitality space. The activities of tourists in the public space of Guanhu Village tend to be in the scenic area, so it is reasonable that their activity distribution leads to the difference public spaces vitality in the village. The public spaces close to the beach should have good space vitality, while the spaces deep into the village are generally reasonable compared with the former. However, it is found that the evaluation of the public spaces vitality near the sea are general and different from the expected results through analysis. In order to find out the problems in these public spaces, IPA analysis method is introduced in this study

The four quadrants in an IPA correspond to specific conditions of the subject (Duke & Persia, 1996). Connecting to this PSV study, the "keep up the work" quadrant (I) indicates a desirable condition with great importance and satisfactory performance, while the "concentrate here" quadrant (II) refers to the zone where tourists attach great importance to a space but are dissatisfied with its performance. These are the two areas deserving enhancement and improvement. The quadrant with “low priority” (III) is accorded as tourists consider less important in the space and are also dissatisfied with the space’s performance. Lastly, the “possible overkill” quadrant (IV) defines a public space with high performance (and perhaps resource allocation or management) but is of less important according to the tourists.

For example, for seaside square, the items in the upper-left quadrant of the matrix are the most significant evaluation items of PSV with poor performance: Density of user (C_3), Duration on site (C_4), Type of activity (C_5), Frequency of activity (C_6), Distance between public space and beach (C_8), Number of public transport station (C_{10}), Function type of building (C_{11}), Density of leisure facility (C_{27}), Frequency of cleaning (C_{33}). These items represent the weaknesses of seaside square’s PSV and deserve further attention (Fig.2).

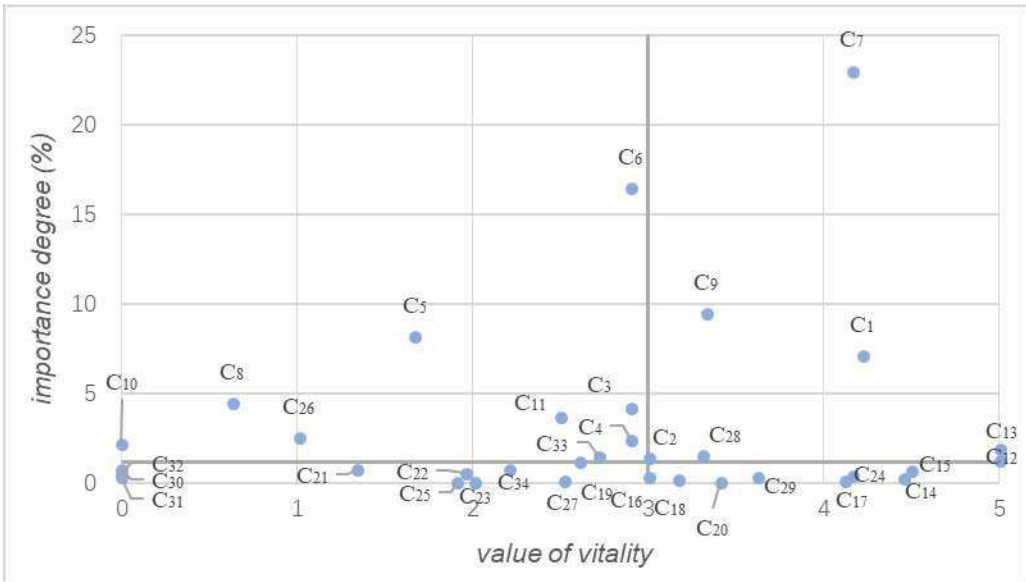

Figure 2:Result of IPA of seaside square

For beach, he items in the upper-left quadrant of the matrix are the most significant evaluation items of PSV with poor performance: Distance between public space and parking(C_8)、Number & layout of entrance(C_9)、Number of public transport station (C_{10})、Function type of building (C_{11})、Density of shopping (C_{12})、Proportion of assessable building(C_{13})、Density of leisure facility(C_{26})、Density of light facility(C_{28}), and Frequency of cleaning (C_{33}). These items represent the weaknesses of beach’s PSV and deserve further attention (Fig.3). As the beach is a special forbidden area, many service facilities will become a safety hazard in bad weather, so the optimization strategy should be put forward according to the actual requirements.

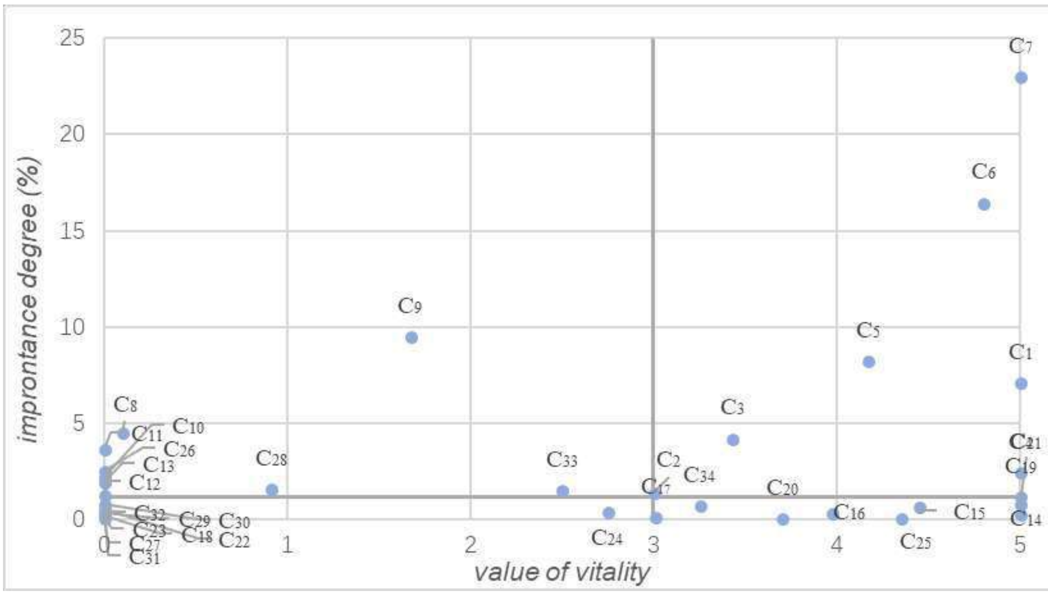

Figure 3:Result of IPA of beach

5. Conclusions and Implications

5.1 Key findings

The primary objectives of this study are to identify PSV of based-scenic villages, and to measure strengths and weakness of PSV of Guanhu Village via AHP and IPA. Although exploratory in nature, this study offers useful insights into the theoretical investigation and practical development of PSV.

First, this study contributes to the understanding of PSV of based-scenic villages on the theoretical grounds. While the development of based-scenic villages is gaining popularity, there has been insufficient research on PSV of based-scenic villages. Based on a literature review and factor analysis, this research identified 33 key evaluation items of PSV and grouped them into seven categories: “user”, “activity”, “traffic accessibility”, “surface”, “internal environment”, “service facility” and “management & maintenance”.

Second, this study provides insights into the approach for measuring and identifying the strengths and weaknesses of PSV. Given the limited literature on quantitative evaluation of PSV, it is deemed necessary to investigate the evaluation approach of PSV. Employing the AHP, this paper conducted the PSV assessment of Guanhu Village in Shenzhen, China. Further investigation using IPA shed light on diagnosing the strengths and weaknesses of PSV in Guanhu Village. Collectively, the methods used in this study are instrumental for quantitative assessments of PSVs.

5.2 Managerial implications

The findings of this paper will not only contributes to the academic research of PSV, but also chart new directions for the planning and construction of public space of based-scenic villages in practice.

First, the items of PSV identified in the present research are useful for the management of based-scenic villages. This research could help practitioners understand how to improve PSV of based-scenic villages according to tourist needs, wants, and preferences and, in turn, enhance tourist experience and improve PSV of based-scenic villages.

Second, the weights of PSV evaluation items in this study can shed light on the construction sequences of PSV. The weights of PSV evaluation items can inform the managers of the roles these key items play in PSV. As shown in Fig.2 and Fig.3. Those items should be given priority when improve an effective PSV.

5.3 Research limitations

This study used convenience sampling to survey the tourists in Guanhu Village, which may limit the ability to generalize its research findings to the entire tourist population there. It is necessary to extend the research approach to other PSVs will respond to the survey in a different way. In other words, further research could use other based-scenic villages as the study sites to examine whether the findings from this study are replicable.

Women and sustainability

Abdelmalik, Rafif, KHARTOUM, Sudan

ABSTRACT:

The environmental and health consequences of climate change, which disproportionately affect low-income countries such as Sudan, profoundly affect human rights and social justice. Environmental consequences include increased temperature, excess precipitation in some areas and droughts in others, extreme weather events, and increased sea level. These consequences adversely affect agricultural production, access to safe water, and worker productivity, and, by inundating land or making land uninhabitable and uncultivable, will force many people to become environmental refugees. Yet the very groups who are most affected by climate change impacts are least likely to be involved in climate adaptation discussions. Climate change, which reduces crop yields and food production particularly in developing countries, affects women's livelihood strategies and food security, and therefore their right to food. Women are responsible for 70-80 percent of household food production at West Sudan. Traditional food sources may become more unpredictable and scarce as the climate changes.

Women's role in communities is not formally recognized or accounted for in mitigation, adaptation and relief efforts. Women's knowledge about ecosystems and their strategies, experiences and skills for coping with natural disasters and water shortages, are often ignored. Strategies and policies to cope with climate change are neglecting the gender dimensions of climate change and the current gender-climate change agenda. Women are poorly represented in planning and decision-making processes in climate change policies, limiting their capacity to engage in political decisions that can impact their specific needs and vulnerabilities. The integration of gender appears most likely to succeed at the regional and local levels but even here it is the exception rather than the rule. Women's knowledge and experience of maintaining bio-diversity through the conservation and domestication of wild edible plant seeds and food crop breeding is key to adapting to climate change more effectively. This paper will illustrate the rights, strategies, and benefits from involving gender view in solving the sustainability issue taking west of Sudan as a perspective.

Opening Smart City ‘fairy tale’ to Critical Scrutiny: insights from dialogic accounting literature

Evgenii ALEKSANDROV, Nord University, Norway
Elena DYBTSYNA, Nord University, Norway
Anatoli BOURMISTROV, Nord University, Norway
Giuseppe GROSSI, Nord University, Norway

Abstract

Purpose – The paper intends to contribute to theoretical development of Smart City concept and discussions about its democratic governance through juxtaposing the existing critical literature on Smart Cities and dialogic accounting theory.

Design/methodology/approach – This is a conceptual paper which is based on synthesis of literature within and beyond democratic governance, accounting and Smart City. While not presenting a new empirical research, the paper outlines the reflections on existing Smart City rankings and models within European countries from the point of view of dialogic accounting theory.

Findings – Based on critical examination, it can be argued that existing governance mechanisms do not give ability to include local citizens in real decision-making related to Smart City initiatives rather being embedded in logic of monologism. With dialogic accounting framework, the paper highlights new proposals for critical examination of current organizational practices in relation to Smart City initiatives, i.e. how to develop Smart City management which somehow should balance between divergent interests (e.g. technology, business, political elites, bureaucrats, environmentalists and citizens).

Originality/value – The paper responds to the recent calls to critical examinations of the development of Smart City concept and ways how it contributes to the society. In this regard, we bring the new insights regarding the value of dialogic accounting theory in shaping contemporary understanding of Smart City management and its criticalities under democratic governance agenda.

Keywords – Smart City management, dialogic accounting, democratic governance

Paper type – Research paper

Introduction

The idea of "Smart City" enjoys growing endorsement and popularity worldwide (Manville et al., 2014; Neirotti et al., 2014). Despite there is no common definition of Smart City, the core idea lies in attempts to solve problems of densification and excessive urbanization mostly in large cities around the world with promises of increasing quality of life through the use of technologies (mostly IT-focused) which will foster sustainable future: economic, environment and society oriented (Meijer & Bolívar, 2016). With such promises, it becomes a tool to increase city investments, business development and activity of the region in general (Manville et al., 2014) and increasing efficiency and effectiveness of social value creation for citizens in particular (Anthopoulos, 2017). In this way, Smart City idea becomes a 'fairy tale' with smart IT-solutions, smart people and smart collaboration for sustainable future (Meijer & Bolívar, 2016).

However, in contradistinction to the attention that Smart City attracts with its utopian and optimistic rhetoric in practice, there is increasing call to the critical theorization of the topic (Grossi & Pianezzi, 2017; Marvin et al., 2015). Indeed, despite Smart City Concept can give a new impulse for city development through a promise of sustainable future (Manville et al., 2014; Meijer & Bolívar, 2016), it is still unclear how to manage these promises in practice, especially in financial and city governance terms. Technology by itself cannot make a city, leaving a room for 'smart' decisions to be taken by actors involved such as politicians, public sector officers, investors, research institutes and companies giving technology solutions as well as citizens who will live in sustainable future city smarter (Meijer & Bolívar, 2016). Some critical studies already revealed that Smart City concept could lead to the marginalization of environmental, social and economic aspects of sustainability in favor of interests of IT companies and business elites. Those construct the city without asking other stakeholders (e.g. citizens and local authorities) what would be smart for them (e.g. Hollands, 2008; Kitchin, 2014; Marvin et al., 2015), rather using "Smart City" utopia for distracting attention from 'real' urban problems and promoting neoliberal idea(l)s (Grossi & Pianezzi, 2017). Such actions, in its turn, can lead to financial pressure for future generations who will be forced to live in 'smart' but most probably the expensive city. At the same time, there could be a danger of overemphasizing the societal promise of Smart City concept where populistic 'democratic' decisions can lead to threatening long-term financial sustainability (Huston et al., 2015), which, in its turn, can also question the attractiveness of the city for future generations (e.g. "nobody wants to live in smart but expensive city"). This, in its turn, can lead to situations where non-financial and financial information related to Smart City initiatives should be demonstrated/disclosed to the citizens in a way that they could understand and consider long-term financial sustainability of decisions to be approved and jointly committed (e.g. current and future committed costs of Smart City initiatives and consequences for taxation).

Therefore, despite Smart City 'fairy tale' have generated a surge in its attractiveness, it is still unclear how to develop Smart City management which somehow should balance between interests of financial sustainability, citizens, environment and business or/and political elites.

The intention of this conceptual paper is to contribute to theoretical development of Smart City concept through juxtaposing the existing critical literature on Smart Cities and so-called dialogic accounting theory (Bebbington et al., 2007; Brown, 2009; Brown & Dillard, 2015a, 2015b). Being originated in sustainable development, social and environmental accounting studies, dialogic accounting theory argues that value creation and its related non-financial and financial measures should be based on dialogue of divergent voices (Bebbington et al., 2007). This dialogue, in its turn, should be viewed as a complex politically-natured process with acknowledgment of pluralism, difference, ideological conflicts and power dynamics (Brown, 2009). Despite its origination in critical accounting literature (Bebbington et al., 2007) and political ideas of agonistic democrats (Mouffe, 2000, 2005, 2013), during recent years dialogic accounting theory become increasingly employed in critical scrutiny of Participatory

Governance and New Public Governance agendas (Aleksandrov et al., 2018; Brown & Dillard, 2015a). In this way, applying to Smart City idea(l)s' development with the core role of citizens' involvement (Torfing & Triantafillou, 2016), dialogic accounting theory can be valuable to bring new insights into understanding of challenges in citizens' involvement into Smart City decision making and how it is possible to overcome these challenges.

The paper will proceed as follows. Firstly, we will review the existing literature on Smart City management and develop arguments in favor of dialogic accounting theory in Smart City discourse. The point of departure is the acknowledgment by previous studies (Grossi & Pianezzi, 2017; Huston et al., 2015) of accountability problem in Smart City management, i.e. "practice of demanding and giving the reasons to conduct" related to value creation in cities (Robert & Scapens, 1985). Based on critical examination, it can be argued that existing accountability mechanisms (e.g. financial and non-financial measures, performance and planning instruments) do not give ability to include local citizens in real decision-making related to Smart City initiatives rather being embedded in logic of monologism [1]. Secondly, we will review the key ideas of dialogic accounting theory (Brown & Dillard, 2015a, 2015b), followed by its linking with previous critical studies on Smart City and its application to existing accountability mechanisms in cities' governments. Thirdly, we will reflect on how dialogic theory principles [2] can be applied to current Smart City management and accountability practices available via existing Smart City ranking and assessment models within European counties and possible challenges on its way.

Smart City as a modern 'fairy tale'

Nowadays many things become 'smart'. "Smart City" in particular invokes the growing interest during recent decades with particular promise of technology to solve the problems of the future and sustainable development of the city which will become safer, cleaner, richer more accessible, and more innovative (e.g. Anthopoulos, 2017; Greenfield, 2013; Manville et al., 2014; Meijer & Bolívar, 2016). However, what evidence do we have so far in delivering such promises? Do Smart City's promises become modern reality or rather a fairy-tale? What is the plot and who are the main actors here?

As noted by Meijer (2017), two general plots of Smart City promises are evident in the literature: first, the technological/engineering perspective on Smart City and, second, critical social studies telling a story of marginalization of the city by the business idea(l)s and danger of 'technological blindness'.

The technological/engineering plot of Smart City becomes rather active contributor in developing current trends within citizens infrastructures and general sustainable development (Anthopoulos, 2017; Batty, 2013; Kitchin, 2014; Mora et al., 2017; Viktor & Kenneth, 2013; Wiig, 2015). Here, the technology provides novel solutions for cyber-physical integration in the urban space, a growing network of city alliances, forums and marketplaces that aim to bring together scientists, practitioners and city governments in an attempt to define a common urban future and a promising international network of scholars (Anthopoulos, 2017). In such an optimistic technical plot, the main actors represent various ICT solutions, technological systems (e.g. transport, energy, surveillance, security) with the key role of data which would result in effectiveness and efficiency (e.g. better and efficient waste systems and transport infrastructures) (e.g. Batty, 2013; Viktor & Kenneth, 2013). This makes the smart city as an intelligent, interconnected and instrumented set of developments which are scientific, objective, commonsensical and apolitical in nature (Kitchin, 2015; Wiig, 2015). Nevertheless, such fairy tale becomes increasingly challenged with the critical plot of Smart City examination.

The growing number of critical studies has been developed during recent decade (e.g. Greenfield, 2013; Grossi & Pianezzi, 2017; Hollands, 2008, 2015; Kitchin, 2014; Marvin et al., 2015; Vanolo, 2014, 2016). The content of Smart City optimistic plot was in this regard stretched and 'bittered' with issues of politics, bureaucracy, power relations and marginalization within multiplicity of actors and their roles in Smart City initiatives. For example, Smart City concept could lead to the marginalization of environmental, social and economic aspects of sustainability in favor of interests of IT companies and business elites (e.g. Hollands, 2008; Kitchin, 2014; Marvin et al., 2015). Another possible content is "Smart City" utopian vision which distracts attention from 'real' urban problems and promoting neoliberal idea(l)s (Greenfield, 2013; Grossi & Pianezzi, 2017; Hollands, 2015; Kitchin, 2015), therefore, becoming a relatively poor concept if intended as a model of the urban life of the future (Vanolo, 2016). In addition ICT produces the big data which paradoxically can give too much relevant but useless information due to information overload (Leszczynski, 2016; Taylor Buck & While, 2017) and danger of 'technological blindness' when new tools become a passion rather than rational instrument or technology meets bureaucratic procedures (Kornberger et al., 2017; Walravens, 2015).

Reflecting on both technical/engineering and critical discussions on Smart City, the problem appears that these two plots are rather fragmented and do not acknowledge the complexities of urban governance and politics where social-technical dynamics of smart cities should be captured (Meijer, 2017). This becomes critical to examine under increasing complexity of society (Klijn, 2012) and its demands to unfold how to develop Smart City governance which somehow should balance between divergent actors' role in the development of the combined Smart City plot, i.e. bridging a fairy tale to reality. As a solution, Meijer (2017) proposes to see the construction of smart cities in term of "actors" (who are there in Smart City initiatives: private, public and civil society actors) "rules" (what guides the behavior of actors and how it is changed) and "games" (actors play data processing and technology developments in such a way that it maximizes their preferences for smartness). Within these dimensions, we need to move urban governance to the democratic direction where various actors try to win, including citizens.

As suggested by Smart City idea(l)s', citizens become the key actor in the development of Smart City initiatives (Torfing & Triantafillou, 2016). Broadly speaking, such ideological orientation goes with general contemporary discourses of Participatory Governance and New Public Governance which stress more wide citizens participation and involvement into decision-making related to cities' government (see e.g. Almquist et al., 2013; Fung, 2015; Grossi & Steccolini, 2014; Klijn, 2012; Osborne, 2010). From these perspectives, divergent voices/needs of citizens should be translated into political choices including agenda in relation to Smart City initiatives (Meijer, 2017), i.e. the local authorities will be accountable for 'smart' value creation in cities. In his sense, from Participatory Governance perspective, Smart City initiatives should be seen as an element of co-production (Fung, 2015) where citizens can be active contributors to complex problem-solving in government though bringing local knowledge (Lovan et al., 2017) and their participation gives ability of divergent/plural voices to be heard without consideration of people's current social status and whealth through delibration process (Fung & Wright, 2003).

Nevertheless, there is accountability problem in Smart City management (Grossi & Pianezzi, 2017; Huston et al., 2015), i.e. "practice of demanding and giving the reasons to conduct" related to value creation in cities (Robert & Scapens, 1985). Based on the critical examination, it can be argued that existing accountability mechanisms (e.g. financial and non-financial measures, performance and planning instruments) do not give the ability to include local citizens in real decision-making related to Smart City initiatives (Brorström et al., 2018). Similar concerns go to Participatory Governance, where the formation of deliberative democracy can be highly problematic (Aleksandrov et al., 2018).

Being motivated by this practical and theoretical conundrum along with increasing calls for critical evaluations of Smart city (Bibri & Krogstie, 2017; Meijer, 2017), we juxtaposing the existing critical literature on Smart Cities and dialogic accounting theory which is presented below. Despite its origination in critical accounting literature (Bebbington et al., 2007) and political ideas of agonistic democrats (Mouffe, 2000, 2005, 2013), during recent years dialogic accounting theory become increasingly employed in critical scrutiny of Participatory

Governance and New Public Governance agendas (Aleksandrov et al., 2018; Brown & Dillard, 2015a). In this way, applying to Smart City idea(l)s' development with the core role of citizens' involvement (Torfing & Triantafillou, 2016), dialogic accounting theory can be valuable to bring new insights into understanding of challenges in citizens' involvement into Smart City decision making and how it is possible to overcome these challenges.

Bringing dialogic accounting theory to Smart City: from deliberative to agonistic democracy view and taking divergent actors more seriously

Dialogic accounting theory (Bebbington et al., 2007; Brown, 2009; Brown & Dillard, 2015a, 2015b), being originated in sustainable development, social and environmental accounting studies, argues that value creation and its related non-financial and financial measures should be based on dialogue of divergent voices (Bebbington et al., 2007). Applying to Smart City discourse, the dialogue should be constructed among various actors where all interests should be aligned, decisions are based on consensus and knowledge constructed by all actors who want to intervene (but not necessary allowed). In such conditions, the dialogic process of Smart City construction for example would argue for creation of relations where the borders between citizens, technology companies, local authorities and political elites become fluid.

Nevertheless, under the dimension of dialogic approach, the existing practices of sustainability and environmental accounting rather claim for representation of one dominant voice of business and political elites, therefore, forming a monologue (Brown et al., 2015). Some similar concerns evident in Smart City plot which while encouraging for citizens engagement rather shows disappointing results (Bibri & Krogstie, 2017; Meijer, 2017).

The problem appears that while the literature already acknowledges the complex agenda of Smart City governance and its political nature (Meijer, 2017), the existing mechanisms of democratic engagement and dialogue are still based on idea(l)s of representative and now even more on deliberative democracy (Brown, 2009). In other words, the existing mechanisms of citizens involvement into Smart City and Smart City initiatives pretend to be deliberative while in reality they are not (Aleksandrov et al., 2018).

In this regard, Brown (2009) proposed moving from a deliberative and representative model of democracy to the agonistic one (Mouffe, 2000, 2005, 2013), which can influence our understanding how we approach democratic governance, including accountability relations and modes of governance in Smart City case. According to Brown and Dillard (2015b, p. 964), "democratic participatory governance requires that affected stakeholders and publics be able to scrutinize and debate the values and interests at stake from diverse perspectives". The general claim of political ideas of agonistic democrats in this regard is that any dialogue and its consensus, while requre pluralist actors to be heard, is also irrational and full of antogonism and conflicts where even if consensus is achived conflicts can remain with issues of power and domination (Mouffe, 2000, 2005, 2013). Based on these ideas, Brown (2009, pp. 319-320) criticizes the depoliticization of politics and the "difficulty dealing with the conflictual side of pluralist relationships" in deliberative democracy. The central benefit of the agonistic approach to the democratization of accounting is the acknowledgement of pluralism, difference, conflict and power struggles (Brown, 2009; Brown and Dillard, 2015a,b). In this regard, Brown (2009, p. 317) argues "for the legitimacy (and inevitability) of the 'political' in accounting" and its receptivity to the needs, voices and interests of plural society. Therefore, dialogue, in its turn, should be viewed as a complex politically-natured process with acknowledgment of pluralism, difference, ideological conflicts and power dynamics (Brown, 2009).

Based on an agonistic view of democracy, Brown (2009, pp. 324-238) proposed eight principles underpinning dialogic theory that can also be applied to Smart City. We summarize these principles with reflection to Smart City initiative development and citizens role within (Table 1).

Principle of dialogic accounting	Application for Smart City
1. Recognition of multiple ideological orientations	During development of Smart City initiatives, we should recognize that actors are different and 'account' for different things in different ways. Therefore, Smart City should recognize divergent ideological perspectives and give a 'voice' to all of them, as this gives a basis for exploring people's commonalities and differences.
2. Avoiding monetary reductionism	Smart City initiatives should provide a range of quantitative and qualitative data for individuals and groups, who can see diverse effects for themselves and make their own judgements about monetization, incommensurability and the extent to which they are prepared to make trade-offs.
3. Openness about the subjectivity and contestable nature of calculations	Smart City initiatives should not gloss over conflictual aspects of pluralist relations. The 'accounts' introduced should be open to being contested and challenged by other participants.
4. Enabling access for non-experts	Smart City initiatives should enable information to be accessible in technically understandable forms which are available for testing by non-experts.
5. Ensuring effective participatory process	Smart City initiatives should be organized with procedural rules designed to establish a more even 'playing' field and with developing broader structural change.
6. Attention to power relationships and their dynamics	Smart City initiatives should be aware that it wields considerable power and authority, giving a space for powerful elites to sustain and filter the big data and initiatives. During smart technology introduction, even when relations are win-win, asymmetric power relations mean that some groups may win far more than others.
7. Recognizing transformative potential of dialogic accounting	Smart City initiatives and mechanisms of involvement should encourage social actors to become more critically reflective and facilitate better discourses across groups with different perspectives. This assists in bringing the limiting beliefs and assumptions of all actors into consciousness and allows them to contest each other's limit situations.
8. Resisting new forms of monologism	Smart City initiatives and mechanisms of involvement should not be only about dialogic rhetoric where the 'banking' concept of communication in which speakers 'deposit' their beliefs is introduced or through dialogic means still aims to guide people to a predetermined 'right answer'.

Table 1. Principles to underpin dialogic accounting theory and its application for Smart City (adopted and based on Brown, 2009; Brown and Dillard, 2015a,b)

Reflections on existing Smart City ranking and models within European countries from dialogic accounting theory (in progress)

It is argued in this paper that existing accountability mechanisms do not give ability to include local citizens in real decision-making related to Smart City initiatives with rather symbolic roles attached to the citizens and in monologic developments of governance. By considering the existing Smart City rankings and frameworks within European counties that contain financial and non-financial measures, performance and planning instruments we can reflect on how dialogic theory principles can be applied to it.

Smart City rankings and frameworks have been flourishing in the recent years due to the growing interest in the smart city initiatives. They are necessary to assist decision makers among other things to assess cities' progress (Ahvenniemi et al., 2017). It exists several smart city assessment frameworks and rankings that have been developed to assess city's performance measurement systems.

European Smart Cities Ranking (R. Giffinger et al., 2007; Rudolf Giffinger & Pichler-Milanović, 2007) is the result of research project finished in 2007 and conducted by Vienna University of Technology, University of Ljubljana and Delft University of Technology. This ranking deals with medium-sized cities and their perspectives for development. Among the recommendations of their ranking Giffinger et al. (2007) state that more differentiated approach of relevant factors will provide information for policymakers and interested stakeholders. European Smart City Ranking contains six characteristics: smart economy, smart people, smart governance, smart mobility, smart environment and smart living. Giffinger et al. (2007, p.11) come up with the following definition: “A Smart City is a city well performing in a forward-looking way in these six characteristics, built on the ‘smart’ combination of endowments and activities of self-decisive, independent and aware citizens.” To operationalize this ranking, the 31 factors and 74 indicators (Giffinger et al., 2007, p. 11) have been identified hierarchically. Data on indicators is drawn from public and freely available databases (e.g. political activities of inhabitants, satisfaction with fight against corruption, unemployment rate and voters turnout at city elections, etc.) used to impute six characteristics of the smart city. The indicator values are transformed into standardized values and furthermore aggregated to the factors based on coverage rate of each indicator (Giffinger et al., 2007). European Smart Cities Ranking claims that it includes a mixture of local settings and activities carried out by politics, business, and the inhabitants. It is stated that this ranking should consider among other things awareness as “it seems important for a smart city as certain potentials can only be mobilized if inhabitants, companies or administration are aware of the cities position – knowing the city from the inside but also being aware of the surroundings and the system of cities the city is located in” (Giffinger et al., 2007, p. 10). As benchmarking tool, it provides a way to draw lessons from better performing cities or perhaps resulting in policy transfer. The process of data collection and analysis as being transparent and being reproducible by others is as important as possibility to produce ranking depending of the user of the information and his/her needs (Giffinger et al., 2007).

CITYkeys performance measurement framework for monitoring and comparing the implementation of smart city solutions (Huovila et al., 2016) is the project deliverable of EU-funded project (under the Horizon 2020 program) authored by by TNO (Netherlands), AIT (Austria), and VTT (Finland). This framework assists in conducting project and city level assessments. CITY keys represents the selection of indicators that can function as Key Performance Indicators for tracking the progress towards city and project objectives (Bosch et al., 2016). This framework is organized around such categories relevant for smart cities: people, planet, prosperity, and governance (Huovila et al., 2016). In developing smart cities KPIs, Bosch et al. (2016) define smart city as “a city that efficiently mobilizes and uses available resources (including but not limited to social and cultural capital, financial capital, natural resources, information and technology) for efficiently improving quality of life of its inhabitants[…], significantly improving resource efficiency, decreasing its pressure on the environment and increasing resiliency, building an innovation-driven and green economy, and fostering a well-developed local democracy” (p. 6). CITYkeys performance measurement system has been developed based on mapping the identified needs against 43 existing sustainable and smart urban performance measurement systems and their indicators and filling the identified gaps (Huovila et al., 2016). Data on indicators is based on available information about smart city projects with IT component describing all kinds of inputs and outputs that it then generalized to be able to cover many different projects (Bosch et al., 2016, p. 15). The KPIs for smart cities under the defined categories include such indicators as data privacy, innovation hubs in the city, citizen participation, etc. Bosch et al (2007) claim that CITYkeys assessment method and indicators are supposed to assist to evaluate the success of smart cities and what are the possibilities to conduct these projects in other contexts. It also builds on specific policy goals that can be a part smart city strategy. This performance measurement framework as developed by Bosch et al. (2016) answers the wishes of cities and citizens for the coverage of their priorities and reflects city goals.

Endnotes:

[1] Monologic accounting and accountability are associated with the production of conventional mainstream which is overwhelmed by the pre-given values/ assumptions of neo-liberal and capitalism ideologies (Brown, 2009).

[2] Critical dialogic principles (Brown, 2009; Brown & Dillard, 2015a, 2015b): recognizing multiple ideological orientations; avoiding monetary reductionism; being open about the subjective and contestable nature of calculations; enabling accessibility for non-experts; ensuring effective participatory processes; being attentive to power relations; recognizing the transformative potential of dialogic accounting; resisting new forms of monologism.

Research on Sustainable Design of Historical Blocks Based on Inhabitant Social Integration Measurement: A Case Study of Harbin

(Research on Sustainable Design of Historical Blocks Based on Inhabitant Social Integration Measurement: A Case Study of Harbin)

Zihan CAI, Harbin Institute of Technology, China
Ming LU, Harbin Institute of Technology, China

Abstract: The inhabitant behavior is the important part of the sustainable vitality for the historical blocks. In order to solve the conflict between inhabitant life and commercial tourism in the renewal of Chinese historical blocks, this paper proposes the sustainable design strategy for the vitality of historical blocks from a perspective of inhabitant social integration. Base on the theory of social integration and taking the DaoWai Historical Blocks in Harbin as an empirical case, the paper constructs the evaluation model of inhabitant social integration, uses the confirmatory factor analysis method to quantify the influence factor and its weight of inhabitant social integration by structural equation model (SEM). Empirical research proves that behavior and culture has a significant impact on the social integration. In the end, the paper discusses the sustainable design strategy of historic blocks from the five dimensions of behavior, culture, industry, space and management, and the emphasis of sustainable design should be put on the improvement of behavior and culture.
Keywords: Sustainable Design, Social Integration Measurement, Inhabitant, Historical Blocks

1. Introduction

The sustainable design of urban historic blocks aims not only to improve a dilapidated physical environment but also to redistribute and integrate spatial resources under scarce and confined spatial conditions. Its essence is to restore the cultural vitality and historical characteristics of such street blocks while protecting the interests of various groups and social communities. Urban vitality originates in the economic, social, and cultural interaction between people and the urban public space (Jiang, 2007). The interweaving of people, their activities, and their places of residence helps create diversity in urban life, thus nurturing its vitality (Jacobs Jane, 2006). The sustainable design of historic blocks is a necessary means to maintain economic and cultural vitality as well as the vitality of the social community of such districts.

The Venice Charter advocates the protection of the authenticity of historic spatial environments (Xu, et al., 2010). The key to revitalizing historic blocks is to retain residential inhabitants while conserving their lifestyle (Ruan, 2011). The focus of protection should be the life of the people. Protecting the lifestyle of the inhabitants is a central factor in maintaining the vitality of historic blocks as they undergo renovation (Yuan, et al., 2010). Only small-scale, gradual reconstruction based on the needs of the inhabitants can achieve the sustainable development of historic blocks (Xia, 2008), which is the fundamental means to increase the vitality of such blocks. In the reconstruction and revitalization of historic blocks solely under the guidance of economic values, emphasis is only placed on spatial improvements brought about by the renewal plan and economic growth due to the marketing effect. A thorough understanding of the renewal and a proper distribution of political rights and economic interests among all stakeholders are ignored. This approach will result in a so-called “space bubble” and intensify social contradictions (Chi, 2010; He, 2012; Zhang, et al., 2013).

China has witnessed the emergence of “hollow blocks” in many historic districts. Except for activities that occur during public holidays and daytime business hours, the hollow historic blocks are devoid of popularity and deserted by residents. It is impossible to sustain the internal organic vitality in these blocks. It is also impossible to meet the increasing demand for a satisfying touristic experience. Because of the emphasis on reconstruction and profitability, historic blocks have not performed well in terms of the social inclusion of inhabitants. Conflicts between inhabitants and developers are often rooted in unjust choices among interests. In many aspects, such as lifestyle, survival style, or social status, it is difficult for inhabitants to integrate their lives with tourism development in historic blocks. To socially integrate the inhabitants of historic blocks and sustain the organic vitality of such blocks, this paper constructs a theoretical model for measuring inhabitant social integration. Using survey data collected from inhabitants of Harbin’s DaoWai historic and cultural blocks, the paper adopts confirmatory factor analysis of structural equation modeling (SEM) to analyze the statistical data. In addition, a quantitative study on the influencing factors and their weights with respect to inhabitant social integration is performed. Subsequently, we propose a design strategy to achieve the sustainable vitality of the historic blocks while ensuring the social integration of inhabitants.

1.1 Sustainable Design

Sustainable design includes not only the sustainability of the environment and its resources but also that of society and culture. It is a strategic design activity for the construction and development of sustainable solutions, which weighs economic, environmental, moral, and social issues in a balanced manner while considering design guidelines and the satisfaction of consumer demand (Crosbie M J, 1994). Sustainable design requires the harmonious development of individuals and their environment as well as products, services, and systems that meet the needs of the present generation while ensuring sustainable future development (Szokolay S , 2004).

Sustainable design has four attributes: natural attributes, social attributes, economic attributes, and scientific and technological attributes. As such, it requires that the human living environment be sustained while the quality of human life is improved. The net benefits of economic development are increased to the maximum under the premise that the quality of natural resources and their services are maintained while the consumption of energy and other natural resources is reduced as much as possible (Azhar S, et al., 2011). The sustainable design of historic blocks involves the integration of the socio-economic culture in spatial management. The vitality of historic blocks entails adopting sustainable development in planning and design and using spatial planning to the greatest extent possible to realize the sustainable vitality of such districts.

1.2 Social Integration Measurement

Social integration, which became the core concept of Western social policy research and social policy practice in the early 21st century, has been widely encouraged by government, social policy research, and decision-makers. The definition of social integration by the European Union (EU) in 2003 can be summarized as follows: Social integration is a process to ensure that socially vulnerable groups have access to development opportunities and resources; participate in economic, cultural and social activities; receive social benefits; and receive significant opportunities to participate decision-making (Regina, 2002). The measurement of social integration was pioneered by Park and Burgess, who proposed a view of social integration in which four aspects interact: economic competition, political conflict, social connection, and cultural integration (Park, 1928). Landecker divided social integration into cultural integration, communicative integration, functional integration, and normative integration (Landecker, 1951). Subsequently, many sociologists divided the classification system of social integration measurement into more specific levels. The EU has also played an important role in the design of a social integration indicator system. In

December 2001, the Indicators' Sub-Group (ISG) of the EU's Social Protection Committee proposed 18 indicators divided into two levels: primary indicators and secondary indicators. In June 2006, the Social Protection Committee divided the social integration and social protection indicators into four major composite systems: overall indicators, social integration indicators, pension indicators, and health- and long-term care indicators (Lu, 2014). Different from in other countries that face immigration issues, social integration measurement in China focuses on the social integration of migrant workers, other migrants, urban new immigrants, and other groups (Chen, et al., 2015; Huang, 2011; Yue, et al., 2012).The measurement dimensions include economic integration (Huang, 2011; Yang, 2010), psychological integration (Yang, 2016; Zhang, et al.,2008), cultural integration (Lu, 2014; Yue, et al., 2012), identity integration (Chen, et al., 2015; Yang, 2010; Zhou, 2012; Ren, et al.,2010; Wang, et al., 2008), and community integration (He, et al., 2009). In the literature on social integration, little scholarly attention has been devoted to the inhabitants of historic blocks.

1.3 Inhabitant Social Integration Measurement

Inhabitant social integration introduces the concept of social integration into the revitalization of historic blocks. Inhabitant integration is based on social justice and harmonious integration. It emphasizes fairness regarding cultural, economic, environmental, and behavioral integration in the protection and development of historic blocks and planning ideas that are not solely oriented toward economic development. Attention is paid to the inhabitants' life model and group interests. Drawing on the social integration measurement of new urban immigrants (Zhang, 2008) and the Sydney Urban Frontiers Program (UFP) for socially vulnerable groups (Li, et al., 2004), a system is constructed to measure inhabitant integration in terms of behavior (Yang, 2010), culture (Zhou, 2012), industry (Zhang, et al., 2008), space (Zhang, et al., 2016; Lu, et al., 2017; Cai, et al., 2018), and management (Lu, 2014). The specific integration dimensions include the integration of inhabitant behavior and tourist behavior, neighborhood culture and business culture, the employment economy and the business economy, living space and tourism space, and public management and public participation.

(1) Behavior integration dimension

Behavior integration includes a wide range of aspects, such as interpersonal communication, living habits, community participation, and social behavior. The integration of two groups requires that one group is universally accepted by the other in daily life and the private domain (Blau, 1977). To integrate inhabitant behavior and tourist behavior in historic blocks, inhabitants must accept tourist recreational activities in their living environment. Regular disturbance of inhabitants by tourism should be minimized. The goal is to ensure that the inhabitants' life rhythm remains unchanged and their behavior and habits are respected. It is also necessary to incorporate the customary activities of historic block inhabitants into tourism activities. The integration of inhabitant and tourist behavior should be accomplished while avoiding disruption, providing protection, and encouraging conservation.

(2) Cultural integration dimension

The cultural integration of historic blocks requires tourism development to recognize the culture, local customs, and social concepts that prevail in historic districts. The goal is to overcome the impasse between preserving the traditional neighborhood culture and tourism development. The integration of neighborhood culture and the tourism business culture is the key to realizing the social integration of inhabitant communities in historic blocks. The recognition of traditional culture is based on respect for the culture of a historic block. The business culture created by tourism development should respect existing traditional forms of business and seek to continue an area's original forms of commerce and trade. In this manner, the integration of a traditional neighborhood culture and a business culture can be achieved. Appropriate measures must to be adopted to reduce the commercialization of folk cultural activities and restore the authentic tradition of the historic block. In this way, the contradiction between street culture and tourism culture can be eased.

(3) Industrial integration dimension
The revitalization and development of historic blocks inevitably results in the pursuit of economic benefits by profit-making industries. The tourism industry can bring substantial economic benefits from tourists. However, the realization of industrial integration in historic blocks must address the gap between the inhabitant employment level and the requirements of commercial companies. Industrial integration means the interpenetration and intersection of products from different industries or within the same industry and the eventual formation of a new, unified industry (Li, 2003). Inhabitant employment by companies undertaking the renewal of historic blocks, the comprehensive consideration of business selection criteria, and classifying business types to satisfy multiple demands will help integrate inhabitants into the renewed local economy. In this way, inhabitants can be involved in the life model of "integrating industry with living".
(4) Spatial integration dimension
In terms of social space, a city is a community with an internal growth mechanism that integrates various components. "Organic unity" and "mechanical unity" are different forms of organizing people. People occupy different spatial positions as a result of their differing occupations, status and prestige. The greater that the social differentiation is, the more complicated its spatial structure (Yang, 2014). The spatial integration of historic blocks is the counterpart of the corresponding spatial differentiation. In the process of planning and revitalizing historic blocks, preserving the inhabitant's living conditions inevitably results in the heterogeneity of tourism space and living space. The realization of spatial integration refers to how the physical spatial layout organically divides or integrates the areas in which the inhabitants live and the public places of tourism. In moving toward commercial development, the planning of historical blocks should give priority to considering the disruption of the living environment caused by tourist activity and improving the sharing of resources from public facilities.
(5) Management integration dimension
The most obvious means of inhabitant social integration is to establish a sound public participation mechanism and increase the level of public participation. The management of inhabitant communities and the commercial management of revitalized historic blocks can be integrated in a "two-in-one" approach (Liu, et al., 2017). In this manner, the public interest is represented on the same platform as the commercial interest, forming an integrated management plan in which these interests are balanced. This approach should be implemented throughout the process of revitalizing historical blocks. At each point, the functions of decision-makers and management and the rights of inhabitants should be clarified. The goal is to construct a platform for dialogue regarding the implementation of measures and strategies, to arrange a process of public management, and to establishing a long-term feedback mechanism in an integrated public management system.

2. Methodology

2.1 Data
The data used in this paper were collected by the Research Group of the Humanities and Social Sciences Project Fund of the Ministry of Education in the Study of Inhabitant Social Integration in the Revitalization of Historic Districts. The research team visited Harbin's DaoWai historic and cultural block in the traditional commercial city from June to July 2017 and conducted social surveys there. Harbin's historic and cultural traditional commercial city conservation block exemplifies the Chinese Baroque style. It is the largest such preserved area in China. Constructed in the 1920s and 1930s by Chinese artisans in DaoWai, the buildings imitate Western Baroque architectural styles with additional traditional Chinese decorative patterns. These structures are of important historic and humanistic value and are internationally influential.
To obtain relatively high-quality, first-hand data, the investigators established a team of trained master's degree and doctoral students. A total of 305 questionnaires were distributed, and 282 valid questionnaires were recovered. The recovery rate was 92.46%.

Of the 282 samples (see Table 1), 146 were completed by men and 136 by women. Of the respondents, 27% were 40-50 years of age. Inhabitants identified as business owners represented 92.2% of the total sample. A total of 22.7% of the inhabitants had resided in the district for 20-30 years. The monthly income of resident inhabitants was not high, with 41.5% of the total sample earning between 1,000-3,000 RMB/month. The data sample used in this paper was primarily based on a survey of the inhabitants of the protected area of the DaoWai historic block (purple line) and did not include the inhabitants who had moved out.

Table 1. Demographic and Social Characteristics of the Samples

Variable	Category	Freq	PCT	Variable	Category	Freq	PCT	Variable	Category	Freq	PCT
Gender	male	146	51.8	Identity	owner	260	92.2	Family	Couple	52	18.4

	3000-5000	100	35.5		Junior College	42	14.9		South 9th	29	10.3
	5000-10000	48	17.0		Undergraduate	4	1.4		South 10th	37	13.1
	>10000	10	3.5		Postgraduate	2	0.7		North 4th	33	11.7

2.2 Study Measurements

The survey method combined subjective questionnaires and semi-structured interviews. The scale used a 5-level Likert scale with the following response options: 1 (strongly disagree), 2 (disagree), 3 (neutral), 4 (agree), and 5 (strongly agree). The questionnaire was completed based on subjective feelings. The questionnaire consisted of two parts. The first elicited basic demographic information from the inhabitants. There were 10 items. The second surveyed the inhabitant social integration response indicators. There were 19 measurement items. SPSS 21.0 statistical software was used to conduct the preliminary collation and inspection of the survey data. The data were checked and corrected, and abnormal data were eliminated. Missing data were replaced with average values. A reliability analysis was performed on the 19 measurement items contained in the questionnaire. The Cronbach's Alpha of the data sample was 0.927, which met reliability requirements. In addition, the results of Bartlett spherical test and KMO value analysis showed that P value was 0.000($P < 0.001$), and the Bartlett spherical test was satisfied. The KMO value was 0.908. Therefore, the sample data were suitable for factor analysis, and the validity of the scale satisfied normal standards.

3. Model and Statistics

3.1 Measurement Model

The hypothetical theoretical model adopted to measure inhabitant social integration is a structural equation model using confirmatory factor analysis. In the model, social integration is an exogenous latent variable that is measured using five dimensions. Behavioral integration, cultural integration, industrial integration, spatial integration, and management integration are assigned corresponding indicators as external observation variables. The final social integration measurement model contains 19 observation variables and five latent variables. (see Table 2).

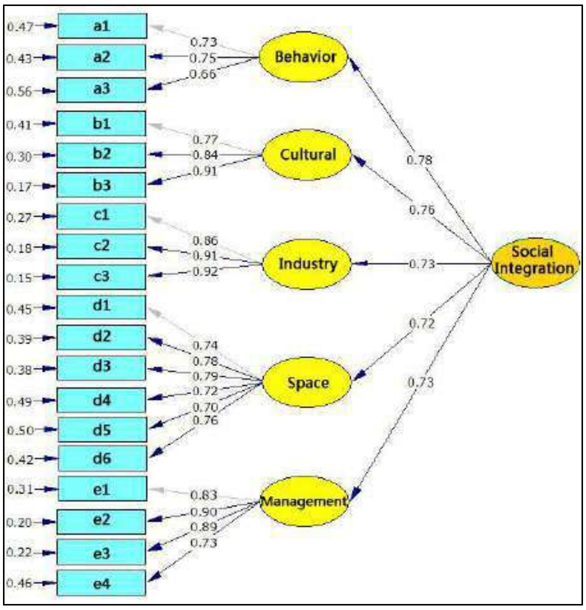
Table 2. Evaluation Model of Inhabitant Social Integration

Latent Variable	Latent Variable	Observational Variable	Code
Social Integration	Behavior	Neighborhood Communication	a1
		Social Community Network	a2
		External Disturbance	a3
	Cultural	Folk Cultural Activities	b1
		Community Cultural Atmosphere	b2

Latent Variable	Latent Variable	Observational Variable	Code
		Local Cultural Elements	b3
	Industry	Degree of Employment	c1
		Degree of Starting a Business	c2
		Traditional Store Management	c3
	Space	Living Infrastructure	d1
		Private Living Space	d2
		Living Environment Quality	d3
		Transportation Convenience	d4
		Public Space Sharing	d5
		Public Facilities Sharing	d6
	Management	Organization Group	e1
		Degree of Participation	e2
		Public Discourse Right	e3
		Management Evaluation	e4

3.2 Statistical Analysis

LISREL8.0 was used to perform the second-order confirmatory factor analysis of the measurement model. The maximum likelihood estimator method was used to estimate the model parameters to obtain the model's parameter estimation results and the standardized path coefficients (see Fig.1). T-test was used to examine the significance of the path coefficients (see Fig.2).



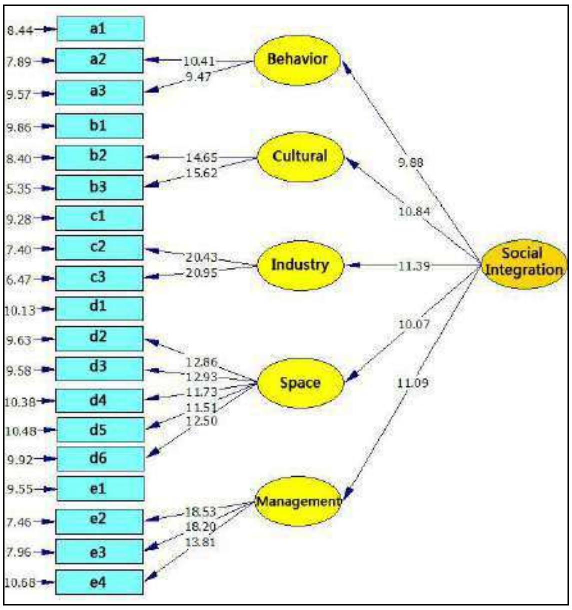


Fig.1. Normalized Path Coefficient of Model *Fig.2. T-test of Model*

The results indicate acceptable model fit. The chi-square value is 307.47, the degree of freedom is 203, and the ratio of the two is 1.51. The P-value is 0.000, and the RMSEA value is 0.043. Other indexes of fit are all within an acceptable range: NFI (0.97), NNFI (0.99), CFI (0.99), IFI (0.99), RFI (0.97), and AGFI (0.89). The overall model fit is good. Therefore, the inhabitant social integration measurement model constructed in this study is statistically supported.

3.3 Results

The study finds that the dimensions behavioral integration and cultural integration have higher path coefficients. Their standardized path coefficients are 0.776 and 0.772 (see Table 3). This outcome indicates that based on the data sample for Harbin's DaoWai historic and cultural blocks, behavioral integration and cultural integration have a more significant impact on social integration. In contrast, industrial integration, spatial integration, and management integration should be improved to more effectively promote social integration.

Table 3. Measurement Result of Structural Equation Model

Observational Variable to Latent Variable				Latent Variable to Latent Variable	
Outer loading (t-value)		Outer loading (t-value)		Path Coefficient (t-value)	
a1←Behavior	0.730(----)	d1←Space	0.737(----)	Social Integration →Behavior	0.776(9.89)
a2←Behavior	0.758(10.355)	d2←Space	0.784(13.224)	Social Integration →Cultural	0.772(10.94)
a3←Behavior	0.660(9.561)	d3←Space	0.788(13.285)	Social Integration →Industry	0.723(11.10)
b1←Cultural	0.771(----)	d4←Space	0.720(12.090)	Social Integration →Space	0.717(10.45)
b2←Cultural	0.839(14.983)	d5←Space	0.693(11.389)	Social Integration →Management	0.730(11.12)
b3←Cultural	0.909(16.048)	d6←Space	0.755(12.401)		
c1←Industry	0.858(----)	e1←Management	0.832(----)		
c2←Industry	0.906(20.290)	e2←Management	0.899(18.620)		
c3←Industry	0.921(21.148)	e3←Management	0.885(18.329)		
		e4←Management	0.733(13.834)		

The explanation of these outcomes can be understood as the failure to reconstruct the existing multi-story residential buildings in the conservation area during the redevelopment of the DaoWai historic and cultural blocks. Some of the district's inhabitants still live there, maintaining their original living conditions and social networks. The neighbor relationships are good, and interactions are frequent. The study period was during block reconstruction, at a time when only two blocks (South 2nd to South 4th Street) had been completed. From the perspective of all the district's blocks, the trade and tourism capacity was small, and there was not much disturbance of the inhabitants. Therefore, inhabitant behavioral integration played a large role in the social integration. The cultural heritage of the neighborhood's original ecology remained intact. Even during the reconstruction period, the original street business culture of the district remained in evidence, and the new tourist and cultural projects did not undermine the original condition of the blocks. These facts highlight the cultural integration of the blocks. However, commercial development did not facilitate inhabitant participation in employment and entrepreneurship. In terms of the space, because redevelopment and reconstruction remains incomplete, separation between inhabitant living space and commercial space has not been achieved. The management of the blocks is dominated by the government office in charge of the reconstruction. A so-called "self-living and self-governing" inhabitant-based management model has not been formed.
Therefore, the variables with higher correlation path coefficients must maintain their current status and improve reasonably as the project continues. Those variables with lower correlation path coefficients represent key dimensions with respect to evaluating inhabitant integration in future block planning.

4. Discussion

There is a statistically significant correlation between the dimensions of the inhabitant social integration measurement and the observed variables in the model. By comparing the loadings of the measurement factors in each dimension, the overall level of inhabitant social integration in the blocks and the factor weight can be quantified. In this manner, one can guide subsequent revitalization planning in the historic blocks and generate ideas for combining theoretical techniques and an econometric model for historic block planning strategies. This paper uses Harbin's DaoWai as an example to investigate sustainable design strategies for historic blocks based on the measurement of inhabitant social integration. From the perspective of improving the infrastructure and spatial environment, the paper suggests integrating social, cultural, economic, and environmental benefits to create a residential, commercial, cultural, and tourism center that reflects DaoWai's traditional business environment and an atmosphere of folk culture and that is adapted to inhabitant needs.

4.1 Behavioral integration promotes interaction and reduces host-guest conflicts

Planning should first consider a compensation plan for inhabitants who had to relocate during the initial stage of reconstruction. This plan should balance the interests of multiple parties from the perspective of interactive decision-making familiar from game theory. It must also reduce conflict as much as possible and retain as many inhabitants as possible, i.e., ensure a stable inhabitant retention rate. The property rights of the inhabitants who choose to stay should be adjusted to protect and preserve long-established houses and courtyards and the ecology of the historic blocks. In consideration of the original texture of the blocks, more public space, such as “pocket parks”, should be laid out spatially, and green nodes with a radius of 100m should be planned (see Fig.3). Green spaces should separate the living space used primarily by inhabitants and the tourism space so as to enhance exchange and communication in the inhabitants’ community and improve the eco-environmental quality of the blocks.

Fig.3. Pocket green space planning

4.2 Regeneration of cultural resources and the creation of traditional folk brands

Symbols of the traditional culture and the identity of the historic blocks should be protected and widely used in the architecture and design of large and small structures to improve the district’s visual and acoustic appearance. The historical and cultural elements in the conservation area should be revitalized, and a reasonable tourism capacity should be planned. Considering the need to reduce the impact on the inhabitants, tourism traffic should be strictly controlled to promote sustainable, stable tourism development in the historic blocks. The tourist routes planned for the conservation areas are shown in Fig.4-5. Inhabitant participation should be strengthened, and emphasis should be placed on creating historic building tourism products, traditional courtyard tourism products, special cultural tourism products, and non-material cultural folk products. These products should highlight the brand tourism image of DaoWai’s authentic and original Chinese Baroque style.

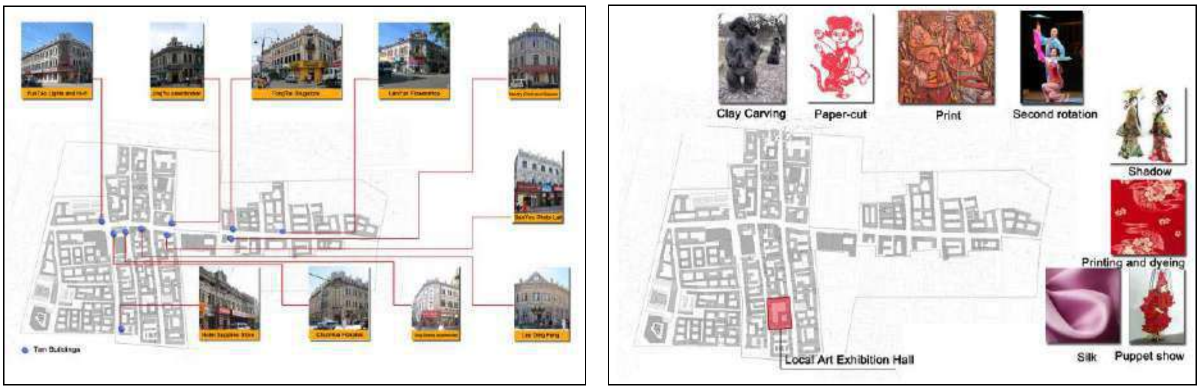

Fig.4-5. Tour of Historical buildings and Folk Art

4.3 Sharing the benefits of industrial resources and promoting innovation and entrepreneurship

The original business conditions in the historical blocks should be adequately preserved. In particular, historic stores with long-established brands and products that exhibit traditional craftsmanship should be protected. The creation of a tourism industry and the selection of relevant companies should complement the characteristics of the local blocks to achieve a distinctive integration and unity. Lifestyle and service business representatives should be improved and supplemented to form an attractive image of the full-scale upgrade and revitalization, giving the blocks appeal as "a place for living, a place for shopping, and a place for tourism". Priority should be awarded to employing local inhabitants and improving their residential areas. The goal should be to realize a lifestyle of "living here and working here". The internal power cycle of the historic blocks should be stimulated. Worn urban spaces should be rejuvenated while retaining historic artifacts. The importance of protecting the material and intangible cultural heritage should be emphasized. A commercial layout with new function implantation, functional replacement, and a functional mix should be implemented rationally (see Fig.6). Inhabitant integration should be the primary goal, with priority given explicitly to commerce, leisure travel, and livability. The vitality and value of the blocks should be increased by emphasizing the development of high-density commerce through a functional and spatial mix of business projects.

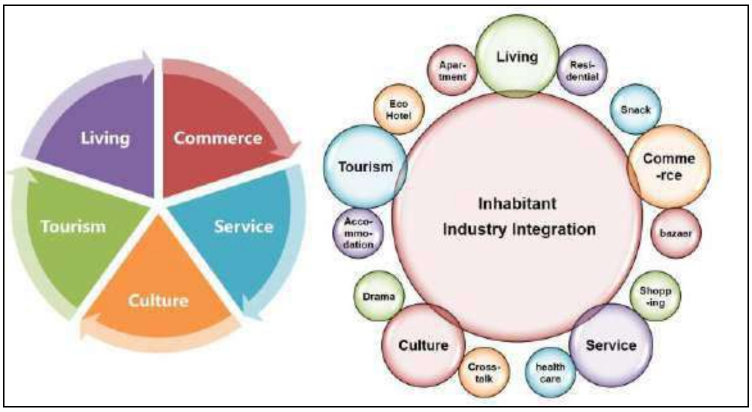

Fig.6. Industrial structure and project planning

4.4 Integrated layout of the spatial environment and people-oriented planning

The planning of historic blocks should divide quiet areas from busy areas to achieve functional separation. In addition to updating commercial areas, residential areas should be updated to preserve their livability for the inhabitants. The first floors of buildings should be planned to host commercial functions, and the second and third stories should be restored to the residential function. A hybrid of commercial and residential spaces should be planned to solve the problem of living space for inhabitants, including renting or selling apartments (Figure 3.18). The plan should emphasize the construction of eco-networks in the blocks and improve the capacity of ecological public services. Plant landscaping and landscaping techniques for small facilities can be used to isolate residential space from business and commercial space. Signs that identify private residences can be used to minimize the conflict arising from the mutual disturbance of hosts and guests in the historic blocks. Within the planning area, there are five functional subdivisions, with Jingyu Street and its traditional commercial axis stringing together various functional subdivisions and forming a spatially integrated tourism-business-residence layout (see Fig.7-8). In addition, the inhabitants' social integration should be incorporated into the planning, and planning decisions should emphasize the measurement and evaluation of inhabitant social integration. The level of detail of the published rules should be enhanced, and the existing approval procedures should be supplemented to benefit inhabitants.

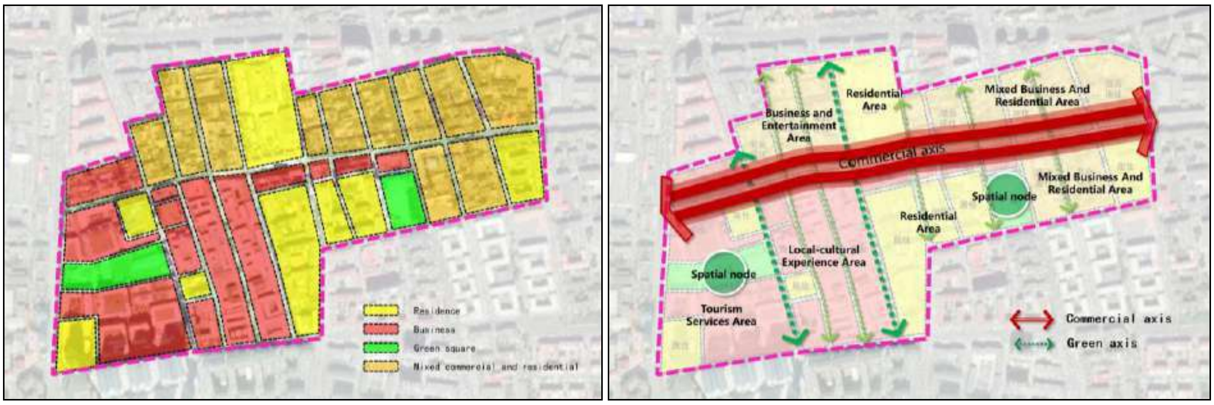

Fig.7-8. Land use and spatial structure planning

4.5 Integrating strictness and flexibility in management and promoting public participation with multiple subjects

A management committee should be jointly formed by inhabitants, business owners, and management decision-makers to uphold the interests of all parties in the implementation of conservation area planning. In addition, community public management entities should be established to supervise the management and development of the conservation area. The long-term follow-up service for planning implementation should be improved, and a long-term feedback mechanism for public planning management should be established. Inhabitant interest groups in the historic blocks should be established, and the financing of the revitalization of the blocks should be formulated and discussed in phases. To improve plan implementation, control must be exercised over the development of the land within the plan's scope, including the environmental landscape. The control management has three parts: prescriptive indicators, guiding indicators, and picture-based guidance. The specific control and management requirements are presented in the form of plans. Planning requirements should be normalized, and planning management should be implemented in accordance with a legal plan to ensure that inhabitant interests are optimally respected in the arrangement of public facilities.

5. Conclusion

With the change of historical heritage protection policy environment in China, the renewal of historical blocks will not only highlight the protection and preservation of the original historical material objects, and also will be more and more towards to the transformation of the traditional cultural protection and community humanistic sustainable development. This paper proposed the evaluation model of inhabitant social integration, and quantify the influence factors and their weights by the confirmatory factor analysis method of structural equation model, then resulted that the point of the sustainable design is the behavior integration and cultural integration according to the evaluation model measurement. Further, we suggest the sustainable design strategy, which provides a new perspective and approach to solve the conflict between trade tourism and inhabitant in the process of renewal and revival of historical districts. It provides new ideas and means for activating historical districts and realizing sustainable development.

ABSTRACT:

South African settlements were planned and continue to develop in maladaptive ways with the most vulnerable households living on the urban periphery in sprawling settlements, far removed from the formal urban economy, public transport and amenities. The spatial configuration and the ways in which land is used and developed in South African settlements is often unsustainable and place communities and settlements at risk of, among others, the impacts of climate change. Place-based adaptation of the built environment, cognisant of the urbanisation challenges, will protect the development gain, contribute to the resilience of settlements and address their development goals. The objectives of the presentation are to: 1) Briefly present the evidence of the future risk trajectory of South African settlements as the rationale for the type of adaptation options that were selected from good practice examples. 2) Discuss the general urbanisation challenges and development goals of South African settlements in light of climate change adaptation. 3) Explain the process of how place-based adaptation options were linked to each settlement’s risk profile. 4) Consider the implications for policy and practice in South Africa as well as other countries with similar development contexts. For this body of work, climate change projections over South Africa were downscaled to an 8x8 km resolution. The projections allowed researchers to model future hazard trends to better understand the impacts of climate changes on settlements. Combined with future vulnerability scenarios, the future risk trajectories of settlements in South Africa could be determined. A menu of adaptation options in the urban planning domain were compiled from examples of good practice. Based on the future risk trajectory, the urbanisation challenges and development goals of South African settlements, specific place-based options were proposed per settlement. The finding include that, based on climate change projections, South African settlements will in future generally become hotter and drier. Risk of future extreme events in settlements include flooding, drought, coastal and inland storms, and heat waves. This complicates the urban context even more. Key challenges include water, food and energy security, poverty, informality, inequality, service and infrastructure backlogs, lack of funding, capacity and political will to implement adaptation options, etc. Adaptation options that are place-based and context-specific will be showcased, while also reflecting on the process of developing these adaptation solutions. This body of work will 1) assist municipalities to adapt urban planning and development practices to climatic changes in line with development goals, 2) influence policy development at the urban planning/climate change adaptation nexus, and 3) identify priorities for mainstreaming climate change adaptation into local development planning. The project findings, methodology and outcomes will be of interest to many other countries with similar development and capacity challenges at the local scale as South Africa.

Towards setting up a contemporary planning system

Cool Planning for Qatar urban future

Nagy ELGIRTLY & Noora AL SUWAIDY, Ministry of Municipality and Environment (MME), Qatar

Abstract

This paper emphasizes the vital role that the Urban Planning Department – **UPD** of Qatar can play, and how to enable it to implement both the New Urban Agenda[i], and the Sustainable Development Goals[ii]. Such UPD role should be integrating, matching with and responding to the Qatar local planning context.

Throughout this paper, we will show how to assist **UPD** as a professional entity to plan for a sustainable urban future for Qatar. In addition, it will elaborate how to create an effective, efficient and a creative professional atmosphere through building networks and alliances with respectable international, regional and local academic and professional institutions such as (**ISOCARP** – **URA** Singapore – **APA** American Planning Association – Qatar Foundation **QF**– Qatar University **QU**).

This paper attempts to cover the newly emerging planning system in Qatar in an analytical context that highlights the positive aspects achieved in reality and accommodates the challenges. It is expected to conclude with a set of recommendations in which we adopt mechanisms for dealing with those challenges in the future.

Introduction

Over the past twenty years, Qatar's development program has made great strides where it has experienced a rapid growth in the urban areas, which has brought about fundamental changes to the physical built environment. This requires to set up an integrated Planning System.

In order to deliver this goal, this paper is divided into **Four** main parts: the first one provides a synopsis of Qatar (its historical background and existing status), the relevant planning authority "**UPD**" and the Qatar National Master Plan "**QNMP**" project. The second part unveils the elements of the emerging Planning System for the country, whereas the third part highlights several creative tools and mechanisms to strengthen the country planning system. Finally, the fourth part provides set of recommendations to develop the performance of the Planning Department in the context of the New Urban Agenda and the Sustainable Development Goals.

1. Synopsis of Qatar

This part provides a synopsis of Qatar (its historical background and existing status), the relevant planning authority "**UPD**" and the Qatar National Master Plan "**QNMP**" project.

1.1 Brief background of Qatar

The State of Qatar is a peninsula situated halfway down the western cost of the Arabian gulf, bordered to the south by the Kingdom of Saudi Arabia. The coastline is 550 km. long and bounds the county to the west, north and east. With the exception of scattered hill formations in the north west and sand dunes in the south east, Qatar is generally a flat desert terrain.

The state's territory comprises a number of islands. Halul, Shira'wa, Alashat are the main ones. The total land area of Qatar is approximately 11 627.04 square kilometers. Doha is the capital city of the country. For more information the following web site can provide more detailed information https://www.mdps.gov.qa/en/knowledge/Publications/Other/QIF-30-2015-En.pdf .

The development and urbanization of Qatar in January 2003. The priority of the country is to improve the local welfare of citizens, which includes the establishment of health care systems, advanced education and the expansion of the country's infrastructure in preparation for hosting the World Cup2022 Where the people were moved from a traditional closed society to an open, development-oriented society that embraced modernity in its lifestyle. Under the enlightened leadership of HE the Ex – Prince Sheikh Hamad Bin Khalifa Al Thani who sought to establish the rule of law and institutions in all areas and its role in the 10 years of June 2004 under the era of the Emir Sheikh Hamad Bin Khalifa Al Thani, which was adopted by all institutions in the State. Exposing these services in the last three years all over the world.

The country's policy of developing and growing high-tech education worldwide has given Qatari consumers more choices in education, health and social development than ever before. Qatar Foundation for Development, Science and Community Development was established in August 1995, thus promoting the education of the people of Qatar and a strong state institution. This was completed in schools (2004). This opportunity is offered in an educational and sports environment. It also hosted several companies in 2006 and hosted the World Championship in 2006. The World Cup (2022) was hosted in a bid to achieve its support in sports.

The State has not only done so, it sought to pay attention to the health of the individual by providing all health requirements from health care centers and specialized hospitals throughout the country. And to establish the principle of development and maturation throughout the world. The Qatar National Vision 2030 aims at transforming Qatar into a developed country by year 2030, capable of sustaining its own development and providing for a high standard of living for all of its people for generations to come.

1.2 Evolution of Urban Development Process for Qatar:

Since the urban Planning Department (UPD) inception, His Highness Sheikh Khalifa Bin Hamad Al-Thani assumed power in 1972 and followed the rulers of the State to this day (2018), Adopting the principle of the importance of making the Qatari society live in a luxury.

When the General Authority for Urban Planning was established, a consultancy office was contracted to prepare Qatar National Master Plan (QNMP). At the same time, the team of QNMP was formed. The project was Entrusted to enhance and develop a plan for future. The planning system will be addressed in the remaining parts of the research.
The Ministry of Municipalities and Environment has taken upon itself the development of the state and the drawing of lines for future urban development through Qatar National Master Plan, which set a clear vision provided" "Create a Role Model for Sustainable Urban Living and the most Livable Towns and Cities in the 21st Century "

2. Key elements of Qatar Planning System

This part will review the key elements of the planning system currently being established in the State of Qatar, which consists of FIVE main pillars that can be summarized as follows:

2.1 Qatar National Master Plan project: QNMP

The Qatar National Master Plan Project is guiding the physical and spatial development of Qatar from now up to 2032". In other words, it is a program of work to prepare spatial Master Plans to guide the future sustainable development and growth of Qatar, its cities and towns from now until the target year 2032.

QNMP consists of three main parts, firstly, the National Development Framework Document 2032: **QNDF** which is the strategic component of the project and considered a crucial to advancing sustainable development and producing a high quality urban lifestyle. There are 17 strategic planning objectives which have been generated to guide its preparation:
Secondly, the Municipal Spatial Development Plans **MSDP** 2032, which consists of four main parts

1. Vision and Development Strategy
2. Zone Regulations
3. Municipal Zoning Maps
4. Centres Plans

Thirdly, the sectoral strategic studies and projects (including but not limited to: National Housing Strategy, Climate Change Study, National Open and Entertainment Strategy). The project also highlights the detailed planning projects and local plans. In addition, it assesses the contribution of the concerned stakeholders and various segments of society in the course of the preparation and implementation of these projects and schemes.
The project has been approved from H.E. the prince, the cabinet and becomes official guidance for the whole of government ministries and institutions since 2014. Also during the course of the project components a Participatory Planning Approach has been adopted with the concerned stakeholders.

2.2 Qatar Planning Legislation: QUPL

It is one of the strategic studies that It has been preparing in coordination with a local QNMP small team as well as representatives of the legal department of the Ministry of Municipality and Environment - **MME**. The purpose of this project resides in developing planning legislation that will formalise the planning system and give clarity and statutory effect to plan-making, development assessment and decision-making processes.
The ***QUPL*** aims at developing a legal framework that ensures the delivery of **QNV2030** and supporting national, regional and local development policies. Moreover, it activates the role of the concerned stakeholders by conducting consultations with the target ministries, agencies and institutions and integrating them to present their concerns, views and opinions. Thus, the main purpose of the legislation is to formalize Qatar Planning System and legitimize its legal status, as well as to strengthen the application of the law at the level of development plans. In other word, ***QUPL*** provides an effective mechanism for monitoring the implementation of urban development projects in accordance with approved plans.
The law is considered one of the main guarantees for the implementation of **QNMP** project. To put it another way, it is seen as the cornerstone for setting up the emerging Planning System of Qatar to achieve transparency in decision-making; effective evaluation of projects and processes; consistency in the implementation of planning policies. In addition to the clarity of the powers and mandates of the competent authorities in the preparation and implementation of planning projects and development application requests for urban development.
It is also perhaps worthy of note that the final draft of the law is under way, once to be acceptable by the QNMP project Management team, it will be proceeding to the higher authorities for approval, ratification and finally enactment of the law.

2.3 Setting up QNMP Project Local Team

This entity is one of the main sections of Urban Planning Department - **UPD**, whose mandates and responsibilities reside in the formulation of long term planning studies, strategies and urban policies at the national, municipal and local levels. It also focuses on preparing immediate and short term plans. The team are vaccinated with qualified national staff.

This section includes an integrated professional teamwork from various backgrounds and specialties that includes all the whole spectrum of professional specialties related to the urban planning field such as: strategic and regional planning, urban design, environmental planning, socio-economic planning, housing, Public facilities, transportation and infrastructure planning.

To facilitate the flow of work and accuracy of assignment, The QNMP team comprises of main four Groups: Strategic Planning and Studies, Master Planning, Mega Projects and GIS Groups – as shown below.

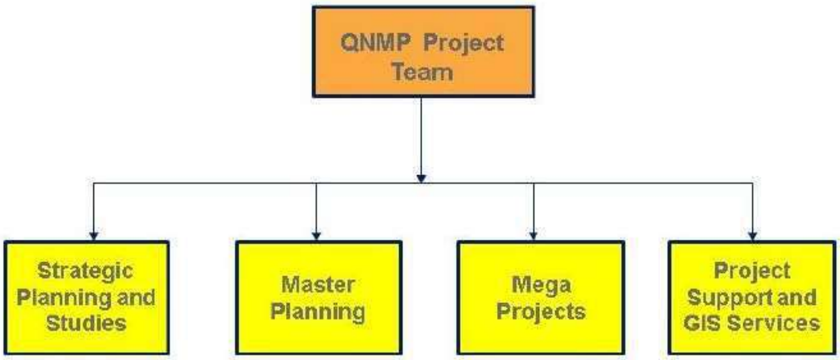

Figure 1: the Organizational structure of QNMP Project

2.4 A documented and reliable Planning Database

The process of constructing a documented and reliable planning database during the previous period has gone through four main stages:

<u>Phase I</u>: During the period (2005-2007), the data were scattered and were available only in the personal computers of the **UPD** staff, where it was difficult to track. Moreover, the data and information of the concerned authorities and departments, whether in the ministry or outside it, were not available because there were no effective communication and effective coordination between **UPD** and the concerned stakeholders.

<u>Phase II:</u> During the period (2008 - 2012), the establishment of the first comprehensive planning database was completed after receiving it from the consultant office entrusted with the preparation of the **QNMP** project. However, such data and information were available only at the national and regional levels, whereas no data available at the plot level. It is worth to point out that such work has been conducted during the preparation of **QNDF** document.

<u>Phase III</u>: Until 2015, the **QNMP** staff provided spatial data up to the plot level during the preparation of the **MSDP** study, where all the data were obtained from the concerned stakeholders and our preliminary database has been updated.

<u>Phase IV</u>: It has been on going up to now, where the continuous updating of the land use database and the planning regulations for each land use at the level of the plot.

This work has resulted in the implementation of GIS-Web-Application, which was built on the Ministry's Website and it is now available to the public with a simplified version whereas a more sophisticated version that includes all the data and information layers have been made available to the concerned stakeholders.

Figure 2: the GIS-Web-Application concept

2.5 Establish a Capacity Building Strategy for the planning local staff

This point deals with one of the most important pillars of the emerging planning system in Qatar, namely "Training and Capacity Building – TCB" unit that was established and approved. This strategy adopted a future vision to establish a teamwork who is keen to practice training and activate capacity building initiatives on a sustainable basis. Moreover, the strategy included three main directions in the field of TCB: firstly, conducting technical training in the field of urban planning. Secondly, refining experiences of managerial capabilities and leadership skills, and finally, consolidating the team spirit and enhancing the teamwork atmosphere.

Example of the workshops conducted during the TCB Program

3. Innovative mechanisms and tools to consolidate the Emerging Planning System

This part of the research is developed to provide assistance to the competent planning and development government authorities through several mechanisms and tools on how to enhance and support the emerging Planning System in Qatar. Such professional mechanisms will cover **SIX** major areas as it will be shown below.

3.1 Stakeholders Consultation Engagement Approach

At the outset, such approach has two levels; the first one deals with the official and formal level through conducting consultation sessions with the public agencies and government departments in addition to the private sector and investors. To a great extent we achieved acceptable results by establishing strong contacts through preparing many planning deliverables.

However, we are in the process of setting up community engagement with a full respect of local customs and common traditions. To apply successful and meaningful consultations and community engagement approach, we are aspiring for applying some international tools that suit the local traditions and common customs in Qatar. They can be briefly explained as follows:

- **Designing Online Applications for community consultation and engagement** in order to engage the widest possible targeted general public (including the marginalized people with special needs who are suffering from vision problems or color blindness). These applications should be visually rich, interactive and visually appealing media in a way to be easily understood and perceived by users.
- **Conducting Pop-Up Engagement** by setting up kiosks or providing tables in a public place or a busy commercial complex where the passers-by are surprised in a funny and cheerful ways. This can be an excellent opportunity to inform the public about the content of the project and its purpose.
- **Using Public Blackboards tool hanging in public areas** where the public is encouraged and stimulated to give their opinions and raise suggestions regarding what they wish to see in the project. Such tactic can resolve several problems and issues of the targeted community.
- **Using Simple Stickers method** in public areas that say “I wish this was… “. By writing these stickers, members of the local community can express their choices and hopes in prioritizing the planning options of the target project for developing their community.

Example of Simple Stickers tool

3.2 Marketing and reach out of QNMP project

The initiative of setting up an informative office for the **QNMP** Project has been introduced during the launching of applying the new planning regulations for all municipalities of Qatar which was inaugurated by His Excellency the Prime Minister on the 3rd of January 2018.

The launching of this unit is considered as a focal contact point between the various segments of the public versus **UPD (**including **QNMP)** staff to respond to all the technical inquiries and questions that to be raised. In addition, to inform and notify the public about the QNMP project's website and how to access the new zoning regulations in order to be aware of the planning and design requirements for developing their plots. This in turn, will consolidate the principles of transparency and credibility as well as enhance confidence and trust between the concerned government authorities (including **UPD**) and the general public.

افتتاح مكتب تعريفي عن الخطة العمرانية الشاملة

Launching the QNMP Customer Service Unit

3.3 Setting up QNMP project Website

The Ministry of Municipality and Environment took care to announce the Qatar National Master Plan (QNMP) by adopting the principle of transparency in setting all the outputs of QNMP on a website that allows everyone to access the documents of it . The site produce the Achievement, Initiatives and other subject related to Qatar National Master Plan.

The site was designed for simplicity and clarity to make it easier for users to access the required information. The aim was not only to use it for citizens and developers, but also to be more comprehensive as a guide for consulting firms working in the field of development to see whether Development of the project can be apply or not through the planning requirements available on website.http://www.mme.gov.qa/QatarMasterPlan/default.aspx

Figure 3: the GIS-Web-Application concept
QNMP project Website

3.4 Enhancing the media role

In order to announce the Qatar National Master Plan (QNMP) the team had prepare a Media plan. The media plan has been aim to awareness the public of Qatar National Master Plan and to inform the community about the date of implementation of the new planning regulations.

3.5 Negotiation as a tool to ease the application of Zoning (Planning & Design) Regulations

Through the practical and professional experience in dealing with daily development application in urban planning department at the Ministry of Municipality and the environment and based on the State's orientation on the importance of private sector participation in development processes in order to reduce dependence on the government support in country development .

In this context, the Urban Planning Department (UPD) has adopted a modern thought in the process of managing the development projects in the State with the participation of the private sector so as not to act in isolation from the wishes of the developers and the needs of the community.

Urban Planning Department (UPD) adopted process of negotiating with owners and developers as a tool in planning field. Where the practices proved successful in the participation and support of the private sector in development processes in line with the realization of the wishes of developers in exchange for providing a public service to the community and the surrounding area to not be conflict with the approved planning Regulations.

4. Recommendations for developing UPD Performance within NUA2016 & SDG2030 context

This part will be concluded with several recommendations regarding how to promote the good governance of the emerging planning system of Qatar, how to develop UPD management performance, and how to develop **TCB** program.

- Ensure that all relevant stakeholders are involved in the development planning processes including public, private as well as community sectors.
- The Urban Planning Law and its By-Law are being drafted,and should be taken to the ratification and enactment processes as soon as possible.
- Improve the level of managerial skills so as to promote the planning decision-making process.
- Giving municipalities more powers, delegations, responsibilities and liabilities to participate effectively in both planning and implementation process.
- Set up the Qatar Urban Observatory - QUO whose purpose is to collect and analyze the available related data & information in respect to all areas of the QNMP Project.
- Seconding competent cadres from the concerned authorities so as to overcome the shortage of staff that UPD is suffering from in several related planning field (such as Socio- Economic planning, Transportation and Infrastructure planning).
- Set up a municipal QNMP unit under the direct chairmanship of the municipality director. Such unit will serve as a link between the municipality and the UPD & QNMP Project.
- Support and strengthen the qualified staff resources of the TCB Unit.
- Create a new organizational unit within QNMP project, to be responsible for conducting and organizing consultation and Community Engagement sessions with the concerned stakeholders.

- Set up a new organizational unit within QNMP project whose responsibility resides in acting as a focal point with the concerned authorities of transportation and infrastructure planning as well as Socio –Economic planning.
- Establish a clear mechanism and work methodology for the negotiation process as a reference for **UPD**.
- Organize a forum to invite accredited consultancy offices in Qatar as well as the Qatar Engineers Association to discuss the problems and obstacles facing the consulting offices in applying the new planning regulations.
- Organize a forum to invite senior developers, investors and real estate finance companies in Qatar through the Qatar Chamber of Commerce and Industry as well as major mortgage banks and companies to discuss the problems and obstacles facing them when implementing the new planning regulations.
- Organize periodic meetings (e.g. twice a year) with engineers working for the municipalities to identify the problems and obstacles facing them when applying the new planning regulations.

INTENSSS-PA: a Governance Approach for Integrating Energy and Spatial Planning. Its Results in Castilla y León (Spain)

Miguel FERNÁNDEZ-MAROTO, University of Valladolid, Spain
Juan Luis DE LAS RIVAS SANZ, University of Valladolid, Spain
Sergio CANTERO CELADA, University of Valladolid, Spain

Synopsis

The INTENSSS-PA project has developed and implemented an institutional capacity building approach related to energy and spatial planning, addressed to public authorities and societal stakeholders in order to support them to enter in a new era of holistic planning through a participatory, multi-level, interdisciplinary decision-making process.

1. Introduction

Planning energy matters in relation to their spatial and socio-economic context is normally very complex. This is because it involves and affects a whole range of participants who often have objectives or points of view that do not coincide, or even are diametrically opposed. Consequently, there is a need to explore innovative decision-making processes that cut across boundaries and encourage participation. The intention would be to ensure that energy plans and projects are feasible, viable and acceptable from technical, financial and social angles.

In the light of this, the project entitled INTENSSS-PA (*A systematic approach for INspiring & Training ENergy-Spatial-Socioeconomic Sustainability to Public Authorities*) implemented a process of training aimed primarily at those engaged in public administration. The reason was that they have the competences for setting standards and the greatest capacity to co-ordinate and lead both energy and space planning. Hence, they can encourage participation by others associated with such matters.

The final objective of this process was to build up a new method for designing and for decision-taking based on creative collaboration and participation by all those concerned with this question. It was not so much a case of telling public administrations what they should do, more a question of completing a training process that would lead to new institutionalized decision-making models. These should be innovatory, involve a wide range of social and business participants, and be integrated into any institutional agenda in a way running across bounds.

The project received funding from the European Commission within the Horizon 2020 framework programme. It ran between February 2016 and July 2018, and comprised a consortium of seventeen partners from seven countries in the European Union (Greece, Italy, Spain, The Netherlands, Denmark, Slovenia and Latvia). These partners included various public administrations at regional and local levels, academic institutions, professional associations, and businesses in both the public and the private sector.

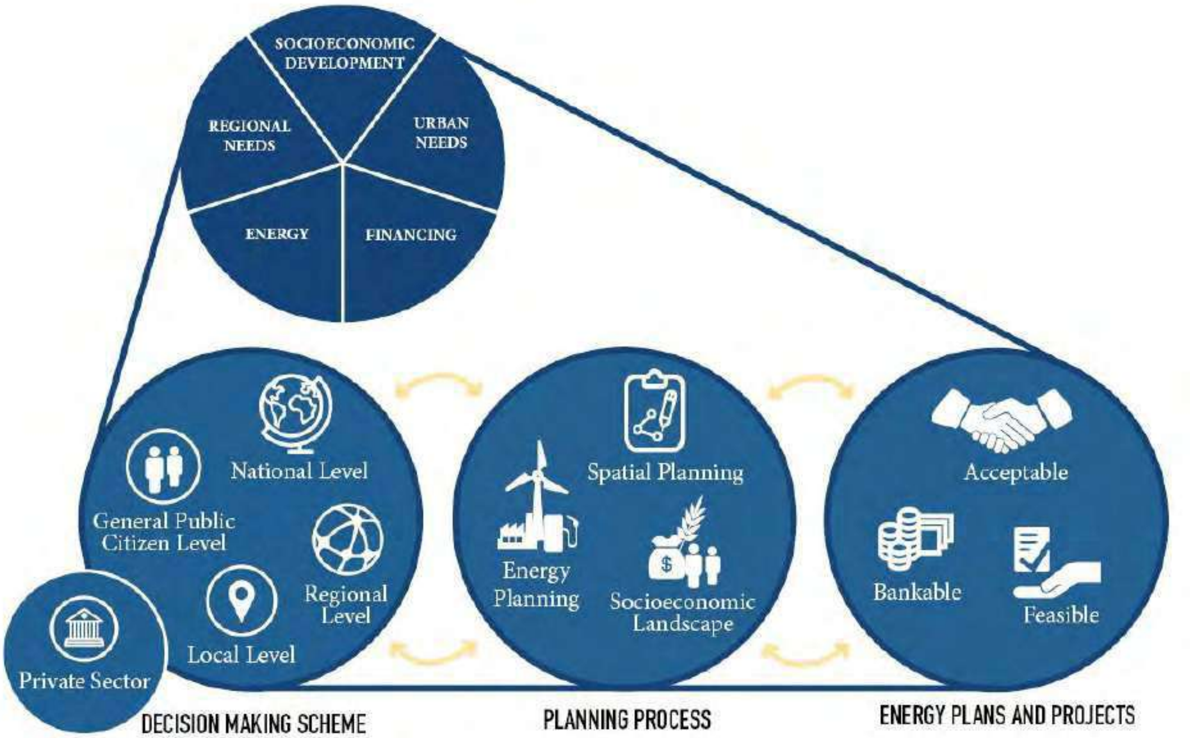

Figure 1: INTENSSS-PA Conceptual Model. Source: INTENSSS-PA.

2. The INTENSSS-PA Project: Objectives and Stages

The INTENSSS-PA project was organized around the following objectives:

2.1 Creating a Cluster of Local Regions and Communities

INTENSSS-PA took as its reference framework for development one region or municipality in each of the seven European countries participating in the project. This was intended to reflect both the particularities of their various systems for energy and spatial planning, and the diversity of their socio-economic characteristics. This variety, combined, however, with a shared working method, allowed continuous exchanges of experiences, advances made, and results obtained in each country.

Specifically, the seven work areas were the peripheral zone of Karditsa (in Greece, within the region of Thessaly), the Calabria Region (Italy), the Autonomous Community of Castilla y León (Spain), the Municipality of Groningen (The Netherlands, lying within the Province of the same name), the Municipality of Middelfart (Denmark, within the so-called Triangle Region), the Pormurje Statistical Region (Slovenia) and the Zemgale Planning Region (Latvia).

2.2 Building up an Online Database of Materials and Reference Cases

The work undertaken within INTENSSS-PA was intended to be supported by all the knowledge already existing with regard to the integration of the energy variable into spatial planning. It was also necessary to take into account related socio-economic variables and the end purpose of contributing to the objectives of energy sustainability (use of renewable sources, efficiency of utilization, and the like) envisaged by the European Union. All these prior experiences were considered from two angles: training materials (publications, methods, tools, and so forth) and instances taken as examples.

Consequently, the first phase of the project, co-ordinated by the *Instituto Universitario de Urbanística* of the University of Valladolid, comprised the carrying out of research procedures and the organized gathering of references useful for the later development of activities specific to INTENSSS-PA. This search for materials and cases was to concentrate essentially on the seven countries participating, so as to remain close to the real context of the regions involved in the project. Nonetheless, efforts were made to incorporate references corresponding to third countries, or of a European or international nature, as well.

To ensure easy interchange and consultation of the materials and cases, a model entry format was adopted for identifying, classifying and briefly analysing each of them. This included the basic data for the material or instance under consideration. It also classified them thematically into three large groups (each split into four sub-groups, with a total of 71 variables established). Finally, it contained short texts describing their content, characteristics and usefulness. Overall, in this first phase of the project 189 items of training material and 134 cases of good practice were analysed.

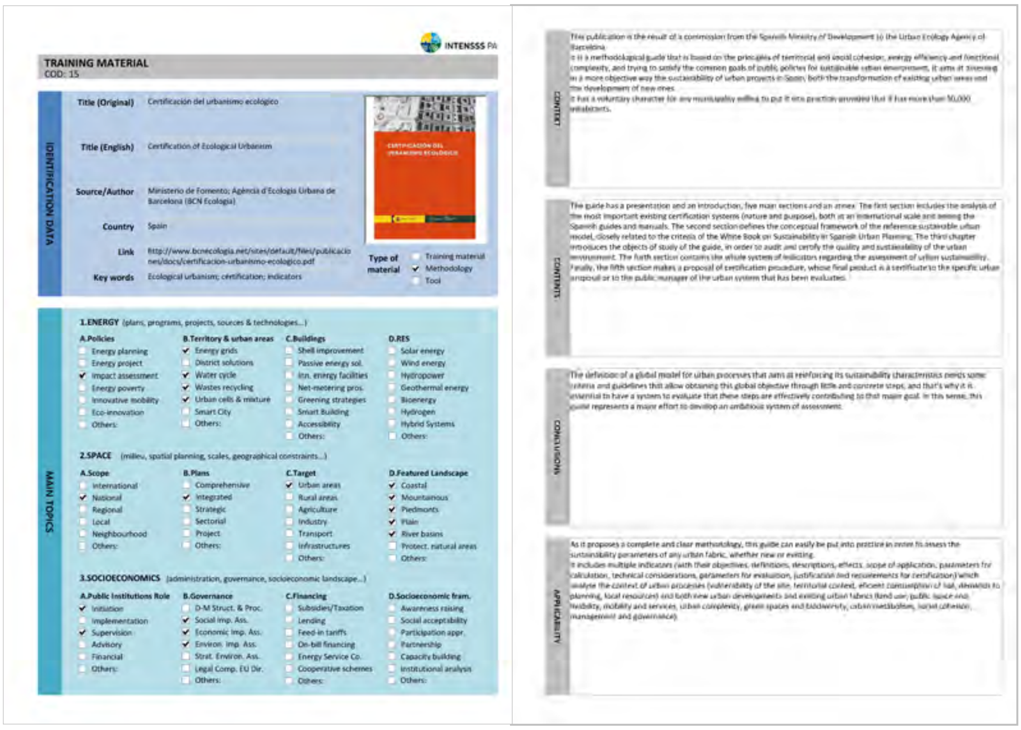

Figure 2: Example of a recorded training material. Source: INTENSSS-PA.

To make consultation of this information simpler for all those taking part in the development of the project in each country, and also to put such information at the disposal of anyone interested in these topics, all the entries were incorporated into a database available from a website permitting open access at no charge. In later phases, as the project progressed, this on-line database continued to be expanded with new materials and cases, both from external sources and generated by the INTENSSS-PA project itself. Similarly, the database remains available for collaborative contributions from third parties wishing to add materials and instances, which will thus carry on enhancing the amount of information it contains.

2.3 Establishing, Co-ordinating and Putting into Operation Seven Regional Living Labs (RLL)

The implementation of new design and decision-making processes, constituting the main aim of the INTENSSS-PA project, was supported by use of the *Living Lab* method, first put forward at M.I.T. in the 1980s. This allowed the building up of an ecosystem based on collaboration between the government and private sectors, and the general public (*public-*

private-people partnership). This was directed towards the resolution of a complex problem (the integration of energy into its spatial and socio-economic framework) in a real context, by means of a specific product, intended to be the outcome of a process permanently open to innovation.

In practical terms, a Regional Living Lab (RLL) was set up in each of the seven regions or municipalities enumerated above, so as to allow trialling of this innovative method of decision-making. The establishment of these RLLs required the bringing together of all those concerned with matters of energy and space planning in each region or municipality taking part, thus defining the panel of participants. To this end, the aim of contributing to the training of public administrators in these matters also being kept in mind, each RLL was co-ordinated by the corresponding regional or local authority, assisted in its work by the other associates in the project.

From here onward, the effective putting into operation of the RLLs consisted of squaring up to the real problem of integration of energy into spatial planning by following a working method comprising four fundamental phases: 1) *Context Analysis:* Consideration of the aspects that in each region proved to be key in making progress in the sustainable integration of energy and space planning, while taking into account socio-economic features. This implied detecting strengths, weaknesses, opportunities and threats (*SWOT analysis*) and defining the specific weighting for each element evaluated (*materiality assessment*). 2) *Co-decision*: The formulation of a problem (*planning focus*) incorporating the needs and expectations expressed by participants in the RLL on the basis of previously completed analyses, such that it could lead to a specific product directed at it and aimed at resolving it. This also required the identification of possible training needs (*gap analysis*). 3) *Co-planning*: The drawing up of a holistic energy plan, that is, the joint defining within the RLL of a plan for solving the problem envisaged in the previous phase, all needful information being provided (*experiential training*). 4) *Evaluation*: An assessment by each RLL of the planning process undertaken.

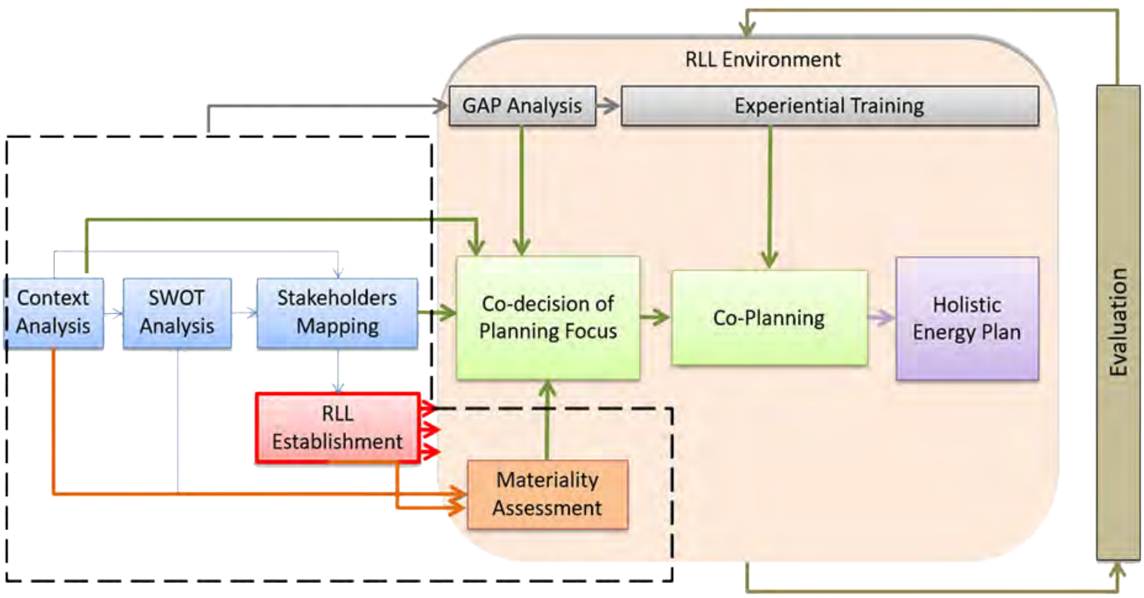

Figure 3: RLL Operation and Work Phases. Source: INTENSSS-PA.

2.4 Designing an Integrated Sustainable Energy Plan

As has just been noted, the planning process carried out in each RLL had as its ultimate objective the designing of an energy plan that would be both sustainable and integrated (*The Integrated Sustainable Energy Plan*). This was intended to respond to the conditions and needs in each region and reflect a consensus between the varying points of view of participants. In this way the plan should be workable, feasible, financially viable, and acceptable, and thus represent a contribution to attaining the aim of energy sustainability in the European Union. Simultaneously, it could constitute proof of the effectiveness of RLLs as a method for designing and for taking decisions.

Hence, the RLL of the Calabria Region concentrated on rural contexts, energy efficiency in public buildings and integrated management of water and waste. The Slovene Pormurje Region the plan attempted to achieve increased exploitation of biomass and hydro-electric energy, offering great potential in this zone. The RLL at Karditsa in Greece also focused on taking advantage of local biomass resources as a positive contribution to its economy. In the case of the Latvian Zemgale Planning Region, the RLL proposed a plan for encouraging use of alternative energy sources for more sustainable transport. As for the city of Groningen in The Netherlands, the RLL allowed the development of new co-operative working methods bringing in the various local agents concerned. The Danish Municipality of Middelfart involved the other municipalities in the Triangle Region in the development of joint actions, mostly aimed at the exploitation of geothermal resources, such as to contribute to the achievement of Danish national objectives for the use of renewable sources of energy. Further details of the approach taken by INTENSSS-PA and the results obtained in Castilla y León in Spain will be provided next.

2.5 2.5 Publicizing Results Achieved and Assessing Incorporation of the RLL Method into the Institutional Framework of the Countries Participating

Once integrated sustainable energy plans had been developed, the INTENSSS-PA project envisaged the possibility of incorporating the planning method constituted by RLLs into the institutional planning and decision-taking frameworks of the seven participant countries.

This first involved an assessment of RLLs as a method, investigating to what degree and in what form it might be possible to include them in the day-to-day processes of design and decision-making in the area of energy and space planning within the various public administrations co-ordinating the RLL in each region. For this purpose, the evaluations made by all of the participants were available. This permitted advantage to be taken of the networks that had been generated and use to be made of their potential to continue contributing to the objectives of energy sustainability in these regions or municipalities.

Furthermore, the INTENSSS-PA project also envisaged that it would be of interest to demonstrate this planning process and the results obtained to other regions in each participating country. This was to be done by putting the public administrations involved in touch with their counterparts in other areas so as to exchange experiences and facilitate possible adoption of the RLL method in contexts initially outside the work of the project.

Similarly, the project put in train a plan for publicizing and communicating the work done and results achieved. This included publications (in various formats), the organization of, and attendance at, events (whether at regional, national or international levels), which comprised informative seminars, open days, trade shows, and international academic conferences, and the creation of an extensive network of contacts to be kept up to date on developments within the project (such as members of other research projects on similar topics, those responsible for public administration in other regions or municipalities, and the like).

3. INTENSSS-PA in Castilla y León: Approaches and Results

Castilla y León is one of the seventeen Spanish regions (termed Autonomous Communities). It lies in the interior of the Iberian Peninsula and is one of the most extensive regions in the European Union. However, it is sparsely populated, having just over 2.5 million inhabitants, and a population density barely more than 25 people per square kilometre. In fact, half of the population of the region is concentrated in its fifteen urban areas exceeding 20,000 residents, whilst its extensive rural zones have for decades been suffering from an ageing and declining population. With these basic data in mind, an explanation can now be given of the approach taken by INTENSSS-PA in this region and the results obtained:

3.1 Structure of the Castilla y León RLL

In accordance with the project guidelines, the Castilla y León RLL was organized to reflect the energy, town-planning and socio-economic panorama of the region, covering three crucial areas: local authorities, the private sector and the general public. The structure of the Castilla y León RLL was also shaped as a function of four main roles. Firstly, co-ordination work was undertaken by the Directorate General of Housing, Architecture and Town Planning [*Dirección General de Vivienda, Arquitectura y Urbanismo*] of the Office for Development and the Environment [*Consejería de Fomento and Medio Ambiente*] of the Regional Government of Castilla y León [*Junta de Castila y León*], the regional authority that was a partner in the project and responsible for town and country planning policies in the area. Secondly, technical support for the RLL was provided by the *Instituto Universitario de Urbanística* of the University of Valladolid, the other Spanish associate in the project.

Figure 4: Structure and members of the RLL Castilla y León. Source: INTENSSS-PA Castilla y León.

Thirdly, in view of the project's focus, it was decided to take as associates collaborating with the RLL two further departments of the regional government directly involved in the matters addressed by the project. The first was EREN, the Castilla y León Regional Energy Board [*Ente Regional de la Energía de Castilla y León*], charged with energy policy in the region. The second was SOMACyL, the Castilla y León Public Infrastructure and Environment Corporation [*Sociedad Pública de Infraestructuras y Medio Ambiente de Castilla y León*], which has a department for energy efficiency and renewable energy responsible for designing, putting into operation and managing a large number of energy projects in the area.

Finally, the RLL was rounded out with a range of participants, corresponding to six large groupings: local authorities and municipal public companies, businesses working in the areas of energy and engineering, associations of various sorts (of ecologists, consumers, neighbourhoods, and similar), professional bodies (of architects, for example), research organizations and foundations (linked to the energy field) and co-operatives.

3.2 Guidelines for Integrated Energy and Space Planning

The Castilla y León RLL had two fundamental benchmarks when drawing up the contents of its integrated sustainable energy plan. These corresponded to the main lines taken by regional policies, firstly in energy matters and secondly in town and country planning.

Of the two, the first is ETR, the Renewable Heat Strategy [*Estrategia Térmica Renovable*] for Castilla y León covering 2016 to 2030. On the basis of an assessment of the demand for heating in the region, this document aims to encourage the production of thermal energy for this purpose from renewable sources, as against the current predominance of fuels such as natural gas, at present accounting for 50% of heat generation. The strategy lays special stress on the role that can be played in this matter by three alternatives: solar power, bio-energy and geo-thermal heat. With regard to the second of these, the document points out the great potential the region enjoys, in the light, for example, of its extensive areas of woodland. At present only a tiny portion of the potential for the production of biomass is exploited for energy, yet this would be an economic activity which would render rural areas in Castilla y León more dynamic, creating new employment possibilities.

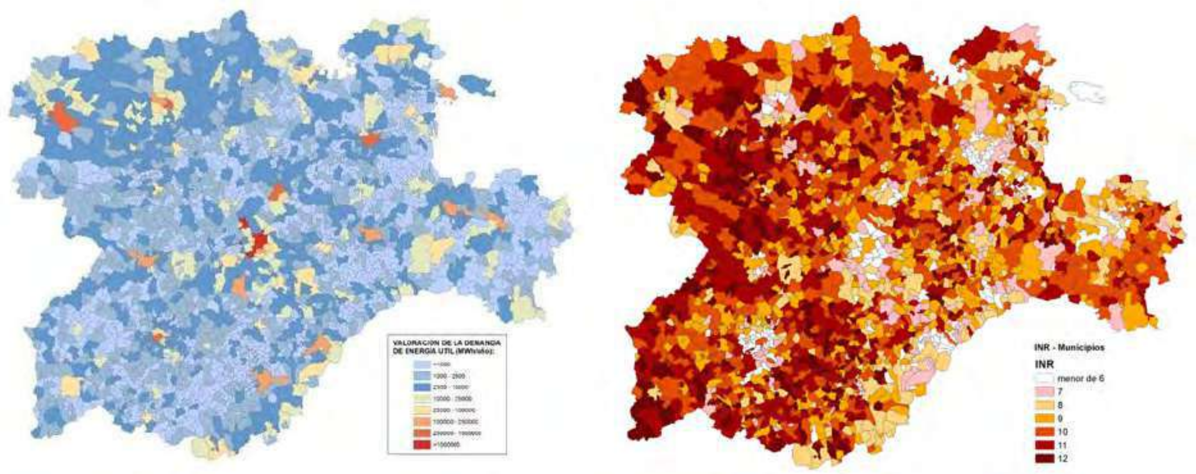

Figure 5: On the left, evaluation of the thermal energy demand in Castilla y León, according to ETR. On the right, index of regeneration needs of the municipalities of the region, according to ERUCyL. Source: Junta de Castilla y León.

The second benchmark is ERUCyL the Castilla y León Urban Regeneration Strategy [*Estrategia de Regeneración Urbana de Castilla y León*], which was adopted in 2016 and marked an orientation of town-planning policies in the region towards urban rehabilitation, regeneration and renovation. After a period dominated by town planning of an expansionist nature, the aim of this strategy is to encourage improvement of existing urban areas by ensuring they are functionally, environmentally and socially appropriate. With this purpose, the strategy focuses on the outer suburbs of towns in the region built between 1950 and 1980. This is because a large part of the population lives in such areas and they are where the greatest problems of urban vulnerability are concentrated, linked to aspects of demographics, such as ageing, of the economy, such as unemployment, or to the very nature of the housing stock, which suffers from considerable deficiencies, for instance with regard to accessibility or to energy efficiency. For its implementation, the strategy has first built up a system for evaluating regeneration needs in every local government area in the region and in all of the quarters of its fifteen cities, so as to concentrate efforts (investment of public funds) at those points where these are greatest. Likewise, it has established a set of criteria for orienting rehabilitation, regeneration and renovation actions, so that they will incorporate an integrated approach that will increase their efficacy. This includes aspects directly connected with energy, whether passive features, such as improving building insulation, or active measures (installations supplied with energy from renewable sources).

3.3 Definition of Objectives for the Integrated Sustainable Energy Plan

The Castilla y León RLL took these two benchmarks as a starting point. On the basis of consideration of the context and of strengths, weaknesses, opportunities and threats it proved easy to decide to orient its integrated sustainable energy plan for the region towards pressing for urban heating networks fuelled with biomass.

In the first place, an increase in the use of biomass to produce energy offers advantages for the extensive rural environment of Castilla y León. This is because it would boost economic activity and employment, as well as facilitating better management of the woodlands in the region, with positive effects such as a reduction in the risk of forest fires. Moreover, biomass is a resource native to the region and a renewable fuel that can easily replace imported fossil fuels such as natural gas.

A combination of utilization of a local renewable fuel like biomass and encouragement of centralized production of thermal energy through heat networks is aimed at achieving both environmental and financial benefits. On the one hand, centralization facilitates optimization of resources and hence increases energy efficiency. On the other, this brings about a reduction in costs together with beneficial effects from a social viewpoint. This is because a reduction in customers' bills provides a contribution to solving problems such as energy poverty, as well as enhancing the level of comfort in homes served by this type of solution.

From the viewpoint of town and country planning, there is also an interesting synergy, since the installation of heating networks can be combined with the urban renewal actions which the regional government wishes to promote. This allows centralization of production to be effected in tandem with complementary measures reducing demand, for example by improvements in the insulation of walls and roofs, normally included in operations of this sort.

Figure 6: Visit of the members of the RLL of Castilla y Léon to the DH of the University of Valladolid. Source: INTENSSS-PA Castilla y León.

Similarly, an additional factor kept in mind was the fact that the regional government, through SOMACyL, had already initiated a policy of rolling out urban heating networks which could thus be reinforced and supported. On this point, the members of the Castilla y León RLL had the opportunity to visit several of these networks. In doing so, they gained first-hand information about the obstacles met by their promoters when attempting to set them up, measures that might aid in managing them, and also good practice that could be learnt from them. Among these visits one highlight was the heating network serving a large part of the buildings of the University of Valladolid, currently among the most extensive networks in Spain. Complementary learning activities were also organised, such as a seminar on the possible contributions from urban planning to energy transition.

3.4 Guidelines for Sustainable Development and Integrated Management of Urban Heating Networks in Castilla y León

Once the work had been given a focus, and as a consequence of the learning activities and later discussions, the Castilla y León RLL decided that its integrated sustainable energy plan should take the shape of Guidelines for the sustainable development and integrated management of urban district heating networks in Castilla y León. The intention was to draw up a document that in itself would represent an integrated and action-oriented approach. In other words, it would be directed towards the putting into practice of specific measures facilitating the rolling out and the most effective operation possible of urban district heating networks in the region.

1. Improvement of Regulatory Framework	1.1 - Develop a regional strategy to promote district heating 1.2 - Promote forest management facilitating sustainable energy use 1.3 - Elaborate specific local ordinances on district heating 1.4 - Regulatory consideration of district heating as an urban service
2. Guidance for energy projects	2.1 - Compulsory participatory localization studies for thermal plants 2.2 - Achieve the critical mass of consumption through public buildings 2.3 - Compulsory completion of feasibility studies 2.4 - Energy optimization and inclusion of complementary solutions 2.5 - Promote bioclimatic solutions in buildings
3. Spatial Planning Strategies	3.1 - Incorporate district heating in municipal urban planning 3.2 - Promote to incorporate district heating in urban regeneration 3.3 - Promote to incorporate district heating in new urban areas 3.4 - Application of good practice criteria in the design and development of district heating 3.5 - Promote a more sustainable design of the public space
4. Good practice of governance of management of projects	4.1 - Adoption of the Living Lab approach in the design and development of projects 4.2 - Creation of interdepartmental working teams in Public Administrations 4.3 - Promotion of the mixed management (public / private) of district heating 4.4 - Advanced use of ICT in the management of district heating
5. Actions of communication and participation	5.1 - Organization of participatory processes during the design and development of each specific project 5.2 - Organization of information and training activities oriented to technicians 5.3 - Organization of informative and training activities oriented to the citizenship, with special attention to the young population

Figure 7: Guidelines for the sustainable development and integrated governance of urban district heating in Castilla y León. Source: INTENSSS-PA Castilla y León.

To this end, a total of 21 guidelines were drawn up, grouped into five main fields of action. These were improvements in the regulatory framework, guidance for energy projects, strategies for spatial planning, good practice in governance and management, and actions aimed at better communication and participation. Each guideline, presented in a record-card-like format, proposed a set of actions to be put into practice. These ran from modifications to certain standards to recommendations for projects or management, based on tried and tested experiences. They also included a number of general considerations, explaining the nature and aims of the measures proposed, the resources and tools affected by them, and an indication of which agents should be responsible for their application. The Castilla y León RLL deemed that effective application of the measures incorporated within the guidelines would boost the number of projects for heating networks in the region over the short and medium term. This would be an outcome of facilitation of services for residential use and the entry of the private sector into promotion and management of such networks. Finally, the guidelines were presented through three roadshows that took place in different cities of the region, and a book was edited to summarise the work and result of Castilla y León RLL.

4. Conclusions

The progress of the INTENSSS-PA project, especially in the case of Castilla y León, demonstrated the advantages of an innovative approach to mechanisms for designing and decision-making within public administration, based on bringing in all those involved in, or affected by, the decisions taken. From the viewpoint of public administrations, the setting up of a participatory forum from the very start of projects guarantees to a large extent the adoption of solutions that are consensual and shared, as well as being technically better informed and more finely tuned, since they are worked out within a framework of collaboration, and of transparent and open debate. In this way, there is a noteworthy reduction in the risk of rejection of, or social protest against, the projects emerging (such as NIMBY). In the specific field of energy, such problems are habitually encountered, very often as an outcome of a lack of any precise understanding of the socio-economic context in which these projects must be undertaken. Similarly, the importance of including spatial, town-planning and territorial variables was made clear, if an overall understanding is to be achieved of the consequences that every project must have in its field of application.

With regard to those actors and agencies involved in the RLL, it was clear that they were strongly motivated to participate, and derived much satisfaction from the fact that their points of view and interests were valued and taken into account. The members of the Castilla y León RLL also rated very positively the training activities occurring as the plan progressed, such as visits to heating networks, and stressed that the principal result of the project was not just the plan drawn up, but also the RLL itself as a forum for participation which also allowed them to get to know one another and compare ideas.

However, incorporation of this method for designing and decision-making into the day-to-day functioning of public administration requires profound changes in the current administrative and institutional structure, no simple matter. First of all, it implies changes in the working philosophy of the administration, which would be obliged to cede part of its prime role and its control, and to open up its operations in a very clear and unrestricted way to the society it serves. From that starting point, there would also be a need to provide some form of structure for choosing, and ensuring participation by, the various members of whatever forums were established, which might be either of a permanent nature, directed towards the production of wide-ranging plans, or linked to the drawing up of specific targeted projects.

Planning for diversity

Moderator: MAGNUSSEN, Tone (Nordland Research Institute, Norway)
Speakers: FØRDE, Annieke (UiT The Arctic University of Norway); MAGNUSSEN, Tone (Nordland Research Institute); TAFF, Gregory (NIBIO)

ABSTRACT:

Cities in northern Europe are increasingly inhabited by people with diverse cultural backgrounds. The social, economic and environmental sustainability of cities requires capacity to live with differences. Recent increases in refugees and asylum seekers pose new challenges, which adds to challenges already faced by the cities: affordable housing, transport, community meeting spaces and new economic opportunities.

The cold climate of the north brings certain challenges related to creating new meeting places, indoors and outdoors, but the increased diversity has led to a wide variety of new and innovative integration activities, aiming at connecting newcomers and established residents in urban meeting places. This session will focus on exploring the function of and connections between meeting places, interaction and participation in the city. As a part of this broad theme, these questions will be relevant:

How are urban spaces being used by newcomers and established residents?

How and under what conditions do meeting places lead to cross-cultural encounters and interaction?

In what way and to what degree can cross-cultural meeting places and encounters lead to processes of participation in urban life?

The session encourages a wide range of contributions, including from academia, practitioners and civil society. We invite contributions related to new theories or methods for planning for diversity as well as case studies and practical examples, including tools for planning. Both planned activities as well as ongoing or completed activities may be presented.

The session format will be short (10 min) presentations followed by a moderated round table discussion, open for all interested parties. The discussion aims at exploring innovative multicultural integration activities that help us to live with difference, enhance integrative interaction and develop cities' problem-solving capacities. The session will provide a summary from the round-table discussion to be held at the session.

Enhancing urban encounters - the transformative powers of creative integration initiatives

Førde, Anniken, TROMSØ, Norway

ABSTRACT:

Sustainable cites requires capacity to live with difference. In a world of increased mobility and migration, our cities become more and more diversified. While national discourses on diversity often are problem-focused, social initiatives are emerging in diverse cities addressing the positive potential of the city as a cross-cultural meeting place. In Norway, such initiatives have increased in numbers since “the refugee crises” in 2015, and we see creative approaches rising from the civil society, the voluntary sector as well as private companies and local government aiming to facilitate encounters with difference. This paper explores innovative integration initiatives in cities in the north, emphasizing how new forms of engagement and responsibility might be engendered. The cities are seen as sites of experiments, where new relations across difference are developed. Framing encounters as emergent, transitory, fragile but yet hopeful, we discuss the transformative powers of such initiatives for planning diverse cities.

Local identities on change: urban waterfront regeneration within the global city Istanbul

(Local identities on chance within the global city Istanbul)

Serin GEAMBAZU, Ion Mincu University of Architecture and Urban Planning, Romania

1. Transformations in Halic

Over the last decades, many cities worldwide have promoted urban waterfront regeneration for a variety of reasons building on the particular scenery of these sites. The success of the first well known urban waterfront regeneration project, Baltimore Inner Harbor regeneration (1960), has served as a prototype for cities around the world with the desire to position themselves in the race to become Global Cities (Harvey 1989) by providing strategically located high-quality investment opportunities to attract global capital, or by constructing attractive spaces to promote tourism and leisure. Nowadays, almost every city at water's edge is engaged in regeneration projects with strong political impetuses and interest from various parties: authorities, developers and neighboring communities (Hoyle 2001).

These developments have been critically examined by many scholars, many of which share the belief that urban waterfront regeneration is often not addressing the underlying, deep-rooted problems of the cities and furthermore, ignoring the socially and economically unstable landscapes in which they often occur, veritably contributing to the escalation of inequality, polarization and deprivation in the city (Harvey 1989; 2005; Brownill 1990; Gordon 1997b; Hoyle 2000; Saarinen and Kumpulainen 2005; Butler 2007; Healey 1997; Gordon 1997a, 1997b; Feldman 1999; Fainstein 2001; Granath 2005; Butler 2007).

Studying urban waterfront regeneration as a complex urban intervention, specifically its special governance, resistance and impacts on the neighboring tissue, could be considered a prism through which broader societal transformation processes and related planning challenges can be understood. For the scope of this study, the empirical research gathered both primary and secondary data through: literature review, review of laws, review of official documents and land-use plans, 31 interviews, 91 questionnaires, participatory- observation, an workshops, observation and photographs.

In order to understand the planning processes of the regeneration of Halic's waterfront, a reflection is done upon the peculiarities of Istanbul's urban regeneration policies and the institutional framework at city and national level that have facilitated it: Istanbul, Turkey has been experiencing a neo-liberal reconfiguration that is now in its final stage. In this context, urban regeneration is steered as a tool for development within a special legal framework and while the purpose of the projects seem to be in the name of upgrading the built environment and improving the living conditions of the poor, the top-down approach, reduce the projects to just transformation of physical space and neglecting the social, economic and environmental dimensions, which along with the unwillingness of government to allow grassroots participation in the planning process become the focus of discontent and protest.

Halic, a 7,5 km bay of the Bosphorus and the cradle of settlement since the birth of the city, was heavily industrialized and contaminated in the 1970s and since then has been experiencing a long process of transformation along its waterfront. In line with popular North-Western examples of urban waterfront regeneration at that time, this process was triggered by Mayor Dalan in 1983 who famously stated his mission: „The water of the Halic will be as blue as my eyes'". Behind the environmental concerns, there was also an economic motivation to bring Istanbul between the competitive global cities with a vision of a "Cultural Valley".

The following forced de-industrialization process of the 1980s was impressive and did indeed improve Halic from an environmental perspective, but the clearing process was pursued with a heavy-handed, top-down governmental approach to planning and the legacy of Dalan is contested: The project created an approximately 50m wide strip of vacant land– a great opportunity in terms of offering open green spaces for the city- but also mass unemployment and poverty in the backstage neighborhoods populated by former dock and shipyard workers.

The following initiatives to regenerate Halic's waterfront showed no intention of resolving the social and economic burning issues of the neighboring communities. Within the same top-down planning approach, as in the 80's clearance intervention, urban waterfront regeneration projects are ad-hoc initiative of different bodies of the government depending on ownership and planning rights over the land, creating developments for middle-high income citizens: "With empty convention centers in the middle of poor neighborhoods, a few art galleries right beside demolished historic buildings, and newly built museums next to squatter housing". (Bezmez 2008 pp. 817).

Still, this 7,5 km green belt of parks and recreational spaces in the heart of the city, represents an enormous opportunity for a congested global city as Istanbul and its citizens, but mostly for its low-income neighboring communities in need of public space.

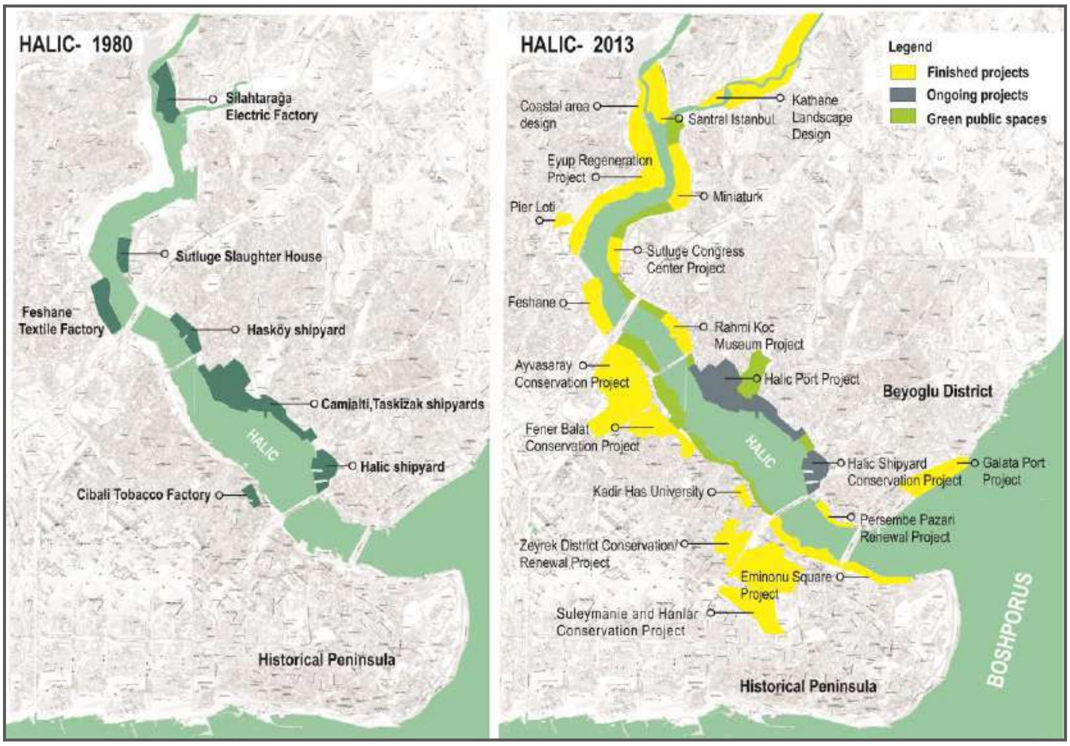

Figure 1: Change of Halic's waterfront from 1980s until 2013

1.1. Halic shipyard conservation project

Halic Shipyard Conservation Project is an urban waterfront regeneration project in on-going planning process, initiated and subsidized by Istanbul Metropolitan Municipality and creates hope in tailored outcomes, serving the citizens interest as a public project, but is missing its transparency.

The site of Halic shipyard was for long under pressure of transformation due to the opportune location and also being one of the last projects that could complement to the “Cultural Valley” vision. For understanding the area of the project and its relevance, it must be noted, that the shipyards aimed to be transformed are also important for their cultural and historical value at global, national and local level. Considering the legal framework, all three shipyards are under Law of Conservation and designated to regeneration and their current function will be changed with the suggested functions from existing plans: culture, recreation areas, commerce and education. Also Conservation Board No. II (representing Ministry of Tourism and Culture) will be added to the planning process.

The ownership belongs to different governmental bodies which makes a collaboration between these actors challenging. Major actors in the planning process of Halic Shipyard Conservation Project are: Istanbul Metropolitan Municipality, the initiator of the project, owner of the land and also the provider of the finance in realizing it.; the Department of Historic Environment Protection managing the project, having mainly the responsibility to assure the conservation and restoration of the historical monuments in the area; the Conservation Board No. II, representative of Ministry of Culture and Tourism, having also the main responsibility to assure the conservation and restoration of the monuments; Istanbul Metropolitan Planning in charge of the plans and design of the project and also IDO (private company), having the tender of the land.

In the interviews with representatives from the planning department of Istanbul Metropolitan Planning, the team planning Halic Shipyard Conservation Project, it has been revealed that the outcomes of the project will take into consideration the previous suggestions. Halic Shipyard Conservation Project will respect the 1/1000 Plans of Beyoglu in terms of conservation of the shipyards, along with the recommendations of implementing cultural and recreational activities. Moreover, creation of green spaces is emphasized, the vision being to open the waterfront for the broad public, the citizens of Istanbul. However, the project contains no analysis of impact assessment such as: environmental, economic or social, this showing the physical focus of urban waterfront regeneration in planning, putting in doubt the success and purpose of this project. Strategies concerning the development have been proposed by Istanbul Metropolitan Planning: "conservation of the buildings, enhancing the transportation in the area, introduction of recreational and exposition areas, bringing the city to the waterfront, protection of green spaces and ensure the participation of the local people of the area." But although these strategic points presented, there was no information for the broader public about the project or the request for any collaboration from the citizen’s side. This leads to questioning the outcomes of the project because of this type of non-transparent planning process that leaves no input from the citizen’s perspective. As seen and criticized in other examples of projects along the Halic, the project could also potentially enhance existing socio-economic problems, a matter that will be presented in the following part of the article, by analyzing the neighboring community in rapport to the project.

2. Bedrettin inhabitants, a neighboring community on struggle

This part presents the evaluation of the Halic Shipyard Conservation Project, considering the impact on the neighboring community. Bedrettin Neighborhood is chosen for analysis because it is the closest community next to Halic shipyard, also being the first group of actors impacted or that could benefit from this project will be exposed.

Bedrettin Neighborhood is a low income neighborhood (according to median monthly household income 2010) at the shores of Halic, in Beyoglu District. It was strongly connected to Halic Camialti and Taskizak shipyards, being occupied by blue collar workers at the shipyards. Therefore, the neighborhood was much affected by the clearance process done by Mayor Dalan in 1983, the first regeneration along Halic, its current problematic economic condition being outcome of the forced deindustrialization process of that time. Today, approximately 1500 people live in Bedrettin Neighborhood and are mostly divided as retired workers from the shipyards, people coming from Anatolian side of Turkey and a considerable group of roma minorities.

Based on the interviews with the "muhtar"(mayor of neighborhood) of Bedrettin Neighborhood, the questioners realized with the community and the personal observations of the researcher on site, is found that the neighborhood is in on-going transformation due to several reasons. First, Bedrettin Neighborhood was declared as Renewal Area in 2005 and, according to Law of Renewal, the neighborhood will go under a process of regeneration which will put in danger of displacement the poor citizens living in the area. Although 80% of the citizens living their own their land, the houses built are not in good condition, being classified as "gecekondu", squatter housing, and have to be renewed and improved for their safety, this being a hard task for the majority of the community which is poor. Second, the increasing prices of land in the area are the proof of the process of gentrification seen also along the whole waterfront of Halic.

These changes bring a strong opposition from the community, who is against this renewal project and afraid of displacement. Together with their muhtar, the community found a neighborhood association named Bedrettin Neighborhood Association. This has the purpose to fight in court, as the only way of challenging decision-making, against the regeneration of their neighborhood and all other regeneration projects that could affect them. All citizens of Bedrettin Neighborhood signed a list opposing this intervention and the municipality’s project was given to court. However, the results were not positive ones and this created mistrust between the community of Bedrettin Neighborhood and municipality along with loss of hope towards the actions of the government. In this context, although the purpose of the urban renewal project seems to be in the name of upgrading the built environment and improving the living conditions of this poor community, the top-down approach along with the unwillingness of government to allow any participation from the citizen’s side can be questioned.

The reason for opposition, from the citizen’s perspective was not only the fear of displacement, but also the difference between the new proposed plans and their actual needs. As reason for this are the un-transparent processes of planning with no collaboration or participation from the community’s side. Public planning policy in Turkey gives rights of involvement in planning process just to the owners of the land and welcomes participation from the citizen’s perspective at the end of the planning process. Still, studying the neighboring community of Halic Shipyard Conservation Project, it was found that the citizens have been informed about the development of the shipyards and active in influencing the planning process. The community doesn't believe that the project will be done for their interest and that will bring them job opportunities or other benefits of such. Also there is a lack of information regarding the project which proves the lack of transparency in planning.

The lack of information regarding the project makes the community come closer to Chamber of Architects, Neighborhood Associations and Halic Resistance urban social movement, the actors currently engaged in a fight against the waterfront regeneration of the shipyards. In the questioners conducted during the meetings of Halic Resistance, besides the fear of displacement answers also as: “to learn the truth”, “because this project is being used strategically against us” were given.

2.1. True needs of the citizens

Looking to Bedrettin Neighborhood, one could see a condensed living environment, trapped between wide boulevards and with a great view towards the shore of Halic. Analyzing the built environment, it can be seen through the narrow streets and lack of public spaces, that it evolved organically and unplanned. The lack of public space and also green areas is a main loss for this neighborhood, but also one of the main aspects that Halic Shipyard Conservation Project could improve.

Although, as previously mentioned, the citizens of Bedrettin Neighborhood are against the Halic Shipyard Conservation Project, outcomes of the questioners regarding what they would need in the future development were: green spaces, culture and education facilities, keeping the working shipyards, health facilities. In the discussions with the community, especially with the group of mothers, mostly staying home and taking care of their children, the need of closer public space and green areas was emphasized. It was found that families go to other parks along the Halic and make barbeques or just bring their children to play, this being the only recreational activity for these families. An intriguing vision of the children is the one of the "fisherman", a symbol of the waterfront of Istanbul which should not be blurred in the landscape of waterfront development for global economic gain given by projects in name of tourism and consumption.

The regeneration of Halic shipyard, is understood to be a big opportunity for the community in terms of creating public space for recreation, improving the quality of their life considerably.

Taking into account the vulnerable position of the neighborhood in terms of economic situation, the on-going gentrification process at Halic's waterfront and the renewal project in the agenda of the government, it can be argued that Halic Shipyard Conservation Project will contribute to this picture considerably, creating social and economic impacts on the community. From the questioners conducted in the neighborhood it is clear that the community is against Halic Shipyard Conservation project, the main reasons being in relation with the mistrust towards the regeneration projects initiated by the government, the lack of transparency in the planning processes, the lack of good quality information and the fear of displacement rather than the project itself or its outcomes. These aspects are also the reason why the neighboring community is engaging with other actors in opposition.

The community of Bedrettin Neighborhood is an important actor being the most affected by the project, but also by its potential to give inputs to the project. Due to the lack of consideration of this neighborhood in the planning process the true benefiting outcomes of the project will not be achieved. Opportunities for more inclusive and transparent processes in planning can be found after analyzing the neighboring community as the openness and interest of the community in participatory planning methods and in expressing their need. The community is not only in need of public green space which can be created with the Halic Shipyard Conservation Project, but also in need of programs and solutions for its vulnerable economic condition. Halic Shipyard Conservation Project, if planned carefully, might satisfy and resolve some of the problems faced by the community, but this is possible only if the community is involved in the planning process.

Urban waterfront regeneration in the context of Istanbul reveals the same features of the popular contested cases of North and Western examples . The leading factors are an entrepreneurial government and also a national policy on urban regeneration designated by the central government. The strong and constantly growing opposition is not only the resistance to this particular urban waterfront regeneration project, but it leads to a bigger picture of urban regeneration projects in Istanbul, realized through a top-down approach to planning, creating major social and economic impacts. One may argue that only through a change towards a more inclusive planning approach, along with clear targets for the improvement of the quality of life for the neighboring community, the urban waterfront regeneration project, Halic Shipyard Conservation Project, will be able to escape the current deadlocks and collisions between government, investors, resistance and local community and might have a chance to actually set an urgently needed precedent of a new planning culture in Istanbul.

Author: Iris Gommers, programleader sustainable city, Antwerp, Belgium

- Governance, management, administration and planning systems

Title: A Green tool to measure the environmental and ecological benefits of green areas and to involve different stakeholders

City, Country: Antwerp, Belgium

Area: 20 450 ha

Population: 510 610 (January 2014)

Signatory to the Covenant of Mayors since: 2009

In a nutshell

Green and blue measures or infrastructures help cities become more resilient to climate change, and they also have many other co-benefits. Antwerp's Groentool" or in English "Greentool" allows urban planners to explore the potential of green to improve the living environment (heat stress, air quality, etc.) in a specific area or neighbourhood. The application is giving an insight in the effects of nature based solutions on the human environment: air quality, heat stress, water run-off, noise perception, biodiversity and carbon sequestration. The application shows which nature based solutions (trees, shrubs, green roofs, green walls, …) can be used where in the city and gives the potential impact. Maps give the user the possibility to check what is possible in specific parts of Antwerp.

Adressing heat and flood stress

Although Antwerp has avoided major floods so far, the city is at risk of fluvial flooding, sea level rise and storms. Antwerp also suffers from increasingly extreme temperatures. In the city, it is up to 8 degrees warmer in the late afternoon, evening and especially at night than in rural areas, a phenomenon called the "urban heat island effect". Only green spaces in the city are significantly cooler than the rest of the urban territory, and also contribute to retain excess water.

One of the main reasons is that the city center of Antwerp is highly petrified. As major threat to the City of Antwerp heat and flooding-risks were highlighted in the Antwerp Climate Adaptation Strategy and the Antwerp Green Plan. Both problems identified can be tackled making use of nature based solutions. Most of the time nature based solutions do contribute at the same time to reducing both problems mentioned.

On top of water management and heat stress reduction, greening the city has other environmental and ecological benefits: it also contributes to reducing air and noise pollution, increasing biodiversity, and capturing CO2. The Antwerp's green plan adopted in 2017 acknowledges these environmental and ecological benefits. However, in many cases, even though those benefits are vaguely known, they are not easy to quantify.

More informed urban planning decisions

To address this knowledge gap, the city of Antwerp has commissioned the creation of the Antwerp Greentool (Antwerpse Groentool), aimed at providing information about blue-green measures and their effect on environmental challenges. Initially designed as an application to help Antwerp administrators make urban planning decisions, it has been adopted by private investors willing to invest in green actions and projects, and by technicians in charge of execution and maintenance. The tool, which is entirely public, contains interactive maps that enable sites analysis. The user can visualise the location's current characteristics (soil, plants, etc.) and discover the effect of existing blue-green measures on seven parameters: biodiversity, CO_2 capture, noise, air quality, recreation and proximity, heat stress, and water management. Each parameter receives a score ranked from 0 to 5. It makes it possible to explore the impact of a possible measure (such as green roofs, water tanks or tree planting) on these seven parameters, compared to the existing situation.

The tool helps users by inspiring the design process, quantifying impact on a specific site, comparing and combining measures, stimulating dialogue between stakeholders, and integrating blue-green infrastructures and challenges into the planning process.

The tool provides inspiration and scientific information on nearly 50 bluegreen measures. It is a pedagogical instrument aimed at informing the cityofficers about such measures and their impact on the day-to-day life of citizens.

Use of the Greentool

The tool is being used by the environment-department in their advisory-process. Spacial planners can also use the tool themselves to analyse projects they are working on and to feed the dialogue about the right green on the right place. Examples are the ‘Zuiderdokken’ and the ‘Groenplaats’.

The greentool was used for instance in the neighbourhood Sint Andries in the heart of the city. In a process from the citylab (Stadslab2050) the city aimed to co-create more space for green by setting up experiments together with the local stakeholders. The greentool showed what the importance of green in this particular neighbourhood was and how for instance green roofs could contribute to especially the heat-stress and the water-retention.

The greentool will also be used in the communication- and planningprocess of the so called ‘gardenstreets’, that will be executed on different locations in the city for a better overall living environment.

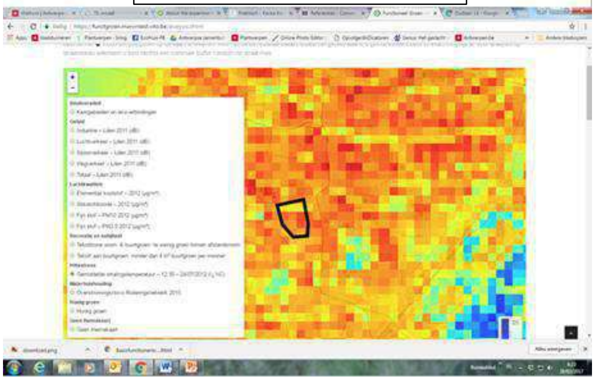
Additional information

Antwerp’s Greentool was designed by VITO (the Flemish Institute of technology and research) and the University of Ghent, and was released in January 2017. The tool was commissioned via a tender. Since 2016, the city of Antwerp is part of the European EnRoute project on urban green infrastructure along with VITO, which maked it possible to further develop the tool. The city of Antwerp decided to develop this instrument because green areas play a mitigating role in every action plan of their environment department. They wanted to make it accessible – together with their mapping-exercises and other research – for every city-officer in an attractive manner.

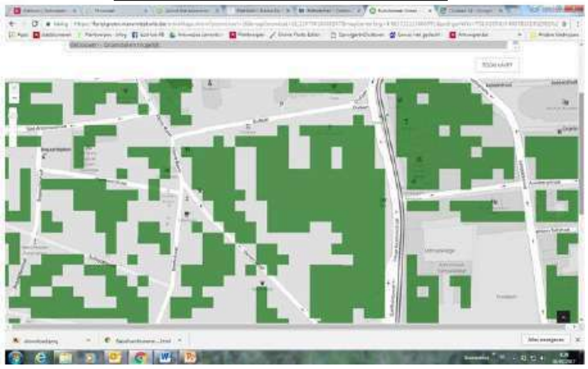
The tool is entirely owned by the city and is free to use for everyone. It was meant for internal use in the first place but the city decided to make it accessible for everybody.

Analysis for Sint Andries

Heatstress



Greenroof possible



Areas with less then 4m2 green / inhabitant

Space production: The interaction between social network and community garden

Yuting GUO, Tongji University, China

Abstract

Nowadays, much attention has been payed to health status and quality of life over the world, health problem is increasingly serious. As activity space, community garden represents the role "directly link individuals, social capital and built environment". It has been used to examine people's habitual interactions with their environment. A growing body of literature conceptualizes urban agriculture and community gardens as spaces of democratic citizenship and radical political practice. Urban community gardens are lauded as open space which residents can alleviate food insecurity and claim rights to the city. It also seems to provide an opportunity for reconciliation between the urban and nonurban realm in a densely built, urban environment and the possibility of introducing new approaches to public policies, urban planning included.

This paper investigated the association between the neighborhood socioeconomic environment and physical inactivity and explored the contribution of neighborhood characteristics to this association. We payed close attention on the community gardens in typical old-fashioned worker village community. To determine the role community gardens play in community development, open space, and civic agriculture, we conducted interviews with community gardens from Shanghai, Yangpu District. This paper investigates urban community gardens as spaces of citizenship through a case study of Anshan Forth village, which is an agelong built community. The residents there are long lived and of a high aging level. The Paraquat garden in the third residential area of Anshan Forth village is a typical positive space to promote residents' intercourse through urban agriculture. Through questionnaires and Grounded Theory interviews, the paper is an attempt to answer three questions: (1) The relationship between demographic attribute classification and public space usage. (2) How to develop positive social relations and citizenship among urban residents. (3) How suitable shaping of public space affects the activation and integration of local residents. We try to find out the interaction that urban agriculture brings to citizens' participation and the residents' life style as public space. The gardens can also be viewed as unique "participatory landscapes" that combine aspects of diversity movements, as well as provide a connection between immigrants and their cultural heritage.

Keywords: community garden; public space; health; identity.

1. Introduction

Nowadays, the process of urbanization continues to advance in various countries. According to data provided by the United Nations Department of Economic and Social Affairs, 3.9 billion people are now living in cities, which is equivalent to half of the world's population. It is predicted that by 2050, the total global population will reach 9.3 billion, of which the total population living in cities will reach 6.25 billion. China's urban population has also increased from 457.06 million in 2000 to 77.16 million in 2015[1]. Such rapid urban population growth will inevitably bring about many urban problems and urban diseases. The role of natural ecology in regulating people's health is particularly important in today's society. In addition, people's lifestyles and form of residence are also changing. High-density residential areas have risen. The mobility of urban population is increasing greatly. The social network structure has been strongly impacted, and the neighborhood relationship is gradually becoming weak. Aging trend is increasingly serious. Therefore, all countries have noticed the importance of developing community gardens in cities to improve the health of residents and build an active neighborhood relationship.

The term “community gardens” first appeared during the First World War. Some European and American warring countries triggered a food crisis, forcing the government to encourage the public to cultivate the earth to grow food, and build community gardens to solve the problem of food and clothing [2]. Later, in Europe and the United States, it developed into the public green space that was divided or leased to residents for planting activities. It could help improve the urban environment, create opportunities for communication and education, and promote the residents' positive neighborhood relations. Compared with other forms of agriculture, the characteristics of community gardens are significant. It relies on the background of high-speed development of urbanization. It has good adaptability in high-density compound neighborhoods. It is usually distributed or rented to the community residents by the government or related departments. The management system is bottom-up and community-based. The participants always various in level of income and age, most of them are old people who have a large amount of leisure time.

The urban community garden that has risen in China in recent years is a revival of farming culture. It also originated from the form of green space in European and American countries. It means that idle land is divided into small pieces for cheap rent or distributed to individuals and families for gardening or agronomy [3]. As the representative of China's high-density cities, Shanghai has an average density of 24,325 people/km^2 in the old city (end of 2015, data). With the rapid expansion of cities and the declining open space, how to use community gardens to improve the quality of life of residents and realize cities sustainable development has become a topic of increasing concern. Since 2014, with the gradual advancement of urban renewal in Shanghai, relevant organizations have begun to appear dedicated to the construction of community farms. At present, there are nearly 21 community gardens built or under construction in Shanghai, which are located in residential areas, neighborhoods, parks, and campuses in Yangpu and Pudong District. With public participation as the main driving force, they provide natural space in a dense urban environment and promote the healthy and sustainable development of the city.

2. Community Garden and Health

In 1948, the World Health Organization defined health as " complete physical, mental and social well-being, not merely negatively as the absence of disease or infirmity. [4]" As the largest non-governmental organization in the United States and Canada dedicated to promoting the development of community farms - The American Community Gardening Association, once summarized the benefits of community farms as: Improving the quality of life of participants, promoting the harmonious development of the community, and creating Good community atmosphere, encouraging self-sufficiency, beautifying the neighborhood, producing nutritious food, reducing family food expenses, saving resources, providing leisure, exercise, rest and recreation sites, and educational platforms to reduce crime, protect green space, and create jobs Opportunity and promotion of economic development, reducing car exhaust from streets and parking lots[5]. This reflects the role of community gardens in promoting personal health, community belonging, and even social development.

2.1 Improve Physical Health Level

Today, in many cities in Latin America, people are struggling to survive on the subsistence level. Developing community agriculture can improve people’s diet and improve their physical fitness. For example, in Colombia's poorest district of Bogotá in 2004, Colombia encouraged the cultivation of home-grown kitchen gardens, which was also an important practice in the municipal project of “Bogota sin hambre” [6]. Even in some European countries and countries that do not currently have an economic crisis, it is equally important to develop community farms. Studies have shown that poor diet and living habits have a large number of negative effects on the health of urban residents. Data show that 60% of European urban People's disease and premature is not only a bacterial infection or genetic problems, but because people lack of a "low victimization mode of life" [7]. In short, community gardens can provide people with healthy food and lifestyle. Healthy living habits such as changing the habit of sedentary and maintaining moderate eating can reduce the probability of suffering from cardiovascular diseases and cancers [8].

2.2 Promote Identity and Integration

The North American Community of Farmers Association proposed in 2001 that “a community garden is a place where individuals and neighbors’ children, businessmen, homeless folks, and artists work together side by side. They share stories and shovels. laughter and water. They slowly build relationships, transcend gardens, and integrate into larger communities.[9]” Yuan Pingping reviewed a research on the relationship between the community gardens and the interpersonal interactions from three aspects: communication between family members, different families, and inside and outside the gardens. As an important communicative space, community garden become an important link between family members, community residents and community administrators. [10][11]. These studies and practical cases have proved that community farms can pool a group of residents together with common interests and strengthen their social network to increase the sense of belonging and identity. This kind of emotional consolidation can promote community identity and community spirit, even extend the impact to other communities and improve the harmony of the entire society.

3. Introduction of Baicao Garden

3.1 Construction Background

Baicao Garden is located in the third residential area of Anshan forth village. The third residential area of Anshan forth village was built in the 1950s. It is a typical old-fashioned worker village. In the 1990s, it became a model of the old housing comprehensive reform. The concept of low carbon and environmental protection has been accompanied by the construction of the community. During the “12th Five-Year Plan” period, the community was included in the energy-saving emission reduction model community. In order to demonstrate the new features of energy-saving and environmental protection in Shanghai through the Shanghai World Expo, a number of achievements have been formed in the community, such as spray cooling system, rainwater collecting greening and watering system, solar energy utilization system, insulation renovation of residential outer walls, and construction of environmental monitoring platform. These achievements have enabled the community to achieve initial successes in building energy-saving renovation, new energy use, and energy-saving management, and have taken the lead over other workers' new villages. In 2016, the third residential area of Anshan Fourth Village was included in the “13th Five-Year Plan” low-carbon pilot community in Shanghai. The Department of Landscape Studies in Colleges and Siping Street Management jointly collaborated in building landscape improvement in this community. The surrounding college landscape design team led the community residents, volunteers, and the “Fang Lin Flower Club” designed and built this Baicao garden.

3.2 Design Process

Baicao Garden covers an area of about 200 square meters, and the designers mainly considers the following aspects: First, the per capita public green area of the district is only 2.23 square meters, the central square has poor maintenance and lacks open space for activities. The second is that the community has a high level of aging, with a total population of about 6,800, of which old people over the age of 60 account for 23.5%. Although there are a large number of tenants, the tenants generally live longer, the sense of belonging to the community is high, and the relationship between neighbors is harmonious. Third, the management effect of the community residents' committee is relatively good. Many horticultural enthusiasts in the community are united to form a horticultural autonomy organization – the “Fang Lin Flower Club” [12]. The association was established in 2015 and consists of a group of hobbyist residents. Currently, there are about 40 members, including management personnel, of whom about 17 are active. The Baicao Garden is intended to create a space where residents can propose ideas, participate in design, and provide residents with a horticultural communication platform. Before designing the garden, the team of designers launched a “little landscape designer” event to allow children to create an ideal garden and let them have a sense of expectation and a sense of belonging to the soon-to-be-faced small garden. The design team positioned the garden function to satisfy residents' leisure activities, parent-child interaction and nature education. Residents’ suggestions have been continuously sought such as the use of wood boards can cause noise and disturb residents’ rest. Under the guidance of professional, nearly 1,000 community residents participated to build the garden by their own hands, from drawing on the fences to collecting rainwater, from composting kitchen waste to “drifting” plants. In that summer, under the collective wisdom of everyone, the bare green belt finally became the creative Baicao Garden. Although these jobs can be completed in a week or so if it was done by professional construction teams, residents all say that personal involvement is far more valuable than anything else. In short, the joint construction of residents and professional teams has provided new ideas for the construction of other community gardens.

Figure 1: An aerial view of Baicao Garden

Source: Liu Yuelai, Yin Kejun, Wei Yi, et al(2017). Community Garden Practice in High-density Central Cities —A Case Study of KIC Garden and Herb Garden in Shangha [J]. Landscape Architecture, 16-22 .

3.3 Activation and Operation

The Flower Club played a key role in the construction of Baicao Garden. The president sorted out the name list of the club members, counted the idle time of each person, combined their respective characteristics and the major abilities to make a construction schedule. The table includes a watering group, a fertilizing group and a garbage picking up group, etc. [12]. At the same time, the community has also formed a "little volunteer" team so that children can participate in the construction of the garden and cultivate their sense of responsibility. In 2017, activities about “ The 24 Solar Terms” were carried out, participants took natural observations and notes every two weeks. Baicao Garden is also used as the school natural education base of Dahushan Road Primary School. Besides, it realized the sharing of activity resources with Nongfang Garden in Fushun Road, which brought closer interaction between neighbors[12]. These activities have all strengthened the building of community cohesion. As an organic public space, Baicao

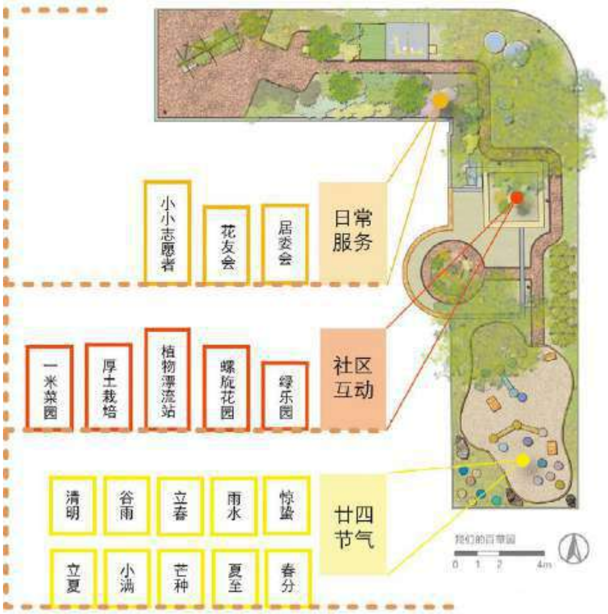

Figure 2: Spatial distribution of community activities in Baicao Garden

Source: Liu Yuelai, Yin Kejun, Wei Yi, et al(2017). Community Garden Practice in High-density Central Cities —A Case Study of KIC Garden and Herb Garden in Shangha [J]. Landscape Architecture, 16-22

Garden is a good place to bring people with common interests together and let them influence other residents so that the community's self-governance ability will become stronger and stronger. It is a good way to change residents from consumers to producers and strengthen their sense of belonging and identity.

4. Health Promotion of Baicao Garden on The Flower club Members

4.1 Basic Information

4.1.1Activities

Although there are nearly 40 members *in* the 'Fang *Lin* Flower *Club'*, which includes many management personnel. There are only 17 people actually participate in the activities frequently, and their basic age is above 60 years old. The person in charge will ask the free time of each member to arrange the worksheets. Every day, two people will maintain the Baicao Garden. Different groups will be responsible for different tasks, such as watering, fertilizing, collecting garbage, etc. The club's core members have a regular meeting once a week. During several field studies and interviews, the author found that the meetings were mainly held in two places. The indoor activities were selected in the activity room for the elderly in the community. Everyone sat together to discuss and exchange the flower cultivation techniques and appreciate the newly cultivated Flowers. They also discussed the difficulties met when maintaining the Baicao Garden and try to find the solutions. Sometimes they would introduce new flower friends to each other and so on. In the recent regular meeting, the members discussed the solution to the theft of two promising roses. They proposed measures such as organizing flower delivery activities and installing monitoring. In some regular meeting, they would hold outdoor activities in the Baicao Garden, such as building shelves for vegetables, watering and fertilizing. Special activities such as the lantern riddles of the Mid-Autumn Festival are held during the festival. The design team will always follow this project. They would make an on-the-spot investigation from time to time to understand the difficulties encountered by residents and would try their best to help solve it. It can be seen that the design team and the residents themselves have a very positive attitude towards Baicao Garden so that it can better become a positive space for residents to communicate.

4.1.2 Questionnaire Results

We had the privilege of conducting a questionnaire survey of 9 members of the Flower Club and found that the members who lived in the community for the shortest period of time lived here for 10 years. The longest is up to 50 years. All of them are basically local people in Shanghai. The average age is over 70. They have a high sense of belonging to the community and have certain requirements for their own living conditions. For example, most of them live in multi-storey buildings and they all want to Install elevators in their unit buildings. More than half of the elderly do not live with their children and do not need to take care of their grandchildren. Therefore, they have sufficient personal time and are in close contact with other residents and managers in the community. Most of the members of the Flower Club have smart phones and can use the Internet. They love to participate in community activities and are fully capable of living independently. Only three people often need to go out to see a doctor. Most members go out to take the community activities 1-3 times a day, more than half of them go to the outside of the community every day, and compared to other public space, the green and the elderly activity center become their favorite places for various activities. These elderly people have a high level of enthusiasm for life. Six of them have travel plans every year, and two of them even travel abroad. In terms of their self-perceived health, except for one person who believes that he is particularly healthy and one person who believes that he is unhealthy, most members think that their own health is basically healthy. All members will focus on a healthy diet, and most will pay attention to exercise and regular inspections. In the survey of personal life satisfaction, six members were basically satisfied with their lives, one was satisfied, and two were very satisfied. It can be seen that the overall life happiness is very high.

4.1.3 Health Status Measurement

In order to better study the health status of the members, in addition to the interviews, we also conducted measurements of some health indicators, including height, weight, blood glucose, blood pressure, and heart rate for these 9 members. It can be seen from the table below, the data are similar with the results we get form the questionnaire survey. Most of the elderly people showed a good healthy status in these indicators. Several members mentioned in the interview that they were worried about their own high blood pressure problems. But in fact, there is only one who has high blood pressure and one who has low blood pressure. The good healthy status may be related to their regular inspection and active participation in physical exercise, such as take activities in Baicao Garden. In terms of blood sugar, one of them have a slight impaired glucose tolerance, two of them fasting blood sugar were slightly impaired and no diabetic patients appeared. From the data, most members obtain good health status, which is closely related to their lifestyle.

Form 1: Health indicators of partial members

NN	Birth	Blood sugar (fasting)	Blood sugar	Weight	High	High pressure	Low pressure	Heart rate	Hyper-tension	Hypo-tension	Impaired glucose tolerance	Impaired fasting glucose	Diabetes

4.2 Influencing Factors

4.2.1 Research Method

The Grounded Theory was proposed by Glazer in 1967. It provides researchers with a complete set of methods and steps for summarizing and constructing theories from the original materials[13]. It uses observation methods, interview methods, etc. to collect data, and explain the behavior of the research objects, construct the concept by coding and summarizing the data, and generalize the concept category to obtain the theory[14]. Therefore, the use of grounded theory to comprehensively understand the influencing factors of community farming activities is a good complement to the previous top-down empirical research methods.

4.2.2 Sample Selection and Data Collection

The sample selection follows the theory saturation principle, and randomly extracts the eligible Flower Club members for one-on-one interview from the predetermined range of interview objects. When the number of respondents reached 17, the theory began to saturate, no new concept appears, so we final interviewed 17 members whose age is between 65 to 75. The samples included 11 women and 6 men, most of them do not need to undertake grandchildren and have a lot of free time.

This study began on May 4, 2018, following the theoretical saturation principle of grounded theory, using open interview to collect data. Through the continuous collation of one-on-one interview data, the theoretical nodes are perfected until the theoretical saturation. In the interview data collection process, in order to get more reasonable interview data, we designed the following several interview questions, and according to the respondents to further questions, so as to obtain more comprehensive data. ①What is your age and self-perceived health status? ②Do you often come to attend the activities? ③Why did you attend the Flower Club at the beginning? ④What impact do you have on your health and relationships after attending these activities? ⑤Are you satisfied with the status of Baicao Garden? ⑥What do you want to improve?

4.2.3 Data Analysis

4.2.3.1 Open Coding

Open coding requires the construction of a concise and comprehensive initial code system. In this study, the original interview data were coded to generate the initial concept, and finally, 17 categories were extracted from the interview data.

Form 2: Open coding normalization

Category	***Initial Concept***	***original statement***
Stability of Organization	*Doubt on stability of organization*	*Many similar organizations do not organize activities often.*
Authority of Organization	*Doubt on authority of organization*	*Many similar organizations have no professional leaders.*
Reliability of Organization	*Doubt on reliability of organization*	*My body may not be able to take part in these activities.*
Value of Organization	*Doubt on value of organization*	*If I feel useful, I will participate occasionally. If it is useless, I will not participate.*
Frequency of Activities	*Frequency of activities*	*The frequency of current activities is suitable for our physical condition.*
Activity Form	*Activity form*	*We have indoor activities as well as outdoor activities, which is very good.*
Actual Effect	*Different actual effects on different kinds of people*	*Some activities are very good, which helps to improve our unhealthy living habits, but it is not suitable for my own physical condition.*

Use	*Help solve the physical problems or not*	*After this year's activities, my hypertension has improved.*
Interest	*Points of interest, hobbies, concerns*	*I really love flowers. I have been paying attention to such organizations before.*
Self-health Awareness	*Self-health awareness*	*I am a hypertensive patient and I am more involved in community activities.*
Free Time	*Having enough free time or not*	*I don't live with my children. I have a lot of free time and want to make new friends.*
Family Support	*Whether other family members support or not*	*My son wants me to join such an organization to enrich my life.*
Financial Ability	*Financial ability can affect the lifestyle*	*I don't have any financial pressure. I usually like to live with these plants.*
Information Sharing	*Information sharing between families and friends*	*I will share the activities with others and ask if they are interested.*
Organization Management	*If the organization management is in order*	*I trust the neighbourhood committee and these partners. We usually help each other.*
College Assistance	*Whether college support is in place*	*We are very grateful for the guidance of the university design team.*
Problem Solved	*Whether the problem is solved in time*	*Recently, some flowers in the garden have been stolen, which make us annoyed.*

4.2.3.2 Axial Coding

The open coding is to explore the category, while the axial coding is to find the main category. The axis coding digs the attribute of category, which can make the category to be more rigorous, and establishes the relation between the category.

Form 3: Main category formed by axial coding

Classification	Main Category	Category
Factors of Organization	*Content of Activities*	*Stability of Organization* *Authority of Organization* *Reliability of Organization* *Value of Organization*
	Quality of Activities	*Frequency of Activities* *Activity Form* *Actual Effect*
Factors of Participants	*Subjective Factors*	*Interest* *Self-health Awareness*

		Information Sharing *Information Sharing*
	Objective Factors	*Free Time* *Family Support* *Financial Ability*
Environmental Factors	*Organization Management*	*Organization Management*
	College Assistance	*College Assistance*

4.2.4 Summary of Influencing Factors
The community garden is one of the most frequent places for members of the Flower Club, they nearly go there every day, it can be said that it has an important impact on their lifestyle. It is mainly reflected in two aspects. First, the daily physical activities produced by maintaining the community garden and fresh vegetables produced by the farm are helpful to their physical health. Second, the community garden provides an active exchange space for members and their interests are promoted. Information is shared to promote the development of interpersonal interaction and community harmony. From the questionnaire survey, we have obtained that most of these members have the will to live independently and are not busy caring for grandchildren, so there is plenty of time for them to realize their self-worth. In addition, the Neighborhood Committee has strong management capabilities. It can bring members together closely and made a detailed schedule. Members are also happy to work in the garden. Occasionally, the community managers organize picking activities when the vegetables are ripe, so that these fresh vegetables can also bring benefits to other residents. In the promotion of human interaction, members always have communication about the selection of seeds and some planting skills. Flower viewing are also a vital activity to the establishment of friendship in the community. In the community garden, the exchange of information, common activities, and home-based participatory learning are all more likely to occur. From the interview of the Flower Club members, we found that they communicated with each other through WeChat group and often discussed the cultivation of their own flowers in the group. Every Thursday, they also took their own beautiful flowers to the elderly activity room to share, and sometimes they would meet new flower friends. They form a very close friendship circle. In addition, because the third residential area of Anshan forth village is the concerned closely by the surrounding universities, sometimes university teams will also come to Baicao Garden to conduct some learning exchange activities. Members are always willing to communicate with the visiting team. Such activities will also deepen their mutual recognition and cohesion. The increasing sense of community identity and pride of residents can improve the effectiveness of the community conduction. Community gardens have changed from the original personal place to a hotbed of community society and participatory democracy[15]. People's interest in urban horticulture also promotes community-based efforts on other social issues[16]. In short, the "successfulness" of Baicao Garden mainly benefits from the following aspects: factors of organization, including content of activities and quality of activities; factors of participants, including subjective factors and objective factors; and environmental factors, including organization management and college assistance.

5. Conclusion

Taking the Anshan Forth village as an example, this article describes how the Baicao Garden promote the physical health of active participants and how to improve their social networks. The main research methods are taking questionnaires, Grounded Theory interviews and health data measurement. They help to understand the health status and community participation of the Flower Club members, as well as the influencing factors of participation. In short, under the background of the lack of green space and the expand of environment pollution, this new agricultural form provides protection for the physical and mental health of residents and opens up new ideas for urban spatial planning.

Child in the City

Understanding the role of children in Community Engagement
Case of Chara Mandi, Delhi

Lekshmy HIRANDAS, School of Planning and Architecture, New Delhi, India

1 Abstract

Local governments have always been an integral part of the Indian ethos. The 73rd and 74th constitutional amendments empowered the local bodies to respond quickly and efficiently to local issues rather than relying on a distant central body. Over the years the notion of participation and citizen engagement have been tokenistic. The Local Area Design studio at School of Planning and Architecture, New Delhi have been trying to execute the participatory planning methods in various neighborhoods in Delhi.

This paper is the analysis of a social experiment conducted in ward 99 Karampura as part of the local area design project in 2017. [i] The case study delves into the challenges posed by the complex social conditions in the ward and the methodology by which children were incorporated into the process of participatory planning. The experiment tries use children to engage people belonging to otherwise opposing ideologies in a productive discussion for the better future of the neighborhood.

Keywords: participatory planning, children, Indian cities

---

2 Participatory Planning in India

"...in serving the best interests of children, we serve the best interests of all humanity."

- *Carol Bellamy, Chair of the Board of the Global Community Engagement and Resilience Fund.*

In India, the 73rd and the 74th constitutional amendments acts (CAA) enacted on 1st June 1993 extends constitutional status to municipalities, empowering people and locally elected representatives the power to act in common interest and have a say in how their communities should develop. (Hamid, 2004)

Local Area Plan (LAP) is prepared with an intent to respond to the context and ground realities. It involves the local people and their perspective and points of view in the planning process. The LAP aims to achieve a holistic vision for the city keeping the focus on the "people" and not the city as a space. It's a bottom-up approach in planning which holistically delves into the intangible aspects of a human settlement which have rarely been used in spatial planning so far. It is important to quantify the social components of a human settlement which are most important in spatial planning and often not responded to in master plans or regional plans.

In the recently launched Smart Cities mission by the government of India, this emphasis on public involvement has been further improved. It entails the preparation of the Smart Cities plan through citizen engagement framework. Public Participation has gathered a lot of attention in social media and has been showcased by many cities as a part of their branding process. Thus, participation from a being a localized project in small communities has now permeated institutional constructions and planning processes, affecting decision making.

This augmented emphasis on participation which got reflected in the structures and programs at national level, also affected town planning. Hence, participation in development projects and plan preparation needs to be Public Participation in Planning in India. Additionally, in the last decade, "stakeholder consultations" and other forms of participation are beginning to emerge. (Prakash & Kumar, 2016)

When we started our work in electoral ward 99, Karampura, an industrial area within Delhi, our understanding of the process of participatory planning was purely theoretical. During our site explorations we realized the diverse environment and the extremely complicated social networks existing in this nation. Being the largest democracy in the world is an extremely daunting task, especially when you have 1.3 billion opinions on any given issue. Thus, the efficiency of participatory planning system gets questioned at every turn.

3 Chara Mandi – Analysis of its social structure

Karampura situated in west Delhi is a pre-dominantly residential and planned industrial area which is currently undergoing rapid redevelopment. Karampura, literally means 'abode of the workers' was envisioned in 1962 Master Plan as a place of work for the city of Delhi. This vision led to numerous industries setting up in the area

Chara Mandi came up in 1980's to cater to the goods transportation services required in this industrial area. Historically a market for animal fodder, the current business of logistics was a mere change in business strategy by the original inhabitants. With a population 3000 and a density of 500 PPHA, the settlement is unique due to its locational characteristics: its sandwiched between a railway line and two city arterial roads. Due to this, it lacks basic services like water and sanitation; lacks access to social amenities such as schools, parks etc.; faces high levels of poverty and has been seeing a constant rise in school dropouts in the past years.

Figure 1 Chara Mandi

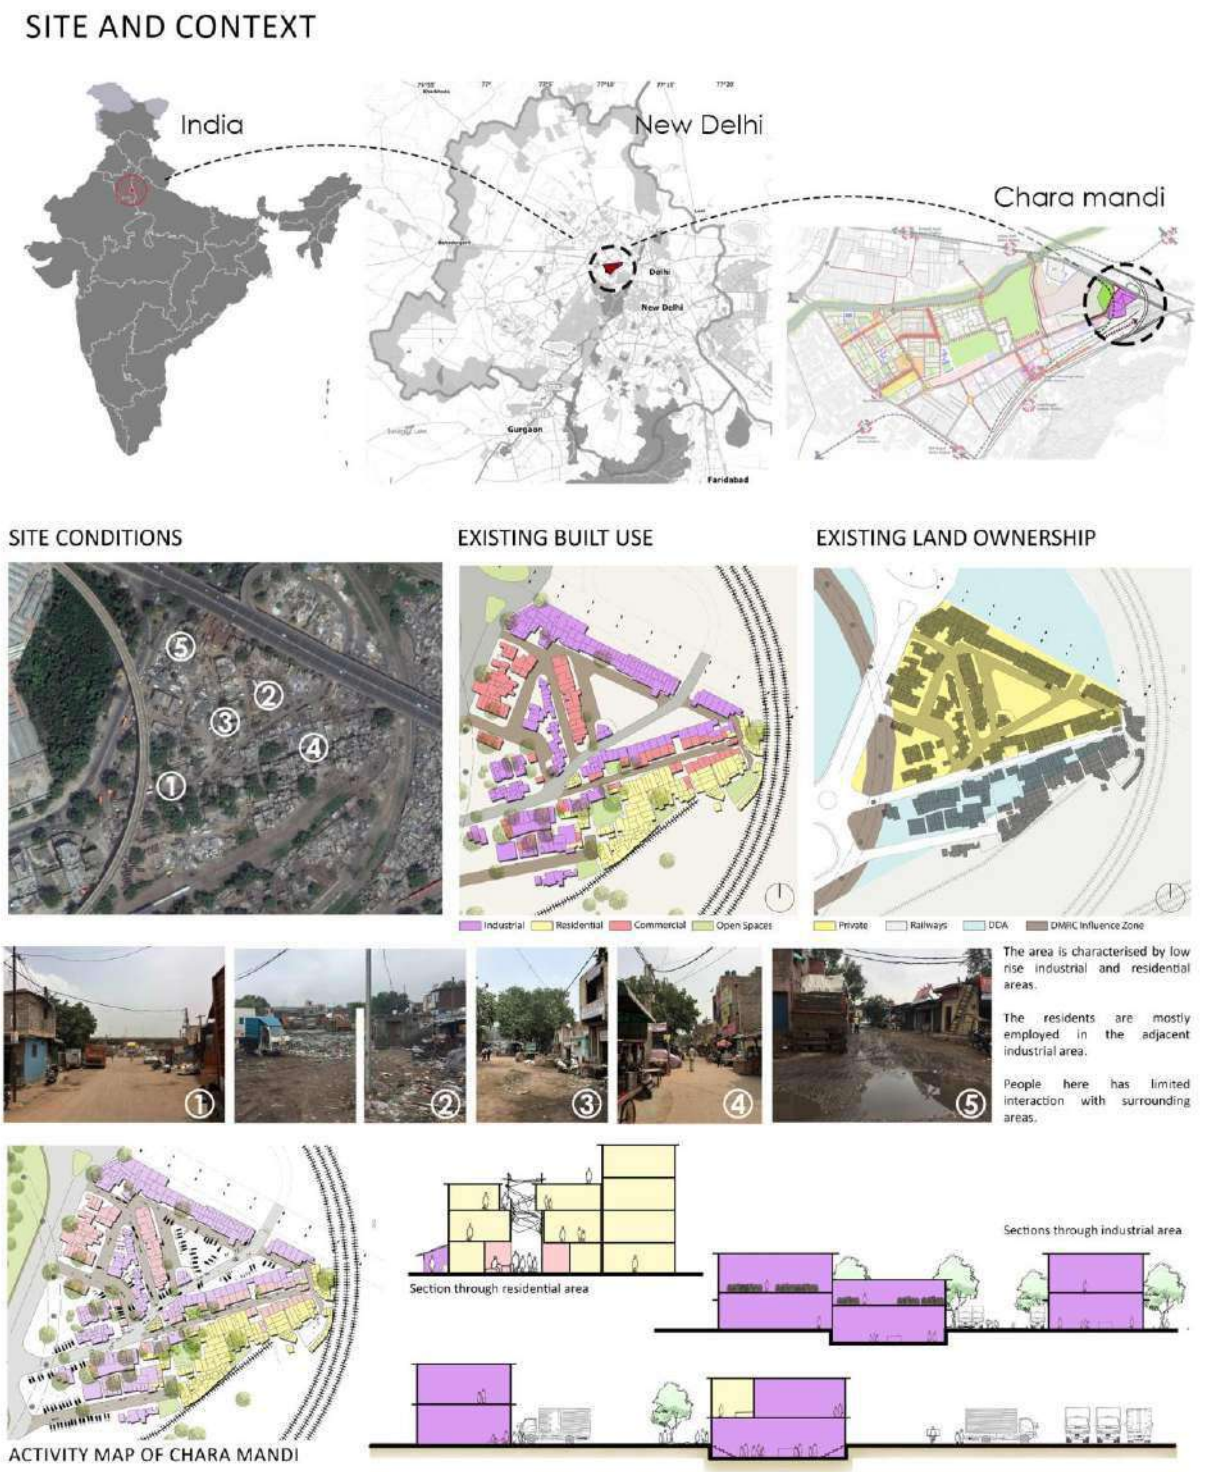

Figure 2 Site Analysis of Chara Mandi

During engagement with the community over a period of two months, we found that beyond other issues that plague Chara Mandi, the key issue was the isolation of this area from the rest of ward 99.

From its emergence as an idea that could lead to the empowerment of the poor and marginalized through the fair redistribution of material resources, participation over the years has been turned into a matter of methods and techniques, rather than influencing radical processes capable of designing fair and equitable decision-making processes with similar material outcomes. (Prakash & Kumar, 2016)

In this context, in order to convey the idea of participatory planning to the inhabitants of Chara Mandi proved difficult. Most people did not understand the need to discuss their issues collectively, some found it time consuming and a hindrance to their work schedule; others were unwilling to sit down with people from other communities and castes. This situation is not unique to this site or Delhi alone. In India we have 9 major religions recognized in the census of 2011. Each religion has many more subdivisions. Hence every neighborhood in India is heterogenous and faces conflict at varying degrees. Complicating the matter further are political parties that propagate opposing ideologies. In most cases these conflicts are minor but they do manifest themselves in the public realm in one form or another.

While initial interactions with people in Focus Group Discussions (FGD's) gave us a broad picture of such conflicts and agendas, we were unable to come to definite conclusions. Further analysis revealed that people we interviewed/interacted categorized themselves as people in power – ward councilor, residence association members, political leaders etc. or as people who are powerless, oppressed or neglected. The issue with this self-categorization is that, the 'powerful' saw their needs as superior to the others since they hold a position of prominence in the society and are considered to be more knowledgeable by the community. The 'powerless' on the other hand, often play this card to excuse themselves of any responsibility regarding their environment and are quick to blame the government or other agencies. Hence, while the former wanted complete redevelopment of Chara Mandi, the latter wanted to retain their place of residence but shrugged off any responsibility of maintaining the place.

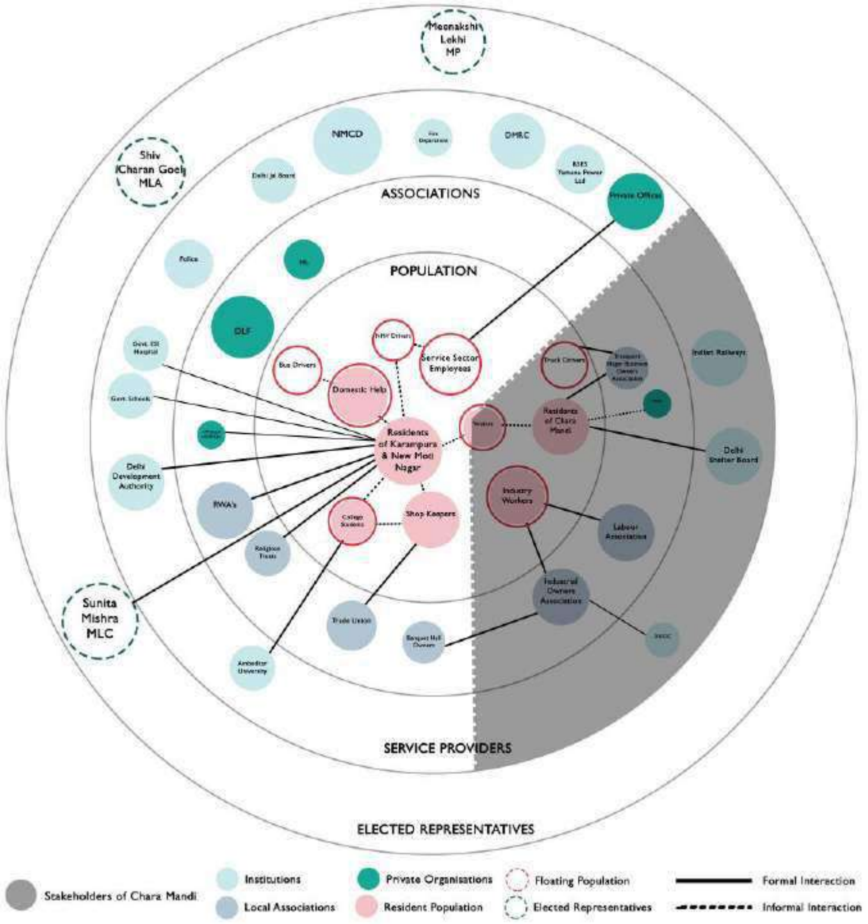

Figure 3 Stakeholder interaction Map for Karampura

3.1 Children as the key for communication

Since Chara Mandi exhibited issues of social segregation and distinct power hierarchy we required the perspective of the un prejudiced: children. It is a well-established fact that children are much more perceptive to their environments than adults. While we try to teach our children all about life, our children teach us what life is all about. Through them we were able to discern the complex social networks and the overlays of attitudes of adults that govern the social structure of a place. The requirement in this scenario was the opinion of an unprejudiced individual who doesn't have specific agenda but can permeate the glass ceiling between the two groups. Children are more perceptive of their immediate surroundings and the behavioral patterns of adults whom they interact with regularly.

3.2 Identifying age group of children using Piaget's Cognitive Development Theory

According to Swiss developmental psychologist Jean Piaget's Cognitive Development Theory, each child goes through the four stages of development, Sensorimotor stage (birth to age 2), Pre-operational stage (from age 2 to age 7), Concrete operational stage (from age 7 to age 11), Formal operational stage (age 11+ - adolescence and adulthood) and child development is determined by biological maturation and interaction with the environment.

Among 2038 people in Chara Mandi, 367 are children, majority (almost 60%) of whom fall within the age group 7- 15 yrs. i.e. the concrete operational stage and formal operational stage.

Concrete operational stage is characterized by the appropriate use of logic. During this stage, a child's thought processes become more mature and "adult like". They start solving problems in a more logical fashion. Abstract, hypothetical thinking is not yet developed in the child, and children can only solve problems that apply to concrete events or objects. At this stage, the children undergo a transition where the child learns rules such as conservation. Piaget determined that children are able to incorporate Inductive reasoning. Inductive reasoning involves drawing inferences from observations in order to make a generalization. During this stage, the child acquires the ability to view things from another individual's perspective, even if they think that perspective is incorrect.

In Formal operational stage intelligence is demonstrated through the logical use of symbols related to abstract concepts. This form of thought includes "assumptions that have no necessary relation to reality." At this point, the person is capable of hypothetical and deductive reasoning. During this time, people develop the ability to think about abstract concepts. This stage is characterized by

- Abstract thought emerges during the formal operational stage. Children tend to think very concretely and specifically in earlier stages and begin to consider possible outcomes and consequences of actions.
- Metacognition, the capacity for "thinking about thinking" that allows adolescents and adults to reason about their thought processes and monitor them.
- Problem-solving is demonstrated when children use trial-and-error to solve problems. The ability to systematically solve a problem in a logical and methodical way emerges.

(Gruber, 2004)

Selecting children aged 7-15 has many advantages, especially from the neighborhood of Chara Mandi,

- They are able to understand the concepts of public and private, home and neighborhood. Also, they actively interact with the public realm on a daily basis.
- Their views are not based on any specific ideology or influenced by caste and gender but mere responses to the stimuli that they face every day.

- They are more educated than most of their parents since 90% of is engaged in loading works in the logistics and warehousing industries population in Chara Mandi and have never been formally educated. hence children can communicate ideas of sustainability and participation with the adults in the community more effectively.

3.3 Methodology

3.3.1 Stage I: Identifying Issues

The first stage in this experiment was to inform the children[ii] about the need for dialogue in improving the conditions of Chara Mandi. In order to achieve this, a painting workshop was conducted with the theme 'my Neighbourhood'.

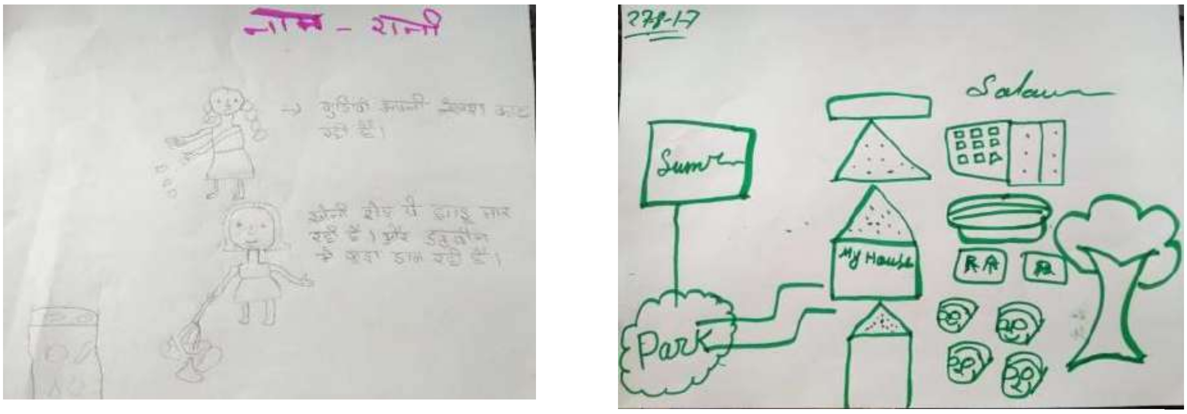

Figure 4 Paintings highlighting the issue of garbage disposal and need for parks

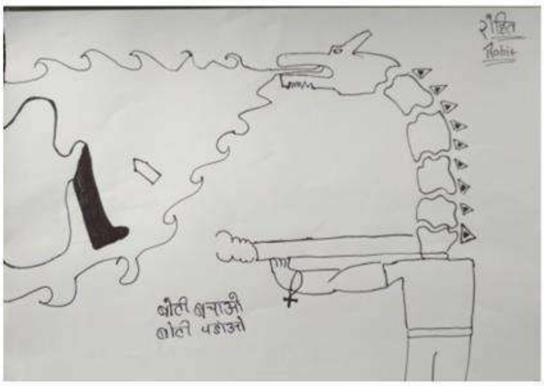

Figure 5 Paintings highlighting issues of female safety

Figure 6 Painting showing the future of Chara Mandi

Figure 7 Children at the Painting Workshop

Outcomes: The competition bought out interesting views about the neighbourhood. Children identified simple issues like lack of playgrounds to complex issues of women safety and water pollution. It was also interesting to note that majority while identifying the issue also presented us with a possible solutions or future scenarios which underlined the fact that they were hopeful of a better future.

3.3.2 Stage II: Design Presentation to Community

In the next stage, the community was presented with possible design solutions to the issues such as lack of housing, unorganised logistics industry and lack of social amenities and open spaces. We first presented to a group of children, explaining the different elements in the design and visualizations of the transformed neighbourhood.

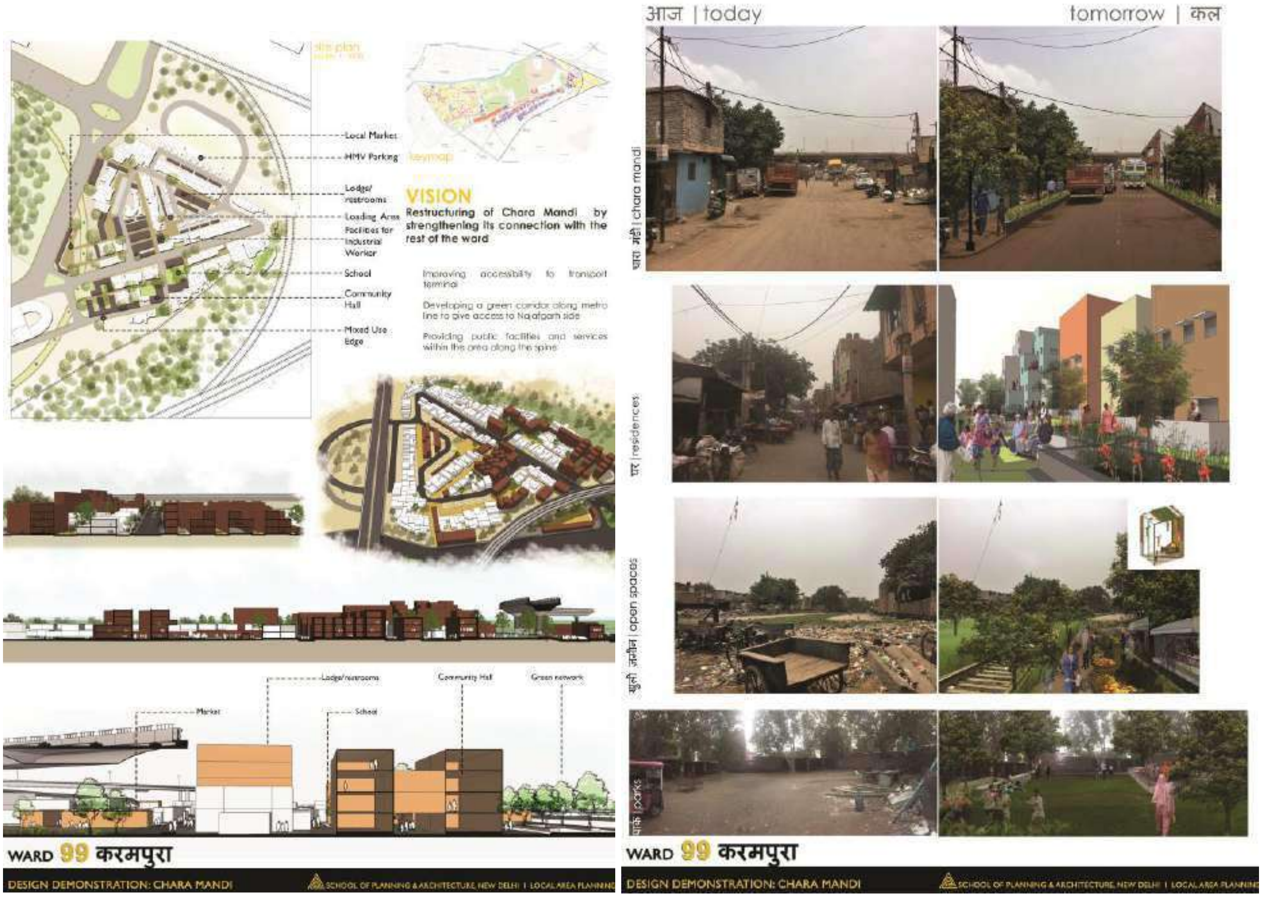

Figure 9 Design Presentation made to the community

Outcomes: After the first presentation children took the lead to explain the design intent and steps to achieve them to the adults in the community. They successfully differentiated between short term goals such as cleaning up streets, planting trees, making sidewalks and long-term goals such as redeveloping housing stock in the area, organizing the logistics industry and improving safety in Chara Mandi. They also started identifying tasks that they could take up individually such planting a tree in front of their house, keeping their street clean etc. and conveyed the same to the adults. This motivated the adults to discuss among themselves regarding the merits and demerits of the design.

Figure 8 Children making a list of short term and long-term goals

Figure 10 Children explaining the design and goals to adults in the community

3.4 Observations

Children Aged 10-15

- Were more active in the whole process and they were willing to take responsibility which inspired the adults to be more involved in the process.
- Were able to connect smaller goals to larger impacts e.g. Planting trees help in curbing soaring temperatures, reduced trucking leads to better air quality.

Children aged 6-9 years

- Were much more enthusiastic participants as compared to older children and more successful in getting the attention of adults.

4 Lessons from Chara Mandi

4.1 Children initiated a conversation between people from diverse backgrounds

The community engagement for the design exercise was based on the social theory of Ripple effect, where the child becomes the initial point of contact with the community. Through him/her we are able to understand the community better and transmit information back to the community.

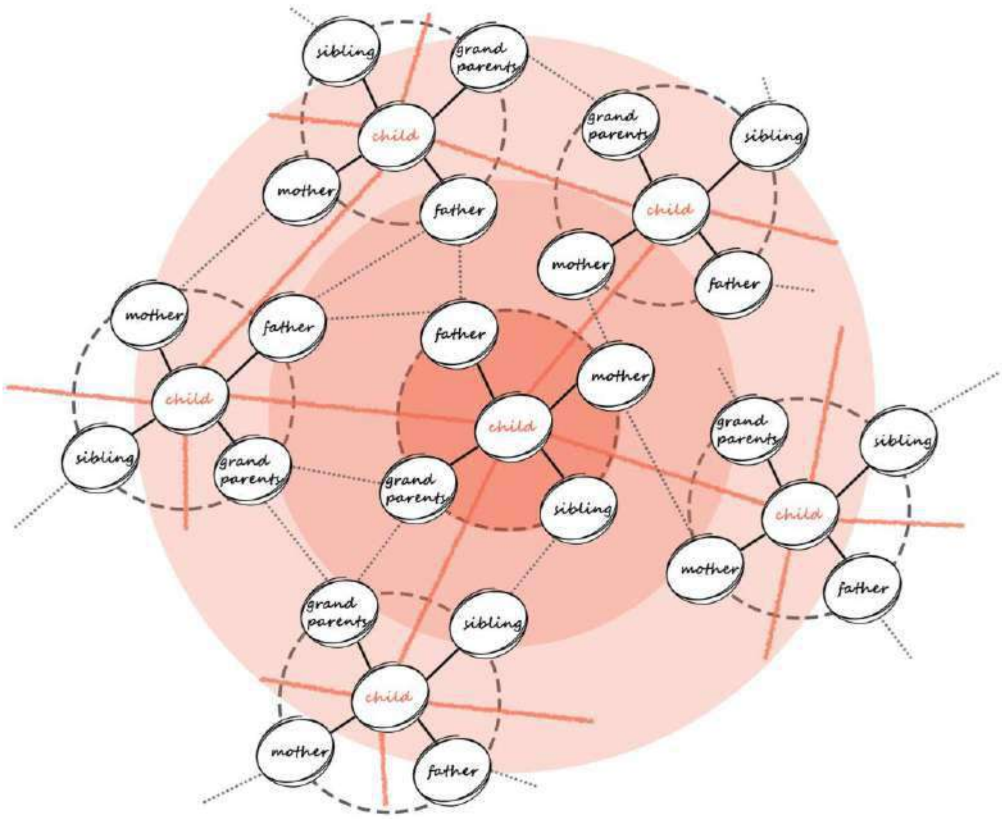

Figure 11 Ripple effect in information dissemination

4.2 Children helped the community to understand different types of goals

Children broke down the final design into two categories: Things we can do and things we need assistance from others. The categories were fairly resembling the technical terminology of short term and long-term goals.

Things we can do now	Things we need assistance for
Plant more trees	Systematic Garbage pickup
Avoid Littering in public places	Developing Housing stock
Reroute trucks from certain areas	Providing deficient social infrastructure

This helped the adults (majority of whom have no formal education) understand the possible course of action to be taken to achieve the goals, e.g. The members of Transport Owner's Association discussed the advantage of designating one area for truck parking, loading and unloading activities after the children pointed out they don't want truck parking in the residential areas.

4.3 Children as agents of change

According to philosopher Jean-Jacques Rousseau (1712–1778) children were innately good and willing to learn for which reason children should interact with their environment (Palmer, Bresler, & Cooper , 2001). They are also largely unaffected by the political, religious and economic biases that govern most of the adult interactions. They have increased sensitivity to nature and environment, they promote social equity and well-being of others and hence act as a catalyst to bring communities together.

If children are given the opportunity to design, plan and perform study with adults, then adults must admit children as involved and capable delegates and be eager to entitle the child as the 'expert'. Such experience would be very influential for a child who may not have ever been in similar situation. (Masri, 2017)

The realization that urban form has a bearing on the psyche of a child and through the child were able to bring the adults to the discussion table were two important findings from our study. The very act of seeking input from children can make an entire community more aware of and responsive. More importantly, the experience of participation is extremely positive for children. At the age of ten to fifteen years old, many are beginning to develop a sense of their own identity. This is precisely when increased interaction with the world may be reinforcing feelings that their particular awareness of place will always be disregarded. By contrast, participation in environmental decision-making fosters self-esteem and self-efficacy, and may lead to a greater appreciation of democratic values. (Moffat, 2002)

An appeal for basic public services will always be stronger if it is backed by the voices of children. It was very evident that few officials will overtly oppose the reasonable requests of a group of children who want to cooperate to improve their environment.

5 Acknowledgement

The author would like to credit Manasa Garikaparthi for her contribution in conducting the study and conceiving the design for Chara Mandi. She would also like to thank Aparajita Santra, Sayali Virulkar, Aniruddha Mutsuddi, Rinky Haldar, Abhirami Prabhakaran and Thejus Augustine for their contribution during initial stages of site study.

How local re-commoning initiatives set a spark for global challenges

Annette KUHK, KULeuven/ Humanarc, Belgium
Guy VLOEBERGH, OMGEVING cvba/UAntwerpen, Belgium

Climate change has been described as the ultimate tragedy of the commons, in which we observe on a global scale how the use of scarce resources in self-interest often develop in contradiction to a collective use of resources (cf. Hardin, 1968; Paavola, in: Cole, Ostrom, 2012). The mitigation of (and adaptation to) climate effects are discussed at international environmental conventions, yet also deployed in many local communities. We argue here that a good share of answers to climate change, and closely related also to the problematic use of scarce resources such as land, can be found in active (re-)commoning practices, where citizens act as responsible stewards for land uses.

Contemporary practices of 'commoning' depart from shared ownership and/or shared use rights by a 'host community' of commoners who collectively agree on a set of rules, which mobilize the existing institutional-political system and who intervene for the maintenance of a collective good. The operational implementation of these grand principles of landed commons for a series of micro-cases in Flanders region (Belgium) have been extensively studied in the INDIGO- project[1]. Based on this research of landed commons, we here elaborate on three domains where commons have been negotiated to intervene in (peri-)urban metabolisms, i.e. in organic farming, in social housing and for slow roads. The (re-)commoning initiatives in these domains develop as sustainable practices to directly or indirectly slow down climate change. Re-commoning is equally raising awareness of communities and the resilience of places, and as such, it is contributing to capacities for adaptation. We briefly discuss the values in which commoning practices are rooted, and how the underlying value patterns can be relevant for the wider discussion on climate change.

1. Structure of the paper

We start from a concise overview of the 'grand principles of landed commons', and we then introduce three commoning examples in Flanders, i.e. on Collectief Goed in the city of Antwerp, on the micro-case Wervehoef with stakeholder 'De Landgenoten' in Wijnegem and on the micro-case Hoofse Hoek with stakeholder 'Trage Wegen' (i.e. 'Slow roads'). In this, we briefly present the main actors and stakeholders in the negotiation of landed commons, and their respective roles as stewards, custodians or users, as well as the role of local authorities to support citizen-led initiatives on commons. From this, we move a step ahead to elaborate on the institutional diversity and on the hybrid forms of governance for (re-) commoning initiatives. Last but not least, we briefly discuss how single cases can set the spark for a more generalized practice, and how the cumulative effort of relatively small scale interventions can possibly

[1] A collaborative research project, with partners from the Katholieke Universiteit Leuven, OMGEVING cvba, Universiteit Antwerpen and Harokopio University, from 2015-2018.

contribute to wider societal challenges. We here assume that a large, encompassing problematic such as global warming requires a fundamental change of behavior and lifestyle of users, which is stronger if rooted in a multiplicity of bottom-up initiatives such as the citizen-induced initiatives on landed commons.

2. Grand principles of landed commons

The Grand Principles of Landed Commons (GPLC) describe the nature of the Landed Commons (LC), and refer to ten principles which are at the core of any discussion on the commons (P1-P10). They are based on a survey of academic literature on urban and rural commons, experiences of activist agents, policy documents, etc. (Saavedra Bruno e.a., in: Van den Broeck e.a. (eds.), forthcoming). The following briefly explain the ten principles, which are listed in table 1. We 'reshuffle' the list of principles to create a match with three widely recognized core features of commons, i.e. the common-pool **resources**, governed as commons by a group of **commoners** and developed within the possibilities and/or boundaries of existing **institutions** (i.e. commoning practices).

Resources

Landed Commons develop as a **collectively agreed or mediated system of inclusive land ownership and/or shared rights of use (P1 and P3).** This diversity of uses, access and management of land develop beyond the current market-oriented dichotomy between private and public ownership. Landed Commons arise where public authorities and the market fail, and where individuals unite to deal with these shortcomings. With this, they attempt to answer to contemporary economic, ecological or social issues, where adequate formal frameworks are lacking, e.g. in taxation, legal rules, organizational forms or land use conditions. Both private and publicly managed goods have been increasingly subject to commodification for several decades, i.e. enclosure, privatization and marketing, which are affecting natural resources and lead to the disappearance of collective spaces. A characteristic incorporated in the landed commons assets, is their 'sharable nature'. Landed commons are sharable in the sense that the resources can be accessed and used by multiple users; at the same time however these resources vary in their capacity to accommodate different users, exhibit different consumption/ valorization thresholds and embody variable reproductive potential.

The **community-based use and/or ownership of landed commons (P2)** depart from two constellations. There are, on the one hand, places that can be regarded as 'community goods' by their nature, such as a coastal strip and dune belt, the banks of an inland lake or a river, the rivers themselves or large areas of nature and forest. In practice, we also see exclusive access rights here though, e.g. with gardens of private homes near riverbanks, private catering establishments along lakes, on beaches and in dunes, e.g. along the Belgian coast, or in privatized green areas. On the other hand, there are also landed commons based on a specific recognition of shared ownership or shared use for a specific group of users (e.g. a passage that remains open on basis of customary law).

Commoners

Commons ask for commoning: in order to develop shared use or shared ownership, **a host community (P9)** tries to obtain user or property rights, and to govern the property carefully. A host community can be a collective, a group, a community, an association, a movement or for instance a cooperative. Landed commons develop where a social-ecological relationship is established between the country and its multiple resources and a group of people who take on the **stewardship for these resources (P6).** Openness and inclusion are important values in managing it. It is the host community and not the market or the government, which is responsible for the governance of the Landed Commons. The collective is a group of people with the same value orientation regarding the use of certain goods. **Collectively agreed rules (P10)** should prevent from the alienation of rights and they should foresee exit and entry rights.

Institutions

A landed common aims for a diversity of **more inclusive property and land use regimes (P4).** For example, a tenant cooperative involves its members in the ownership of its homes and land, and this is not the exclusive right of individual families. Commons usually require a (re-)interpretation of property or user rights, supported by the intervention of a collective and often leading to collective agreements. Landed commons equally require **a hybrid form of 'governance' (P5),** with arrangements that combine hierarchical relations, market regulation, self-organization, affective relations, etc. In order to develop such inclusive regimes and hybrid governance arrangement, **the existing institutional-political system is mobilized (P8)**: which interpretations of laws and rules are possible? Is an adaptation of the current regulations necessary to organize shared land use in a flexible way?

P1. **Diversity of use:** 'Landed Commons' are a collectively agreed or mediated system of diverse land use rights practiced individually, jointly, interactively or in a time-sharing mode.
P2. **Community-based use and/or ownership,** based in two possible perspectives, i.e. as resources which by their nature and use may be regarded as more naturally communal, or as resources that are acknowledged in the context of communal ownership.
P3. **Institutional diversity:** Landed Commons cover a wide array of ownership regimes between private and public, defined by mixed legal arrangements (e.g. the situation of a tenant, of a landlord, situations of usufruct, etc.) and institutional configurations.
P4. **Inclusiveness**: The Landed Commons involve more inclusive ownership regimes which make the practice of shared individual land use rights or the benefiting from common pool resources easier and more efficient in use.
P5. **Hybrid governance arrangements:** Governance as a commons is usually a hybrid relationship combining hierarchical relations (state, corporate structure), market regulation, self-organization through networks and associations, affective relations….
P6. **Stewardship:** The landed commons should be considered as a social-ecological relationship between land, its resources and a group of people who accept stewardship over the resources.
P7. **Resource-based governance arrangements**, which are related to the nature of the resources, the manner in which the resources are utilized, the extent to which they generate value, their institutional and community setting.
P8. **Application of the institutional-political system:** The institutional-political system of spatial planning, property laws and regulations must be mobilized and modified to make the smooth functioning of existent and desired landed commons possible.
P9. **Host Communities mediate use claims**: These communities should by preference be communities in a position to establish the aforementioned social relationship.
P10. **Rules of exploitation:** Landed commons should be governed not just through open access, but by clear rules to prevent overexploitation.

Table 1: Grand Principles of Landed Commons (based on Saavedra Bruno e.a., in: Van den Broeck e.a. (eds.), forthcoming)

3. Commoning examples

The Grand Principles of Landed Commons (GPLC) can be used as a tool to assess the features of Concrete Landed Commons (CLC), in terms of governance, resource use, commoning practices, etc. These features evolve as the commons develop. Over the last fifteen years, we see many different landed commons initiatives appearing throughout Europe in many different domains, e.g. community land trusts and cooperatives in housing, collaborations on energy provision and/or projects in circular economy, cooperative land funds and consumer-cooperatives for organic agriculture, community gardens, negotiations and user groups for the use of open spaces – whether private or public- or for instance negotiations over slow roads. The initiatives differ largely in how they apply and develop various principles of landed commons from temporary shared use to formally agreed inclusive ownership (P1), from naturally communal spaces to privately owned spaces that are forcefully reclaimed for collective use[2] (P2). There are commons that develop within existing institutional boundaries and at times with the support of it, as well as commons-initiatives that powerfully complement, challenge or stretch existing configurations, ownership regimes and governance arrangements[3] (P3 to P5, and P8). There are initiatives with relatively small host communities where stewardship is quite literally 'guarding' a space to the more abstract stewardship through participation in a larger cooperative (P6 and P9), with initiatives that hardly formalize agreements over the use up to initiatives that have clearly formalized rules and explicitly articulated values[4] (P10). Whereas the versatility of new commons as well as re-commoning initiatives risk to stretch the notion of commons, there is also a richness and explorative power in this multitude of actions. We will back to this in the concluding reflection. We first want to zoom in on three micro-cases in Flanders, which we studied in the INDIGO research project.

Three Flemish cases

We studied three cases to see how a host community forms, how ownership regimes are interpreted, and through which hybrid form of governance the land-based common property is managed. The three cases apply a landed commons perspective to contribute in different ways to a more sustainable use of land. The housing cooperative 'Collectief Goed' promotes the re-use of existing housing units and stresses social sustainability. The land fund and cooperative 'De Landgenoten' invests in organic farming and attempts to preserve agricultural land for local, sustainable food production. 'Trage Wegen' then intervenes in the intertwining of different open space claims, and aims at the creation of networks of slow roads at the benefit and health of the most vulnerable traffic users, e.g. hikers.

Commons and housing

'Collectief Goed' is a recently established housing cooperative in Antwerp aimed at providing qualitative and affordable dwellings for large families with low incomes. The cooperation renovates the accommodations and rents them out to vulnerable households. Because of this focus on people in poverty Collectief Goed is rather an exception amongst housing cooperatives, who generally work with middle-class families.

---

[4] Cf. Bologna manifesto

Protagonists in the construction of a housing cooperative

The origins of Collectief Goed lie in the association ‘Arm in Arm’, where fathers of families with a low income talk about the problems they confront and help each other to find solutions. The association is supported by social work organization Samenlevingsopbouw Antwerpen. An often-recurring theme in these sessions is the problem of inadequate housing. Bad quality housing affects every aspect of life: health, social life, job chances, school performance, etc.

For these families the search for affordable housing in Antwerp is virtually hopeless. It is impossible to find accommodation for less than 700 or 800 euro a month, which is unaffordable for families with a total monthly budget of 1200 euro. Meanwhile the waiting lists for social housing are extremely long, in particular for large families. Social housing societies simply have too few dwellings and struggle to keep up with necessary renovation work.

This situation led Arm in Arm to start searching for own solutions. In 2012, not by chance the year of the cooperative, the idea arises with the fathers and social workers of Arm in Arm to establish a housing cooperative. One year later, resulting from a cooperation between Samenlevingsopbouw Antwerpen (city administration) and social housing agency De Ideale Woning (DIW), a temporary solution is found: large low-budget families can take residence in empty social housing that is awaiting renovation. During this collaboration it became clear that DIW was struggling to keep up with renovation work and Samenlevingsopbouw saw an opportunity to include them in the housing cooperative: DIW would provide the dwellings, the cooperation would take care of the renovation and support matching tenants. In return for providing the dwellings, DIW receives shares and becomes a partner. The cooperation is called ‘Collectief Goed’, a clever play on words on collective good(s).

One of the biggest challenges for Collectief Goed was to establish a financially stable model. Creating affordable housing means that the amount of money going to rent cannot be bigger than one third of the total budget, for most families around 400 euro. By adding a rent subsidy to that amount, the cooperation arrives at a rent of 600 euro, just enough to stay financially healthy. But the cooperation also finds more innovative solutions. To reduce the costs of the renovation, Collectief Goed works with internships under the guidance of a professional renovation instructor. An added renovation subsidy of the city of Antwerp reduces the costs even more. This allowed to start with a first project of 9 housing units in Merksem.

The long-term goal however is to become completely independent by 2021 from the support of Samenlevingsopbouw, i.e. for the structural costs of personnel. 1. To reach this goal, the cooperation has to grow at a relatively fast pace of ten dwellings a year. The ‘Achilles heel’ is not the provision of houses ready for renovation, but the speed of renovation with trainees. Additionally, the guiding and mentoring of suitable candidates consumes time and energy, introducing a certain inertia in the process.

Even though the cooperative Collectief Goed inevitably comes with a certain fragility, it is still an innovative and truly social housing model. Over time, Collectief Goed will have to outgrow its niche character to make a significant societal impact on the lives of the most vulnerable citizens of Antwerp.

Commons and agriculture

A second case is the fund and cooperation 'De Landgenoten'. This Flemish organization attempts to grant access to agricultural land for organic farmers. The plots are purchased with money from the shares of the cooperative, and the farmers sign user agreements for the use of land. Whereas the agricultural land is usually rented by farmers from the CPAS, church property or private landowners, the land at De Landgenoten is owned by a cooperative. This ensures that the current and subsequent generations of farmers will only cultivate the land organically. A number of projects are also self-harvest or CSA-farms, where the farmer's income is supported by a community and a multi-level shared ownership arises. In the case of self-harvest, this group of shareholders also literally has access to the land for harvesting.

Commoning land for agriculture at Werve Hoef in Wijnegem

The site 'Werve Hoef' in Wijnegem is one of many micro-cases of De Landgenoten. It is located in the urban fringe of Antwerp. The name 'Werve Hoef' refers to a farm from the 16th century on the site of the current farmhouse. There were also medieval traces of a cemetery and an associated church from the 15th century on the other side of the site. With about 11 hectares in the middle of a densely build-up 20th century suburban area with a multitude of local facilities, the site of Werve Hoef is a premium location for housing development in Wijnegem. Today, the area presents itself as a vast open space, with only one building left that could be used for agriculture. Whereas the area is largely intended as a residential expansion area (and as such defined in terms of land use), the vacant lots are mostly used today for agriculture.

The local authority of Wijnegem and the social housing company De Ideale Woning (DIW) intend to jointly develop a sustainable neighbourhood at Werve Hoef. There has been a chain of interactions with different actors towards a commons-inspired use of the site. Many steps towards communing hold a fragile, future-oriented and at times utopian promise of commoning, without certainty to actually translate grand principles into concrete landed commons. We can distinguish five stages of interaction in this "run-up towards commoning": (1) First, the social housing company De Ideale Woning (DIW), who is the owner of the plot, takes the initiative to develop the site. (2) When 'De Landgenoten' (DLg) joins the negotiations, different plans have already been drafted. (3) The next stage then is to draft a shared project description with DIW and DLg, (4) which equally allows to screen different farmers and to select one. (5) The provisory last stage finalises a series of formal consolidations between the owner, the cooperative and the farmer. An important stage to come is the construction of the social housing units, the actual farming activities and the links with the new inhabitants.

Throughout these interactions, there are three important dynamics in the development of agricultural land as a concrete landed commons. First of all, there is the discussion on the use of land with the social housing company DIW, the cooperative De Landgenoten, the new farmer, the current users of the land and the local community. The discussion is mainly about the collective character of land use and particularly about the link to the existing and the new community. Secondly, the interactions focus on building a host community to govern the agricultural land as a commons. Thirdly, there is a long run-up needed to get to an agreement about the ownership regime, which develop with relatively few actors.

Commons and slow roads

The projects of the 'Slow Roads' organization is another central case in the INIDGO-study.[5] Slow paths are roads that are not accessible for motorized traffic. In the case-study, it is being investigated how shifts in the use of land in private as well as other ownership regimes contribute to making a Flemish network of slow roads accessible (or keeping it) and to increase the collective space. It is not excluded that other, more "common" forms of ownership may arise in the long term.

Commoning slow paths in the case of Hoofse Hoek in South of Antwerp

The Hoofse Hoek path is connecting the municipalities of Hove and Lint in the peri-urban South of Antwerp. The wider area already came under the attention of the newly established inter-municipal network ‘Landschapspark Zuidrand’ in 2012, when 9 municipalities agreed to collaborate to create a regional landscape, i.e. preserving the region-specific open spaces. Slow roads could become a ‘capillary system to the open space’, that would serve to ‘counteract the creeping urbanisation of the region’ (Saavedra Bruno e.a., in: Van den Broeck e.a. (eds.), forthcoming). It took three years from the start of the project to create slow paths to the official opening of the Hoofse Hoek path (May 2012 untill October 2015). The project team with a project facilitator from the ‘Trage Wegen’ organisation, a representative of the inter-municipal network and members of the municipal public administrations of Hove and Lint organised the collaboration with both local and supralocal actors to make this happen, e.g. with farm tenants, with the Flemish Agency for Forestry and Nature, as well as with the environmental organisation Natuurpunt. The definition of the trajectory required in-depth analysis of options based on site visits, public advisory rounds and many separate talks with land owners and land users. Even if it only concerns a relatively short trajectory of 400 metres, it required a relatively broad scope of collaboration, i.e. also including the social welfare organisations from Antwerp and Lier as owners of major parts of land across which the path would run, as well as the Dienst Integraal Waterbeleid since this water management agency demands a 5 meters strip for service next to a brook across which the path would run. The organisation Trage Wegen drafted a ‘use right package’ to be negotiated individually with land owners and land users (e.g. including a right of pasage to be reviewed after one year, and to present the idea of local stewards to guarantee enforcement of the agreement). They equally discussed issues of maintenance, issues on constructions, inclusion in a regional hiking map, etc. The process of negotiating use rights reveals ‘how delicately the project team had to manoeuvre in order to deal with property issues, emphasizing the predominance of the logic of ownership’ (Saavedra Bruno e.a., in: Van den Broeck e.a. (eds.), forthcoming).

4. Lessons learnt from the cases

The three micro-cases from different Flemish organizations illustrate how concrete commons-initiatives mobilize different principles of landed commons, which requires negotiations with a variety of actors to develop tailor-made approaches and hybrid governance arrangements (cf. P5) for particular land uses (cf. P1) and/or ownership regimes (cf. P3). The arrangements need

[5] The main researchers for this case are Sofia Saavaedra Bruno, Pieter Van den Broeck, Constanza Parra and Frank Moulaert (and untill 2016 also Mattias Bussels), also KULeuven.

to comply with the specificity of the targeted common-pool resource (cf. P7), with local conditions and spatial claims of respective host communities (cf. P9) as well as with conditions from the wider institutional-political system (cf. P 8). Whereas commons are a category 'in-between' public and private assets, commons-initiatives clearly also relate to market or governmental practices, to hierarchical and market-led structures, as well as to self-organization and specific affective relations.

Tailormade hybrid governance arrangements

For instance the hybrid governance arrangement of Collectief Goed involved the city of Antwerp as a partner with a management role (i.e. Samenlevingsopbouw), as well as the social housing company De Ideale Woning and the association 'Arm in Arm'. Crucial in this micro-case was the decision to renounce from selling plots at market values, and instead to convert the value into shares for a cooperative, in which also the social housing company is involved as a shareholder. Even if converted: the market logic and value of the plot has been relevant in the calculation of the shares. Collectief Goed stresses social objectives: the involvement of tenants in the renovation of their houses is but one example of how to implement these aims in a tangible way. It incorporates a logic of social economy and of self-organization. Last but not least, the hybrid governance arrangement for Collectief Goed also relied for a large part on the personal commitment of particularly one person: also affective relations and involvement can explain an important share of the tailor-made approach.

We detect an equally large hybridity in the arrangement for De Landgenoten: the fund receives donations as well as incomes from the share of the cooperative in order to purchase agricultural land (at market prices). In its functioning, the cooperative partly relies on government subsidies. On top of this, local authorities can be a partner in a project as a land owner or a mediator. In order to create public support for specific cases, that also leans upon the voluntary commitment of 40 ambassadors, and the support of many interested people and organization for crowd-funding actions. Whereas each micro-case for De Landgenoten knows its particularities, and requires a tailor-made approach, the Werve Hoef case is a novelty for three specific aspects: for the first time, De Landgenoten would agree on a long lease for the land instead of being the owner of the agricultural land. This novel constellation also has a financial impact, since the annual payments for a lease require much less financial means. With the owner still involved when the land is used for organic farming, the owner also has a say over land use and the hybrid arrangement thus is somewhat more complex.

Likewise, the case of slow paths lead to hybrid governance arrangements, which are constructed with the owners and users of paths, who were previously largely disconnected. It is a truly collective, and therefore also fragile endeavour to agree on use rights and ownership regimes. It is desirable to find a stable agreement for these linear structures, which are part of a larger network, also for the case that one or more owners would decide to sell their land.

Renewed interest despite little legal anchoring

If you depart from the strict legal theory, there is currently no room for landed commons in Flanders: there is a finite number of separate legal figures (e.g. in commercial law), that regulate property and use, including naked ownership, easement, leasehold, tenancy rights, co-ownership and usufruct. The 'collective' is largely abolished by law as an organizational form and a legal figure at the beginning of the 19th century. For instance common meadows, guilds or beguinages received a private or a public owner, and well-defined rights. The renewed interest in the Commons, for example in cooperatives, guarantee funds or trade unions, for the collective provision of energy (Ecopower), food production (CSAs) or housing (e.g. Samenhuizen), puts pressure on existing legal restrictions. We witness the emergence of intermediate forms and interpretations of existing legal figures, often starting from commons-based remnants in legislation, such as easements, municipal goods and co-ownership. The question is how from such legal figures the common good can again be given a formal place in the legislation, in order to better support the complex reality of (shared) ownership.

Towards a generalized practice

The different cases and particularly also the organisations behind the case have one shared and recognisable pressing concern, which is to ensure the long term survival for commoning initiatives, or – more optimistically- the growth of the organisation and the evolution towards more generalised practices. This can lead to a scaling up, i.e. a larger organisation or to a process of scaling out, i.e. with a multiplication of the number of micro-cases. All three main INDIGO-cases are confronted with these issues, at time with both scaling up and scaling out. This challenge of organisational positioning leads to different issues[6]:

1. How can a stable financial model and flow of means be built that leads to self-sustaining organisations? Whereas a cooperative or association may at first rely on starting grants or subsidies, this usually does not provide a sustainable perspective for the long term. A financial strategy towards a self-sustainable organisation often implies economies of scale.

2. Building and strengthening an organisation equally requires a widening of the host community. This implies issues of mobilisation, communication and participation, but possibly also issues of consistency and continuity. How can tenants become responsible stewards for the common good? How can a large group of ambassadors for De Landgenoten and farmers be up-to-date with the organisations' evolution? How can be assured that 'road spotters' share the (evolving) concerns of the slow road organisation? What are the limits in upscaling a participatory model to involve commoners?

3. Last but not least, shifts in scales also change relations with other actors, which possibly also forces a transition in the own organisation. A cooperative or association moves beyond being a niche player when it becomes recognised as an actor in a larger transition, but possibly also perceived as a 'competitor' or even 'threat' to mainstream approaches. With this, the organisation's own logic might shift, e.g. from a small-scale movement that emphasised solidarity and sustainability, towards a larger upscale organisation, that equally reflects on economic rational, scientific validity and a business-like project-based logic. Is this a true shift in focus or can it be reconciled with the initial ambitions? For instance the relations of Collectief Goed with other parties would possibly change when it becomes a bigger player for the supply of housing. Targeting at a more general approach in terms of audience (attracting higher incomes) and marketable activities (the provision of services by the residents) may perhaps strengthen the capital base and ultimately help more large poor families from their housing problem. But does it distract from the core aims? Similarly, the cooperative De Landgenoten is expected to grow faster through an alliance with actors from local food strategies, whereas it has to recognise that these actors not necessarily also subscribe to organic farming. At what cost is upscaling defendable?

[6] These issues where developed at a workshop, which was organized by the INDIGO-consortium for the IASC conference on commons, Utrecht, July 2017.

The ambitions towards more generalised practices differ in the three cases. For instance, the cooperative De Landgenoten expects to be able to run autonomously with at least 100 ha of land (i.e. to receive a return from user agreements with farmers large enough to support the operational costs of the cooperative). The organisation Trage Wegen is equally involved in the realisation of different micro-cases, but there is no direct relation to the income of the organisation. Also, the micro-cases ideally contribute to a larger network of slow roads.

Also Collectief Goed illustrates that changing scales does not necessarily lead to more means for an organisation: the tenants cooperative uses rent income to renovate the houses in a breakeven way. Introducing a more generalised practice would imply a multiplication of projects such as the housing project in Merksem, probably still within the same cooperative. In the long run, the cooperative can try to become an institutionalised partner in the housing system, and possibly even a third pillar to private and public/social suppliers.

5. Commons-practices as a game-changer for climate issues?

In a brief epilogue, we would like to link the here described practices to the ‘cool’ theme of the conference, i.e. the role of urban planning for climate issues. We here focused on commons-initiatives, which generally start from civil actions, although the hybrid governance arrangement proved that all projects also have links to public authorities as well as to market logics and market actors. Whereas the projects are no direct contributions to climate action plans, the development of landed commons principally does contribute to a logic of sustainable use of land, involving many different actors as stewards for sustainable use, and therefore also relate to issues of climate issue. The first question of the fifth conference track suggests to consider how climate change can affect citizen participation. Based on the study of the relatively small-scale commons-initiatives, we here would like to invert this question into an active bottom-up perspective: ‘How can citizen participation affect climate change?’

The British professor for Environmental Social Science Jouni Paavola[7] addressed the relation of Commons and Climate Change in the book “Property in Land and other resources”[8]. He states that *“Climate change can be understood as a problem of using common-pool resources”* (Paavola, p. 422), but that *“Land use and land use change (…) are examples of issues that remain wholly or largely unaddressed by the current climate change regime.”* (ibid.). The different examples of *landed* commons take land use and ownership as a point of departure to foster sustainable use of common-pool resources.

Time and scale of commons initiatives matter in this, since they are rooted in local host communities, who act as stewards for a specific common-pool resource. The local communities develop a socio-ecological relationship concerning a specific common-pool resource, for which they agree on a set of rules, based in a consensus on the interests and claims of the various communities of practice and individual users involved. Host communities become effective agents of sustainable development, mediating in possible social or environmental conflicts, ideally not overlooking minority voices. The relation to the resource is developed on the local scale, i.e. a scale that allows for consensus over a detailed scheme of regulations and a scale that allows enforcement.

[7] Professor of Environmental Social Science at the University of Leeds
[8] Published by the Lincoln Institute of Land Policy in Massachusetts

Agreements on the scale of planet earth, with a vast multitude of actors and socio-spatial claims risk to strand on lowest denominators[9], and/or to actually repeat the tragedy of the commons. Over longer periods of time and in a larger scale, one risks to have situations of free-riding, over- or underuse, or even a majority acting according to individual rationalities.

SMALL SCALE COMMONS **Joint use as a commons** **= favorable to all people in a given community, possible to reinforce rules**	Scaling up and/or long term use Joint use with a risk of free-riding and over-use
Scaling up and/or long term use Joint use with a risk of under-use	**GLOBAL COMMONS** **Risks that a majority acts according to individual rationalities > tragedy of the commons?**

Table 2: Commoning practices in small and large scale.

The swiss-based scholar Anthony Patt[10] argues in this that the 'tragedy of the commons' is no longer a relevant problem frame for climate issues when every country and every single household has incentives to actively contribute to climate measures, regardless of what neighbors do (Patt, 2017: 2). He equally stumbles over the idea of negotiated binding agreements when it comes to global targets, and instead, proposes to base policy instruments in an evolutionary approach. We here want to argue that the tragedy of the commons-framing allows to understand why global agreements as well as the implementation thereof risk to be poor. At the same time, the narrative can – as an alternative 'invisible hand'- mobilise many different new commons and re-commoning initiatives on a local scale, which jointly contribute to a polycentric approach for climate governance (cf. Paavola, 2012: 429). Similar to the covenant of mayors for climate and energy objectives, the multiplicity of commons-initiatives that intervene in (peri-)urban metabolisms can have an important accumulated and systemic effect for global common-pool resources. It allows to raise awareness, change behaviours, lifestyles and practices starting from small, tangible examples, yet leading to a multiplication (and not necessarily always also to scaling-up) of collective action interventions that can add to the resilience of places and communities.

The INDIGO-consortium will publish main results from the analysis of Landed Commons in a special issue in the professional journal 'Ruimte' (September 2018). In November 2018, EPO will publish the book 'Op grond van Samenwerking: Open ruimte, Landbouw en Huisvesting als commons', in a collaboration between Dirk Holemans (Oikos) and the INDIGO research consortium. In addition to the cases from this research, we also involved a number of external partners, including Michel Bauwens about P2P, Geert Depauw about Community Land Trust in Brussels, Griet Celen about the toolbox of the Flemish Land Agency or Michiel Dehaene about Agro-ecological urbanism. The INDIGO research consortium is equally preparing an English academic volume on Landed commons, to be published with EE publications in 2019.

Adaptable Planning Strategies of Urban Sport Spaces in Cold Regions for Climate and Citizens' Needs: Case Study of Songyuan, China

Lihua LI, School of Architecture, Harbin Institute of Technology, China
Lingling LI, School of Architecture, Harbin Institute of Technology, China

1. Introduction

Over the past few decades, the role of fitness, recreation, physical activity and sport in improving health has been increasingly recognized (Sawyer, 2013). That high levels of physical activity benefit people's health have been well documented (WHO, 2016; Thompson et al, 2003). The pursuit for health has led to a rising demand for urban sport spaces (Lin et al, 2005). As one of the most important carriers for citizens to participate in sports, exercise and recreational physical activities and enhance their physical fitness, urban sport spaces are now closely related to citizens' health and quality of life (Nicolai, 2015; Fahlén, 2011).

Nowadays, with the development of mass sports and leisure sports (recreational sports), the scopes represented by urban sport spaces have been expanded from the specialized spaces (such as sports venues, gymnasiums) to public spaces (e.g., free sport parks, squares, green spaces and other non-professional sport spaces) in the city which can offer important opportunities and spaces for citizens to participate in sports, exercise and recreational physcal activities (Nicolai, 2015; Villanueva et al,2015; Jin, 2013). Evidence regarding the built environment and leisure sports activities is also beginning to accumulate on urban public spaces and urban public open spaces (Koohsari,2015; Florindo et al, 2017). However, no matter how urban sport spaces expand, their nature is always to serve their users—the citizens (Hassani & Golizadeh, 2016; Liu et al, 2013). To meet the real needs of the local population is an essential goal in the construction of urban sport spaces.

At the same time, as a natural condition of a city, climate acts directly on the leisure sports behaviors of citizens, the efficiency of urban sport spaces and the urban vitality, especially the unfavorable climate conditions (Luo & Li, 2015; Leng et al, 2017). In cold regions for example, clod climate in winter has been proved to reduce people's participation in physical activities (Merchant, 2007). In recent years, with the planning concept of cold cities, such as 'Liveable City', 'Winter-friendly City' and 'Healthy City', increasing importance has been attached to the planning of urban sport spaces in cold regions.

In a review of climate, urban sport spaces and users of sport spaces, relevant literature mainly focuses on two perspectives: one is concerned with the relationship between climate and users including the relationship between climate change and social background (gender, income, age, etc.) (Mizumoto, 2015; Eisenberg & Okeke, 2009; Dunn et al, 2012), and that between climate change and physical activity level (frequency, intensity, etc.) (Merchant, 2007; Nasir et al, 2013); the other pays attention to the association between climate and urban sport spaces such as accessibility (Westhuizen, 2010; Giles et al, 2003), space types (Schebella et al, 2012), and landscape activity (Watanabe & Jin, 2016; Zhao et al, 2018) under the influence of climate conditions. However, there are few extant data describing urban sport spaces in cold regions, especially the regional adaptable planning of urban sport spaces which is brought by the needs of citizens' sports and recreational physical activities under the influence of cold climate.

Under the above background and in China, with the promotion of the National Fitness program and the implementation of the Healthy China strategy, the demand for urban sport spaces in cold regions is more obvious because of the large sports population (Liu et al, 2015). However, due to the traditional making system and backward planning thought, the construction of urban sport spaces in China's cold regions still adopts the 'top-down' supply mode, and this means that the allocation and spatial layout of urban sport spaces are fully determined by the government (Zhang et al, 2017). To satisfy the needs for competitive sports events is still the only target in some cold cities (Yan et al, 2015). These problems of urban sport spaces seriously ignore the effects of regional climate and citizens' needs and hinder the development of cold cities and citizen's physical health.

Therefore, by investigating the characteristics of citizens' fitness behaviors in regional climate, as well as the public preferences and needs for urban sport spaces, this study will focus on a clod city in China as a case study for the adaptable planning strategies of urban sport spaces, underpinned by the Chinese National Fitness policy context. These strategies may be applicable and relevant to other similar cities.

2. Methods

2.1 Study area

For the sake of the surging demand for national fitness, during the 2015-2016 period, as entrusted by the Songyuan government department (Songyuan Sports Bureau), we have prepared the planning of public sports facilities in Songyuan. The process has provided an important opportunity for exploration and research in this study. Songyuan, located in the north east China, between the north latitude of 43°59′-45°32′, is a prefecture level city in Jilin province of China. Under the influence of a temperate continental monsoon, Songyuan has four distinctive seasons, but its winter is cold and long. The cold climate in Songyuan lasts for 5 months during which the average temperature is lower than 0°C from November to March next year.

This study selects the central city as the study area with a relatively concentrated population and a large demand for daily fitness in Songyuan. The study area consists of 23 communities and 48 recreational areas, and had a resident population of 499,600 by the end of 2015. As a whole, the population size and climate conditions of the central city of Songyuan are representative of those of small and medium-sized cities and winter-cities in China. Considering that winter is long and quite different from other seasons in temperature in cold regions, to investigate the characteristics of citizens' sports and recreational physical activity behaviors and the preferences of urban sport spaces, questionnaires and field surveys were conducted during winter (December 2015-January 2016) and non-winter time (May 2015-July 2015).

2.2 Data collection

The data in this study were collected by questionnaires for citizens in the central city of Songyuan. Social characteristics, physical activity characteristics, preferences and needs of the respondents are mainly included in the questionnaires. Social characteristics include the sex, age, education, income, etc. Physical activity characteristics contain the current status of citizens' sports and recreational physical activities in winter and non-winter time, such as frequency, travel mode and activity items. The citizens' preferences and needs for urban sport spaces are reflected in terms of the travel distance, space type, space environment, activity items, etc.

With the help of the Songyuan Sports Bureau, one typical recreational area was selected from each community in the study area to conduct questionnaire survey, and 20-25 questionnaires were randomly issued at each survey point. A total of 500 questionnaires were handed out and 438 valid questionnaires were collected, at an effective rate of 87.6%.

In the valid questionnaires, the youth (under 45 years old), the middle-aged (45-60 years old) and the aged (60 years old and over) account for 36.1%, 35.2% and 28.7% respectively; males and females take up a proportion of 57.3% and 42.7% separately. The questionnaire survey covers different demand groups.

3. Results

3.1 Characteristics of participation in sports and recreational physical activities under the influence of cold climate

1) Seasonal changes in the activity frequency

The cold climate has a negative impact on the citizens to participate in sports and recreational physical activities. In winter, it's found that the severe weather environment in cold regions is considered to be the biggest factor affecting citizens' enthusiasm for participating in physical activities (Fig. 1). At the same time, the frequency of participating in physical activities has distinctive seasonal features: frequent participation in any sports and recreational physical activities (three or more times a week and at least 30 minutes each time) is 26.5% more likely in non-winter seasons than in winter; and the proportion of citizens participating in physical activities less than once a week in winter is nearly three times larger than that in non-winter seasons (Fig. 2).

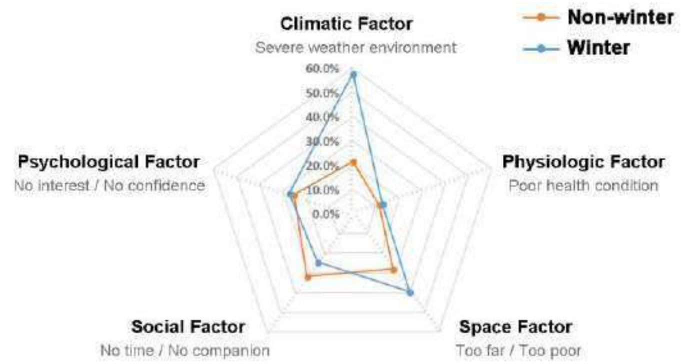

Figure 1: Comparison of the obstructive factors for citizens of Songyuan to participate in physical activities in different seasons

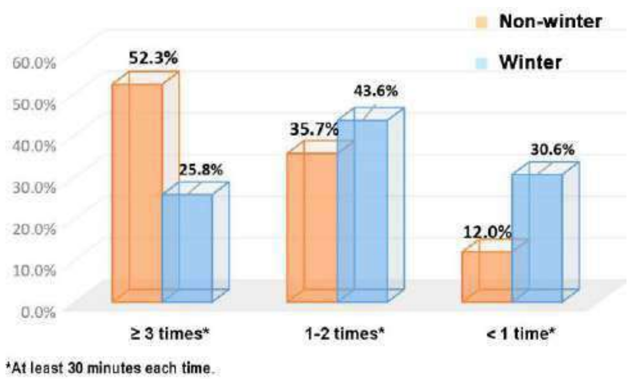

Figure 2: Weekly frequency of physical activities by season taken by citizens of Songyuan

2) Relatively stable choice of the physical activity items

Based on the field surveys on the participation in sports and recreational physical activities in the central city of Songyuan, the physical activity items are divided into seven categories according to the characteristics of sports and recreational physical activities: ball sports, aquatics, ice and snow sports, chess and card games, folkloric activities, walking and running activities, and activities on fitness equipment. It's found that the choice of the physical activity items has the two following characteristics (Fig. 3):

a. Walking and running activities always enjoy the widest participation. In winter, although walking and running decrease significantly compared with that in non-winter seasons, they are still the first choice of citizens in cold regions, taking up a proportion of 50.3%.

b. In addition to walking and running activities, participation in ice and snow sports is most obviously influenced by cold climate, in comparison with other categories of physical activity items. The proportion of citizens in cold regions who participate in ice and snow sports in winter is eight times higher than that in non-winter seasons.

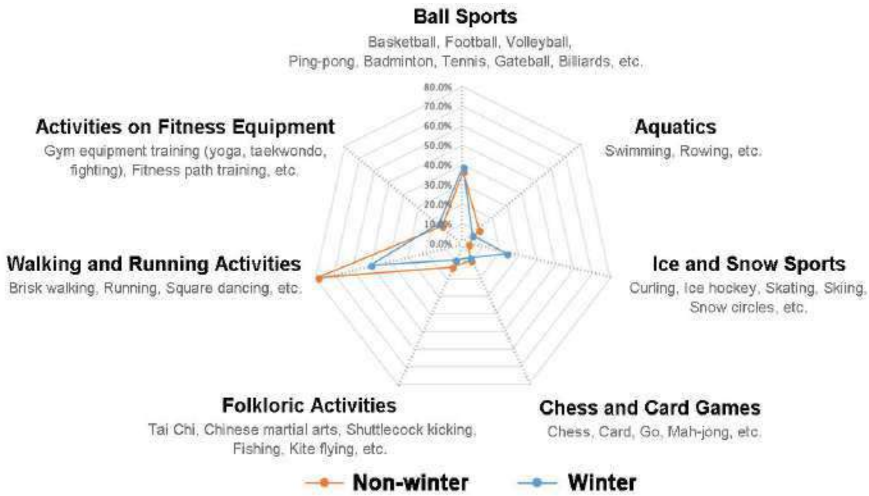

Figure 3: Comparison of participation in various physical activity items by citizens of Songyuan in different seasons

3.2 Needs of citizens for urban sport spaces in cold regions

1) Pedestrian (walking) traffic

It's found that under the influence of cold weather in winter, the choices of citizens of Songyuan for the traffic mode to go to urban sport spaces have changed compared with those in non-winter seasons. However, no matter in winter or in non-winter seasons, the proportion of walking to urban sport spaces is always the highest, which means citizens' need for pedestrian (walking) traffic is the highest (Fig. 4). The choice of walking to urban sport spaces is positively related to the preference of the citizens in cold regions for participation in walking and running activities. In addition, the close distance and easy accessibility is the most important principle for citizens in cold regions to choose urban sport spaces due to the cold weather (Fig. 5), and the distance within 1km is thought by 59.5% of the citizens to be the best coverage. Combined with the previous walking mode which is the most commonly used by citizens, the walking distance of 1km can be controlled within 15 minutes at the normal walking speed of 4-7km /h.

2) Green landscape

Through the field surveys on the citizens participating in sports and recreational physical activities, urban sport spaces are divided into two major categories and six types according to their space attributes and functional characteristics. The first category is green spaces and includes three types: parks and squares, residential green spaces, and green spaces attached to streets. The second category is venues and facilities, including public sport venues, educational sport facilities and private fitness clubs.

From a survey on the demand intention of space type, the need for the type of parks and squares among citizens in cold regions is the highest in winter, followed by the public sport venues and residential green spaces. From the overall categories, the need for the category of green spaces is 7.4% higher in winter than that for venues and facilities (Fig. 6). The interviews of the respondents show that the green spaces are the most needed urban sport spaces mainly because of their beautiful green landscape and larger fitness vitality, and because they can meet the various needs of life, such as fitness, social communication and recreation.

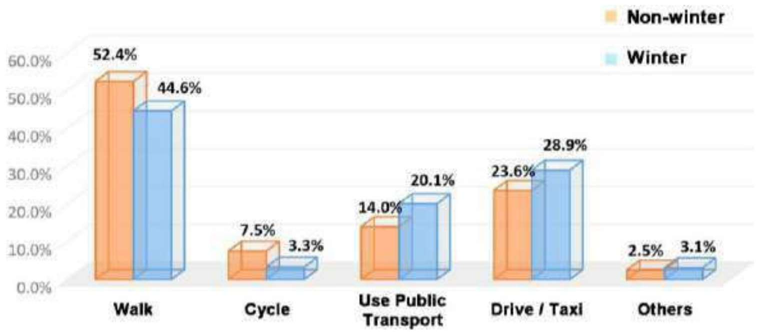

Figure 4: The main transportation modes for citizens of Songyuan to go to urban sport space by season

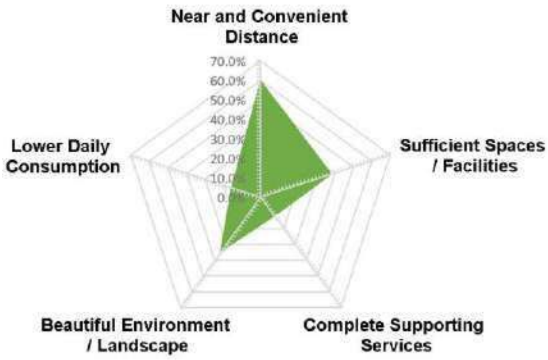

Figure 5: Comparison of factors that affect citizens of Songyuan to choose urban sport spaces in winter

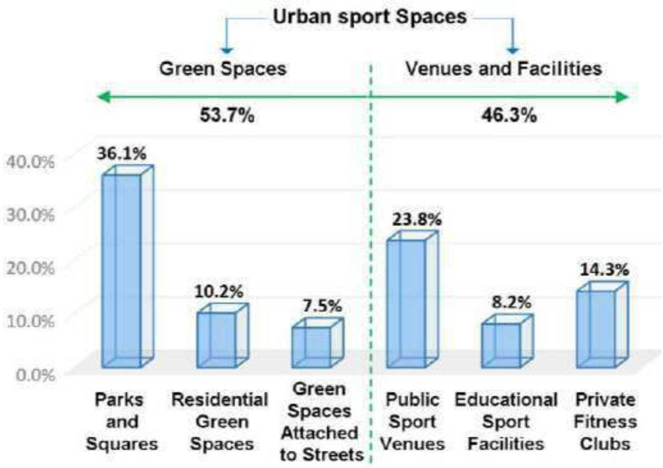

Figure 6: Citizens' need for the type of urban sport spaces in winter of Songyuan

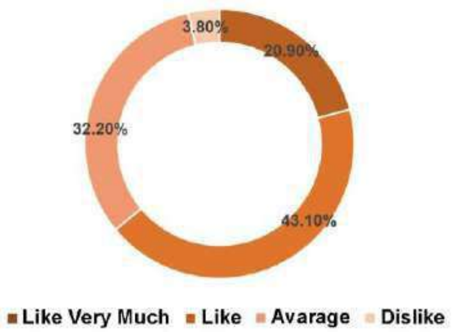

Figure 7: The enthusiasm of citizens of Songyuan for ice and snow sports in winter

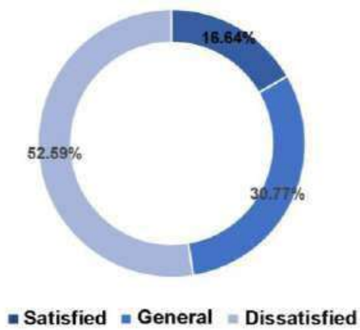

Figure 8: Citizens' satisfaction with ice and snow sports facilities in Songyuan

3) Ice and snow sports

The unique regional environment creates different sports activities, and ice and snow sports are the representatives of sports in cold regions. Considering the unique cold climate and ice and snow environment in Songyuan, it's found that 64.0% of citizens in cold regions prefer to participate in ice and snow sports in winter (Fig. 7). However, their satisfaction with ice and snow sports facilities is negatively related to their enthusiasm for ice and snow sports, and more than half of citizens are less satisfied with the ice and snow sports facilities in Songyuan (Fig. 8). According to field investigations and statistics, the number of ice and snow sports facilities in Songyuan is very small. By the end of 2016, there were three sites of ice and snow sports facilities in Songyuan, including zero ice sports venue and three skiing resorts, while the total length of snow trails in each skiing site is no more than 1km. The lack of ice and snow sports facilities has caused a serious problem that participation in ice and snow sports is lower while its need is greater.

4. Discussion and suggestions

Compared with the non-winter seasons in cold regions, the cold weather in winter is more likely to cause various diseases (Hassi et al, 2012), and the lack of physical activities will aggravate this risk (WHO, 2016). The planning of urban sport spaces should pay more attention to citizens' needs for fitness in winter, so as to improve the activity frequency and increase the vitality of citizens' sports and recreational physical activities in cold regions. Therefore, based on the results of surveys and combined with the project practice in Songyuan, the following adaptable planning strategies of urban sport spaces in China's cold regions are put forward for regional climate and citizens' needs:

4.1 Urban non-motorized traffic system should be linked to improve accessibility and efficiency of urban sport spaces in winter.

In view of the citizens' needs for pedestrian traffic in winter and the preference for walking and running activities, a convenient and comfortable non-motorized traffic network should be established by optimizing the proportion and quality of the urban non-motorized traffic, to enhance the effective connection between various kinds of urban sport spaces and between sport spaces and public service facilities. Thus, it can improve the accessibility and efficiency of urban sport spaces while promoting the vitality of public travel and participation in physical activities.

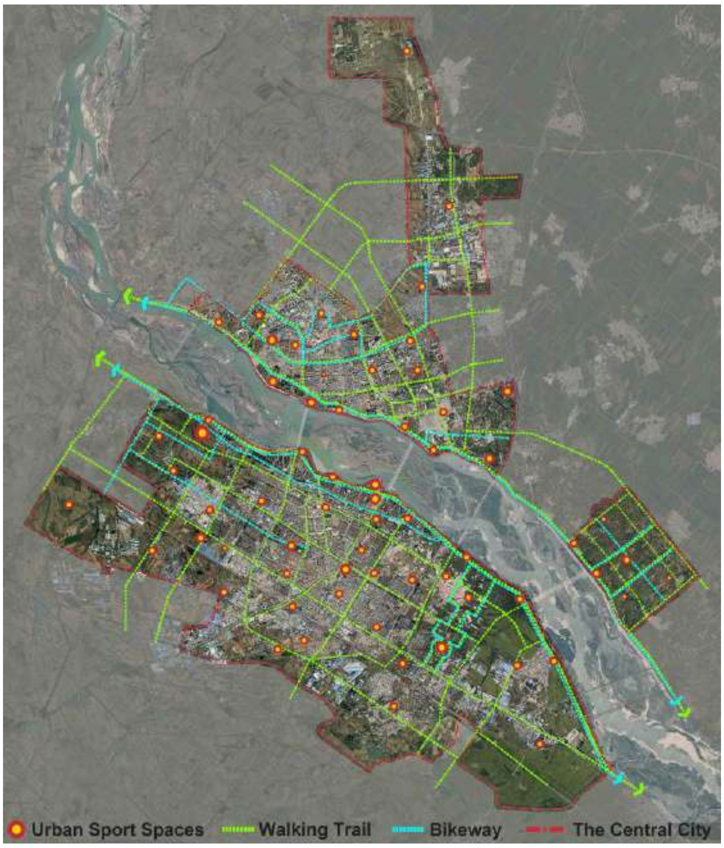

Figure 9: The planning map of the non-motorized traffic network in the central city of Songyuan

In the planning project of public sports facilities in Songyuan, after analysis of the comprehensive traffic network system and the status of urban sports spaces in Songyuan, a convenient and comfortable non-motorized traffic network with the goal of taking walking trail as the main structure and supported by the bikeway has been constructed, which is aimed at building a 15 min walking fitness circle and improving microcirculation of traffic network. The non-motorized traffic network has been designed with climate friendly methods which concern durability, cold resistance and slip resistance, and connect dot-like urban sport spaces to linear spaces and provide more sport spaces for walking and running (Fig. 9).

4.2 Urban green open space should be redesigned to raise enthusiasm for participation in sports and recreational physical activities in winter.

Urban green open space can provide natural ecological sport environment and improve ecological health for citizens (Zhao et al, 2018). Importance should be attached to the fitness function of urban green open spaces and integrating green spaces with urban sport spaces. Therefore, in view of citizens' need and preference for green landscape, two riverside and sports landscape belts have been redesigned by fitting for the urban green space system and closely taking advantage of important urban green space—the Songhua River.

Figure 10: The planning and construction intention map of riverside and sports landscape belts in the central city of Songyuan

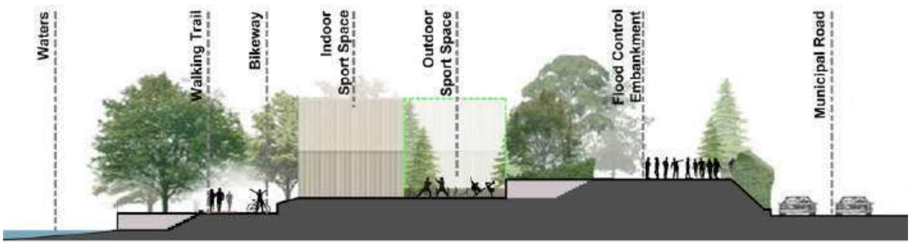

Figure 11: The cross section diagram of riverside and sports landscape belts

The riverside landscape on the both sides of the Songhua River is fully integrated with the national fitness functions, and a variety of functional values such as sports, entertainment, recreation and ecology are added to the green space. While extending along the riverbank, two riverside and sports landscape belts also link up more than ten important parks and squares, which is the most needful type of urban sport spaces, and continue to permeate into the city center (Fig. 10). The quality of riverside and sports landscape belts is optimized by the methods of space enclosure, vegetation protection and overall planning of indoor and outdoor sport space, so as to create a compatible and suitable composite space of sport and ecological functions (Fig. 11). As a result, the landscape belts will not only improve the value of green space, but also meet the need of citizens' sports and recreational physical activities. Finally, they will achieve the win-win goals of enhancing ecological value and boosting enthusiasm for participating in sports and recreational physical activities in winter in cold regions.

4.3 Natural ice and snow resources should be combined to satisfy citizens' need for ice and snow sports in winter.

The unique climate environment in cold regions provides natural conditions for the development of ice and snow sports. In view of the popular demand for ice and snow sports in winter, the structure of urban ice and snow sports space should be established based on regional characteristics, which can fundamentally improve the low and monotonous situation of the ice and snow sports industry in the city, and then actively and healthfully guide the development of ice and snow sports in cold regions.

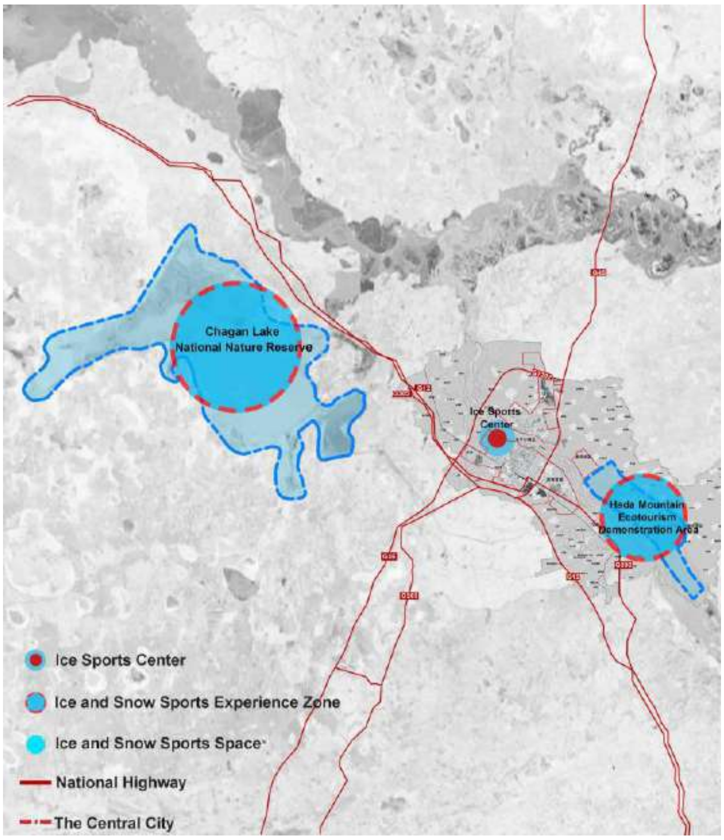

Figure 12: The planning structure map of ice and snow sports spaces in Songyuan

Considering the various forms and different site specifications of ice and snow sports, and after studying the conditions and potentials of natural ice and snow resources in Songyuan, a framework featuring "one heart, two zones and multiple nodes" for ice and snow sports space has been created, to meet the citizens' needs for different properties (such as professional or amateur, recreational or competitive) of ice and snow sports (Fig. 12). In the framework of ice and snow sports space in Songyuan, “one heart” is the construction of ice sports center in Songyuan. On the basis of competition and training, it can maximize the provision of sport spaces for activities such as speed skating, ice hockey and curling. “Two zones” refer to the establishment of professional ski field and ice and snow sports experience center, which respectively rely on the famous Chagan Lake National Nature Reserve and the Hada Mountain ecotourism demonstration area in Songyuan and take advantage of their unique geomorphological conditions. They can also develop the ice snow sports industry in the city while meeting the demand for skiing in winter. “Multiple nodes” are the pouring seasonal ice fields by using frozen waters, idle squares and other space in winter, so as to create a number of sport spaces for ice skating, ice carving and snow carving, and energetically stimulate the enthusiasm for participating in sports and recreational physical activities in winter.

5. Conclusions

Urban sport spaces are important for the development of city, and have been associated with health and wellbeing. However, as urban sport spaces are used to serve the citizens, the construction of urban sport spaces in cold regions has the limitation of cold climate and pertinence of citizens' needs. It cannot simply apply the planning strategies and design methods adopted in other climate regions. Due to the small size of the sample analyzed and the limited statistics performed, we have put forward corresponding adaptable planning strategies of urban sport spaces for specific situations in cold regions of China, based on the investigation of real characteristics and needs for participation in sports and recreational physical activities in Songyuan. These strategies may provide inspiration for the planning of sport spaces or sport facilities in other cold regions, and can be improved for application in other cold cities with the same needs of their own citizens.

Civilizing the public participation practice in post-transition countries

Piotr LORENS, Gdańsk University of Technology, Poland

1. Introduction

Public participation is nowadays commonly understood as the key issue in contemporary planning theory and practice. This relates especially to the well developed planning systems and democratic cultures of the so-called Western World. But with the political, social and economic changes of the 1990-ties this practice has become a part of the global planning agenda. And also the societies of the so-called post-transition countries started to ask for including this into their planning systems.

Although, it can be noted that the local communities in post-transition countries are much more demanding in this respect that societies that were enjoying this practice for decades. In result, new tools and approaches regarding organization of public participation had to be developed. This was due to rapid increase in social demand for organizing massive participation processes and also in relation to the change of the opinion of the politicians regarding the phenomenon itself. In short, from the position of the denial the local politicians have switched to the position of appreciation and promotion of such practices. Same relates to the central governments, which started to consider the public participation processes a regular and obligatory part of the urban planning and development processes.

The main aim of this paper is to discuss the emerging every-day practice of public participation in the so-called post-transition countries and to present current models of its organization and execution. Since the Author of this paper has extensive experience in leading the participation processes, most of the conclusions presented within the paper (including the case studies) are based on His own experience and real-life cases.

2. The phenomenon of public participation

The phenomenon of public participation is not so new to both planning theory and practice. In fact, involving local community in the decision-making process regarding local urban development directions is widely discussed and a number of various forms of these are being introduced. Some of the innovative initiatives associated with this were also promoted by ISOCARP (as i.e. the WikiCity initiative of the City of Amsterdam – 2008). Moreover, developing various forms of public participation in this matter has become a standard planning practice in many countries and communities.

But it has to be noted that public participation may play different roles and – depending on the level of development of the public discourse on development issues as well as on the specifics of local democratic control mechanisms – may be regarded as just an addition to the regular planning procedures or as a some sort of substitute to them [Miessen, Schumon, 2006].

3. Traditional vs. modern approaches to city planning

Although public participation is not a novelty and is widely used in urban management, in the urban planning processes it is still to be grounded. In fact, in many cases we can still observe the presence of the “traditional approach”, based on the so-called “command-and-control system”, associated with allocating the decision power in the hands of the government. In this scenario all planning activities are performed by highly-skilled professionals, in many cases in coordination and discussion of city officials. Due to this fact this is also named the “technocratic approach”, since the planning debate is performed only within the relatively closed circle of urban development technocrats. Of course, in this case there is no public involvement in discussion on the principles and directions of local urban development, and the general public is usually informed about the solutions only after the decision is made.

Described above traditional approach is frequently contested due to an emerging array of possible issues and concepts associated with the traditional planning questions. Also, there is a growing amount of stakeholders interested in solving these in line with their interests and expectations. In addition, some representatives of local communities – frequently named as “urban activists” – are also keen on taking floor within all these debates.

In result, one can state that the “technocratic approach” – based on expert-made decisions – is not valid any more. Moreover, it is also possible to conclude that each of the planning problems and issues may be considered and solved in many ways, which means there is no single “correct” and “best” solution to it. This is also associated with a major paradigm shift – nowadays, the modernistic city planning paradigm (as expressed in the Athens’ Charter) is not the only one source of ideas about urban form and mode of development; on the contrary, many ideas regarding the future of cities compete and many urban development paradigms may be considered while talking about planning of the future city.

In these realities the new planning approach shall be developed. It may be different in case of each of the cities, or even in case of each of the planning problem that has to be solved. Therefore, urban development stakeholders – instead of focusing on the predefined, “blue-print type” solutions – should adopt a flexible method allowing developing the most viable – in given realities – decision. Therefore, it should be based rather on **revised planning method** allowing defining local solutions to local problems, taking local community and local stakeholders’ opinions into account as well as allowing planners to deal individually with particular local problems. This approach asks for the new planning methodology. It should be based on:

- Safeguarding public participation in planning;
- Adopting the different approaches to different types of planning exercises;
- Understanding that planning goes far beyond just policy making and includes both design for high quality of space as well as implementation methods;
- Understanding the differences in methodologies used for developing the “structure”, “regulatory” and “action” plans.

As can be derived from above mentioned list, one of the key issues is safeguarding the “public participation in planning” which means including the local community in the planning process.

4. Public participation in action

As discussed in the previous parts of this paper, public participation may be part of both urban planning as well as of the decision making processes regarding particular urban development initiatives. At the same time, it may be used in the process of defining both the character of the large–scale urban development projects (also referred to as Large-Scale Urban Interventions – LSUI-s) and the new architecture of particular public spaces and sites. Also, it may be employed in the process of shaping the solutions for larger scale planning exercises, like i.e. urban centers and sub-centers, housing districts, regeneration sites etc.

What is important in these cases is that public participation can both mitigate problems which appear along with planning and development of the particular interventions (both large- and small-scale) and help solving them BEFORE they actually appear. This last feature is especially important in case the proposed development or planning initiative is expected to generate a number of issues for local community and stakeholders. What is also important is the fact that properly designed public participation process – which involves all possible stakeholders but does not allow “capturing the participation process” by the so-called “wanna-be stakeholders”[1] – helps in building community and stimulating partnership between key actors on the stage [Miessen, 2013].

As discussed above, the necessity of discussing the key decisions regarding spatial development with local community is obvious and part of contemporary planning and management practice. But what has to be stressed is the fact that it may take very different forms, depending on the level of involving the community. And, according to the so-called “participation ladder”, these forms include:

- Informing – based on simple presentation of the solution adopted; in fact this form of participation does not allow community to influence the decision;
- Consulting – based on presenting the possible solutions to the particular problem and selecting the best possible one (according to the stakeholders’ opinion); in fact, in many cases the outcomes of this process may be in conflict with the opinion of local government or investor willing to implement the cheapest possible solution;
- Participation – based on the direct involvement of the local community in shaping the possible solution to the particular problem / issue; in this case the stakeholders group is frequently confronted not with possible and pre-defined solutions but with the problem itself. In these cases the planning group is asked to solve the problem in dialogue with other decision makers, which allows both parties understand each other and work out the joint proposals;
- Co-investing – based not only on the public dialogue regarding the particular problem or issue, but also on involving the stakeholders (and their resources) in the implementation process; in this case particular stakeholders not only discuss and decide about the shape of the particular decision, but they are part of the implementation process.[2]

As one can note, discussed above forms of participation can be used in different contexts and situations. In fact, not all of them can be employed to each case, and also not in each case it is possible to identify the proper group of stakeholders. This may create the situation that – instead of the real ones – the so-called “wanna-be stakeholders” take the floor.[3]

5. Including the local community into the planning process

Involving local community and stakeholders in public participation process – and in this case by participation I mean real involvement of the stakeholders in the decision-making process – may take different forms. Of course, it can be used only in selected cases, but in case it is decided to employ public participation into the planning process the following key steps should be included in its preparation:

- starting the planning process with the group of local leaders, constituting the planning group;
- carefully drafting the plan of the participation process, including various forms of possible community involvement (workshops, site visits, public discussions etc., which allow stimulating the discussion on key components of the project) as well as a number of sociological surveys (which allow gathering the opinion of the wider scope of stakeholders – including the so-called "silent" ones);
- involving local mass media and asking them to convey information about the process;
- making outcomes of the process available for local community via different forms of publication and announcements.

In case planning process is undertaken directly by the representatives of the local community, it has to be supported professionally. Therefore, it must be coordinated and supported by the competent expert group – responsible for the final success of this undertaking. Otherwise the process may not bring the results as expected and even finish in a not expected way.

6. Post-transition countries

In case of so-called post-transition countries (which include post-socialist states as well as countries facing just economic transformation without the political change) the demand for public participation is extensively and rapidly growing. It has to be noted that just a few years ago involving local community into the urban development decision-making process was regarded as a kind of novelty and rarely treated seriously [Pawłowska, 2008].

But along with development of the democratic societies, understanding by the people that their opinion matters as well as growing mistrust to the local planning and municipal management elites completely changed the situation. Local communities started not only to question the development and planning decisions but also to demand more participation in the decision making process. In many cases this has led to the situation that no planning or development decision could be made without a public consent, which – in realities of diversified opinions and interests represented by different groups of stakeholders – had led towards stopping any development and not making any decisions at all. This means that development of the civil society – in realities of the lack of political and democratic culture – led to the paralysis of the decision-making process, which especially relates to the most disputable projects and plans. And one has to note that in many cases lack of the democratic tradition led to the situation within which anyone whose ideas were not included in the final solution / decision was contesting it and protesting loudly. Also, planning professionals and local government officials started to be accused of lack of professionalism as well as – in some cases – of being corrupted by developers or particular groups of stakeholders [Pawłowska, 2010].

Of course, this issue has not been left unnoted by both central governments and by local municipalities. Also, various groups of local activists have understood that negation of any plans and decisions made (especially) by local governments is not a solution and can lead towards stagnation. Therefore, various programs and initiatives leading towards making public participation part of the "civilized" planning and development decisions-making process were introduced. One can mention here a number of different forms and initiatives of different magnitude, which are currently changing the decision-making procedures. This relates especially to the issues associated with urban and spatial development as this is the key area of potential conflict [Siemiński, 2017]

One of the most interesting is the Polish case, which is due to rapidly increasing demand for participation (rise of the so-called "city movements" – groups of urban activists representing various ideas and concepts regarding local urban development processes), diversity of forms of public participation introduced, an array of practices tried and tested, and – finally – due to making this a part of the formal urban regeneration planning process [Żylski, 2016].

7. Public participation methods in post-transition countries

In case of the post-transition countries, and having in mind the specifics of the public participation processes in these, it was necessary to search for the method allowing – on one hand – full participation of the local community in the planning process and – on the other – getting the process completed in a predictable time. Therefore, the strategic planning methodology was chosen. This method, developed for business management, later on was adapted for the purposes of managing the socio-economic development of the municipalities. It is associated with three basic steps, responding to key questions:

- Where are we now? – meaning, in what situation the particular project / area is right now;
- Where we want to get? – meaning, what is the vision of the future state of the site / project that we want to achieve;
- How to make it? – meaning, how can we implement the conceptualized solution in the given realities.

This method may be implemented in various ways. Having in mind the specifics of public participation in planning / urban development process it seems that the best work methodology is associated with crafting the design workshops – "charrette style" – which allows fulfillment of the following objectives:

- Defining of the basic assumptions and concepts regarding proposed planning solution / project development BEFORE the design is ready;
- Defining – on this basis – a number of possible solutions / scenarios, as well as various priorities;
- Selecting the most appreciated solutions of the ones discussed;
- Developing the final concept – accepted by local community – to be furtherly elaborated.

In this case a number of techniques had to be employed, including public discussions, group works, general presentations as well as voting.

Fig. 1. Discussing and selecting development priorities during the workshop process. Photo credit: Piotr Lorens (2006-2010).

8. Exemplary Planning Workshops structure

Following the adopted methodology, also the experience gained during the process of developing the strategic plans for Polish municipalities was used[4]. In result, it was concluded that the planning process should be structured in form of a sequence of carefully planned workshops, during which the particular elements of the program / plan / strategy are defined. Such a program may also be supplemented by a set of necessary sociological surveys – which, as discussed in preceding chapters – may help providing opinion of the “silent” stakeholders.

Usually – before the real participatory process starts – the so-called Stage „0” of the process is concluded. This usually includes the desk research allowing survey and analysis of the existing planning documents. It may also help in developing the expert analysis of the problems to be solved as well as definition of the intervention area[5].

The second stage of the process is the cycle of workshops. The usual structure of those includes:

- I workshop
  - Group analysis of the problems of the given area
  - Development of the intervention goals
  - Development of the SWOT analysis
- I stage of the sociological survey
  - Getting the people's opinion on the basic problems and issues that have to be solved
- II workshop
  - Selecting the priorities for intervention
  - Identification of the specific projects and other undertakings necessary for implementation of the goals
  - SWOT analysis for the particular projects
- III workshop
  - Creating the „logical matrix" for all projects
- II stage of the sociological survey
  - Defining the priorities according to the population of the area
- IV workshop
  - Developing the final set of priorities
  - Developing the schedule of implementation actions
  - Developing the monitoring and implementation system
- Defining the financial plan
  - Defining hte sources and level of necessary / available funding for projects implementation
- Summing up the works
  - Presenting the outcomes in the form of comprehensive document

After the workshops themselves are concluded, it is possible to finalize the process in a form of written report including all conclusions. In case necessary, this report may become a basis for drafting the final policy / planning document, which can be adopted by municipal administration. In case of planning for urban regeneration, this is demanded by law in Polish planning system.

9. Selected case studies

In order to illustrate how the public participation process may be part of discussing the various types of interventions, three case studies were presented. Within the following parts of the paper only the selected aspects of these were presented. Also, due to space limitations, no conclusions achieved or detailed workshop structure were discussed.

9.1. „Katowice workshop” Reshaping the Korfanty Avenue

In case of Katowice the public participation process was organized to discussed the publicly contested outcomes of the architectural competition for the new development concept of Katowice City Center. This plan, developed by one of the leading Polish architecture office (Konior Studio), was discussed as a problematic solution, especially in regard to the ideas of reshaping the main urban axis of the city – the Korfanty Avenue.

Fig. 2. Aerial view of the Korfanty Avenue. Photo credit: Konior Studio (2006).

Within this plan it was proposed to narrow down this modernistic street and make it more pedestrian-friendly. At the same time the plan allowed massive development of new urban quarters on nowadays vacant areas, which were considered as green spaces by local community. In addition, during the workshop local stakeholders their sympathy to the present layout of the street, which came from feeling that its dimensions reflect the importance of the city. The workshop allowed discussing these issues and understanding the nature of the protests, as well as reshaping the plan and its detailed solutions.

Fig. 3. Street view of the Korfanty Avenue. Photo credit: Piotr Lorens (2006).

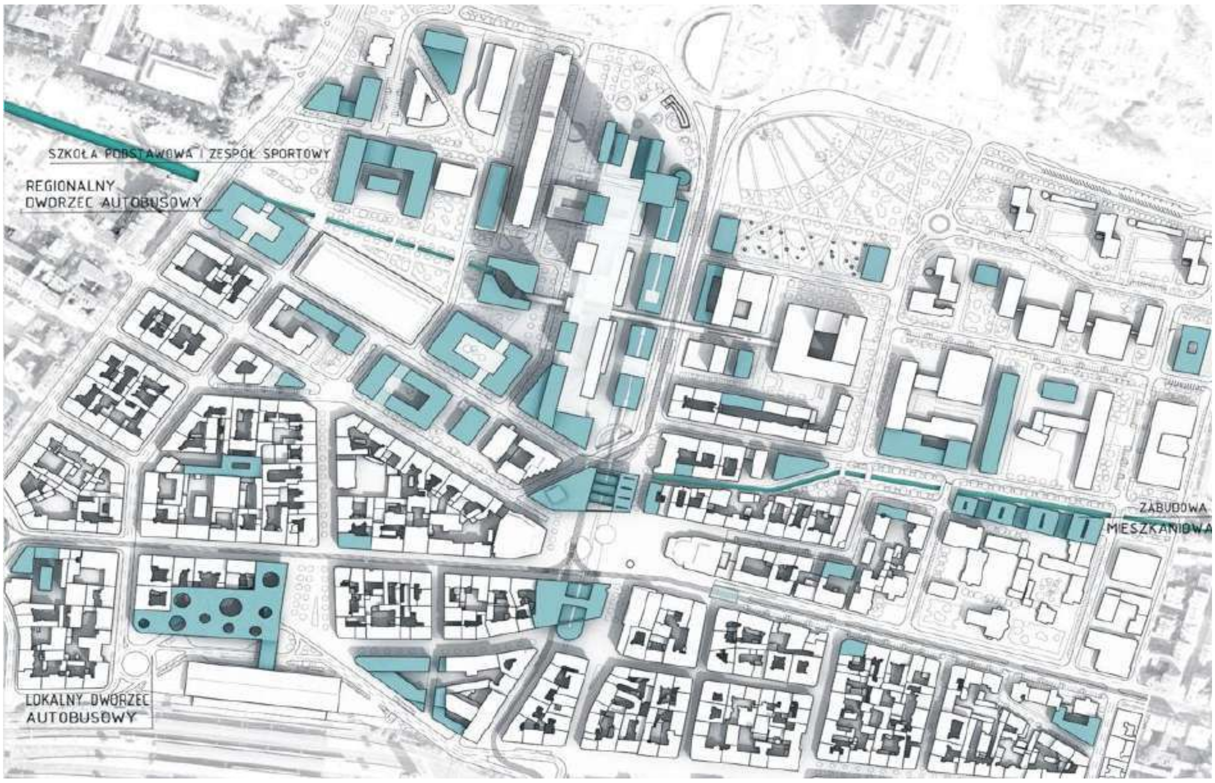

Fig. 4. Proposed redevelopment plan for Katowice City Center, including reshaping the Korfanty Avenue. Photo credit: Konior Studio (2006).

9.2. Redevelopment of the public spaces in the city of Starogard Gdański

The second case study is associated with the process of redeveloping the public spaces of the small-size city (approx. 65 000 inhabitants) of Starogard Gdański in the Pomerania Region. Within this process two key city spaces were subject to participation efforts: the Old Town Market Square and Wojska Polskiego Avenue. Although the latter case is still in the design process, the redevelopment of the Market Square has been completed. One has to mention that public participation helped identifying a set of possible solutions regarding this site as well as extensive discussion on the finally selected proposal.

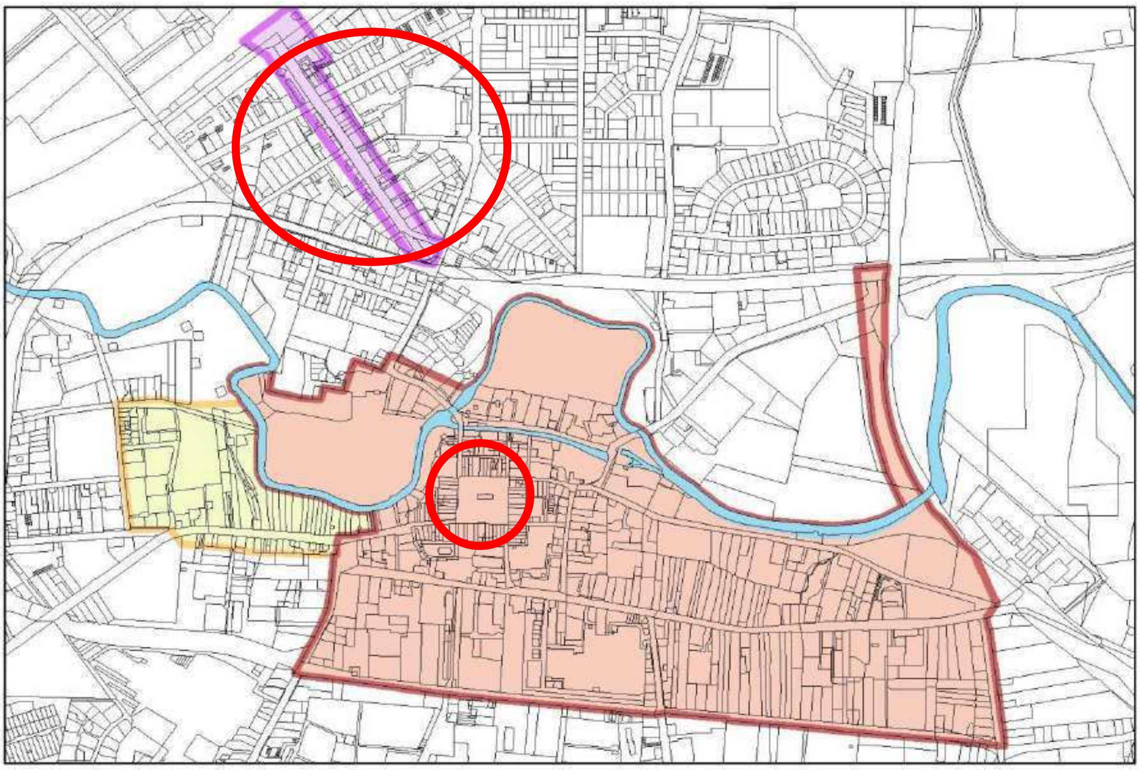

Fig. 5. Central part of the city of Starogard Gdański with marked location of both projects. Photo credit: Piotr Lorens (2014).

Fig. 6. Various concepts for redeveloping the Old Town Market Square in Starogard Gdański – outcomes of the participatory design process. Source Transforma G. Pęczek (2009)

Fig. 7. New design concept for redeveloping the Wojska Polskiego Avenue in Starogard Gdański – outcomes of the participatory design process. Source Transforma G. Pęczek (2009)

9.3. Replanning the Gdansk City Centre

Third of the case studies is associated with replanning the Gdańsk City Center. This project was coordinated not by the Gdańsk Development Office (an "official" planning agency for the city) but by the group of "urban activists" (associated within the NGO called FRAG – "Gdańsk Agglomeration Development Forum"). Development of this project was made possible due to a grant received from the Batory Foundation. Within it a local stakeholders group was working in order to define the new planning principles for the area. The outcomes of this were later on used in the formal planning process for the area.

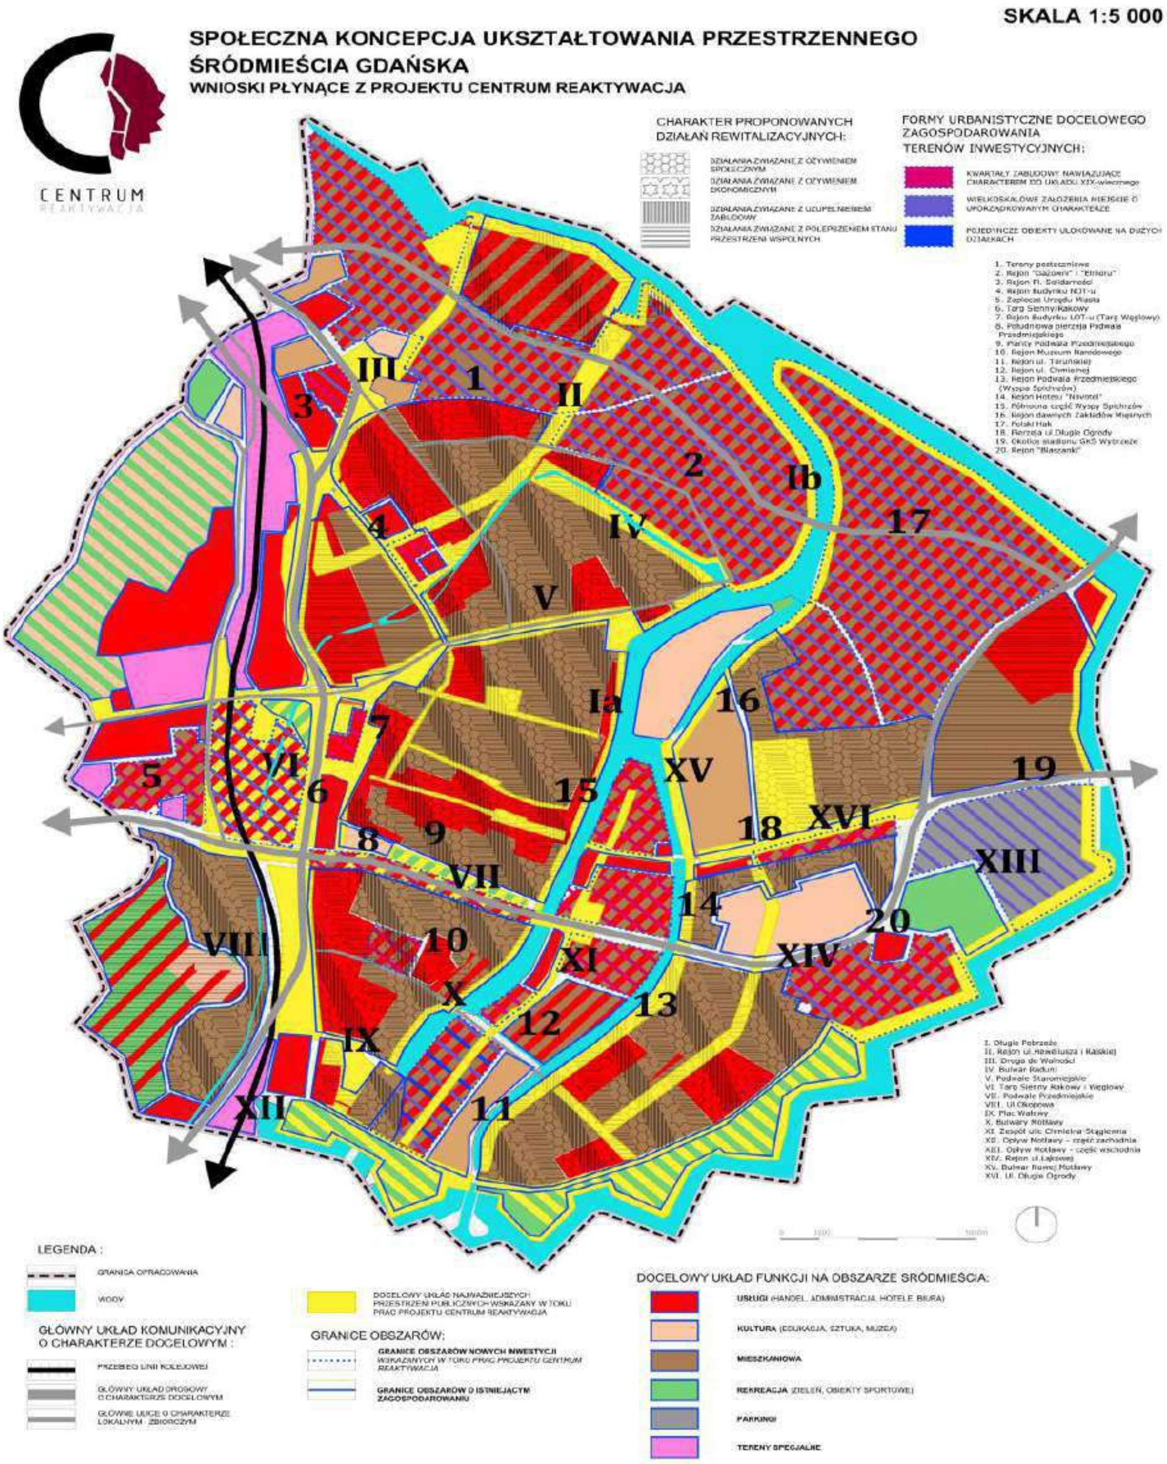

Fig. 8. New design concept for Gdańsk City Center – outcomes of the participatory design process. Source: Piotr Lorens and FRAG (2014)

10. Conclusions

As it can be derived from this paper, public participation is one of the possible tools used nowadays in order to discuss the possible planning solutions. It is associated with direct involvement of the local community in the decision – making process. In case the "solid" results are needed as well as an array of stakeholders has to be involved, participatory process should be based on the methodology of strategic planning . In these cases good results can be achieved through organization of the „planning / urban workshops". This was especially important in case of the "post-transition" countries like Poland.

At the same time Polish experience in this matter proved that there is a need of so-called "strategic approach" in public participation processes. Otherwise, there is a danger of wasting the efforts made and finishing with no substantial results – meaning no decisions and no points made. Results discussed and presented in this paper shall allow discussion of the possible inclusion of the Polish experience in the planning practice of other countries and regions, with a special focus on countries in transition.

Finally, experiences analyzed also proved that both the scope of participation process, results expected as well as group of stakeholders involved have to be defined locally, as there are no two similar situations. This means that also outlining the participation process should be crafted individually and that there are no "blueprints" that can be used.

Miessen, Markus, Basar, Shumon (eds.) (2006) Did Someone Say Participate?, Frankfurt am Main: Revolver

[1] One can define here three major groups of stakeholders: "real stakeholders" (meaning – people and institutions really affected by the proposed action and willing to participate in the participation process), "silent stakeholders" (also affected but do not willing to participate) and "wanna-be stakeholders" (not affected directly but asking to be part of the participation process).

[2] The best illustration of this process is the situation when the local stakeholders not only discuss the solution but also participate in its implementation, i.e. mobilizing their own resources in order to facilitate the urban regeneration process.

[3] This is the case of various post-industrial sites.

[4] I.e. please see the works of the UNDP Umbrella Project.

[5] This is especially import ant in process of shaping the Local Urban Regeneration Plans, which – according to the Polish Parliament Act of 2015 – requires an expert definition of the intervention area based on the statistical analysis.

Constructed and contested legitimacy in urban governance

Moderator: BRYNILDSEN REINAR, Mathias (Norway)

ABSTRACT:

Cities in northern Europe are increasingly inhabited by people with diverse cultural backgrounds. The social, economic and environmental sustainability of cities requires capacity to live with differences. Recent increases in refugees and asylum seekers pose new challenges, which adds to challenges already faced by the cities: affordable housing, transport, community meeting spaces and new economic opportunities.

The cold climate of the north brings certain challenges related to creating new meeting places, indoors and outdoors, but the increased diversity has led to a wide variety of new and innovative integration activities, aiming at connecting newcomers and established residents in urban meeting places. This session will focus on exploring the function of and connections between meeting places, interaction and participation in the city. As a part of this broad theme, these questions will be relevant:

How are urban spaces being used by newcomers and established residents?

How and under what conditions do meeting places lead to cross-cultural encounters and interaction?

In what way and to what degree can cross-cultural meeting places and encounters lead to processes of participation in urban life?

The session encourages a wide range of contributions, including from academia, practitioners and civil society. We invite contributions related to new theories or methods for planning for diversity as well as case studies and practical examples, including tools for planning. Both planned activities as well as ongoing or completed activities may be presented.

The session format will be short (10 min) presentations followed by a moderated round table discussion, open for all interested parties. The discussion aims at exploring innovative multicultural integration activities that help us to live with difference, enhance integrative interaction and develop cities' problem-solving capacities. The session will provide a summary from the round-table discussion to be held at the session.

Session conveners: Marit Aure (UiT The Arctic University of Norway), Anniken Førde (UiT The Arctic University of Norway), Tone Magnussen (Nordland Research Institute), Gregory Taff (NIBIO)

Associations of active ageing; a potential tool for local development

Maria da Graça MOREIRA, University of Lisbon, Lisbon School of Architecture/CIAUD, Portugal

Abstract

It presents a ongoing research on the potential role that "senior universities" can play as tools for the preservation of tangible and intangible heritage in some urban or rural areas, in Portugal. Senior citizen universities as active entities that promote the healthy active ageing of the population are associations with a very significant potential for the recovery of some cultural practices in the territories where the elderly population is dominant.

The cultural activities linked to the preservation of the heritage, namely traditional music groups and respective instruments and in general their contribution to healthy ageing communities can have an interesting role to support touristic activities. The creation of groups of students who are organized to participate in local and regional events promote the process of active aging and create a motivation that spreads in the surrounding communities.

Key words: Active ageing, Citizen participation, Senior University, Tangible and intangible heritage,

1. Introduction

This paper is the first approach of a research about the role that senior universities (SU) can play as instruments for promoting local development especially in the areas of valuation of heritage and tourism.
Such associations have been studied in their social role, directed to an age range increasing, but are not considered as active partners in local development.
In many regions the numbers of the people with more than 65 years old are really impressive, so they must be considered as part of the solution to increase local development.
Some of the elderly populations that currently live in rural areas have developed their productive activities in urban areas, having no direct relation with agriculture and, therefore, need to maintain different social activities and relationships.
They use their time in a different way from the population that always lived in rural areas and that even being old maintain subsistence agriculture activities, keep out of need or pleasure.
The more urbanised population has led to the creation of many nuclei of senior universities with multiple values.
The universities or academies of the elderly, are entities that promote the active and healthy ageing of the population, but till now they don't assume their role in the territorial valorisation of the community;
These are associations with a very significant potential for the recovery of some cultural practices in territories, especially where the elderly population is dominant.
Cultural activities linked to the preservation of heritage, namely traditional musical groups and respective instruments are one of the programs of the US.
The creation of groups of students who organise to participate in local and regional events promote the process of active ageing and create a motivation that involves the communities.
The methodology adopted for this research focuses on the analysis of the impact at local development level, in a set of municipalities where there are senior universities, in areas of low density and permanent loss of population since the mid-50s of the last century.
The SU are characterised by the type of offer they present and the participation they have in community life.

2. Origin and Role of Senior Universities

The Senior Universities or Universities for the third age (U3A) appeared in France, firstly in the Faculty of Social Sciences of Toulouse in 1973 as a movement to promote university-like teaching linked and organised by some Universities.
The origin of this organisation model called "Modèle Vellas" has three objectives:
1. The training of seniors through the university;
2. Research in areas related to seniors, namely health, psychology, legal and the social field;
3. Training of employees and stakeholders working in the field of seniors training

The organisation of the activities was very similar to the traditional university pedagogy with master classes. ((AUTANB), Juin 2013)
Nowadays with the increasing numbers of SU and not all near universities, this view has been changing, and a more friendly approach is developed.
In England, in the University of Cambridge, in 1981, Peter Laslett developed the concept of "self-help" The self-organised learning groups on subjects that interested them and with voluntier teachers who are part of the group; They are not called students but members, this model is called Cambridge Model.
Many of the US are united in an international organisation "Association International de Universités de Troisième Age" (AIUTA) which shows the great importance and dissemination that this type of associations has had in the last decades around the world.
On the generic role that the US has in the territory, these may resemble the local intervention NGOs, as an emanation and representation of the community. (Cernea,1988).
Independently of the functioning model, all aim at the well-being of the elderly and their integration into society, promoting active ageing.
From the activities or courses given by the U.S., the areas related to culture, namely local culture, either local history itself or cultural manifestations such as traditional music, are regularly present.
The increase in the longevity of the population associated with the improvement of their physical condition allowed the development of recreational activities by this group, with age +50 years and functional retired or part-time workers.

3. **Ageing of the population in Europe**

The evolution of median age of the population in Europe is, according to with Eurostat increasing in the last decades, because of the decrease of birth rate and at the same time the increase of life expectancy(Fig.1).
In 2016 it was in Europe of 42.6 years, with some countries like Germany with 45.7 years and Portugal 44.4 years (Beira Baixa 50.3., Alto Alentejo 48.4 and Lezíria 45.6) (Eurostat,2017).
If it is analysed the importance of ageing people, Europe has a substantial population weight of +65 years (19.3%) and has been increasing, distributed very unequally between the countries (Pordata).
In Portugal, the situation is similar, 20.9% of the population are +65 years old but distributed very unequally in the territory. As it can be seen in fig. 2, only a small coastal strip has a younger population.

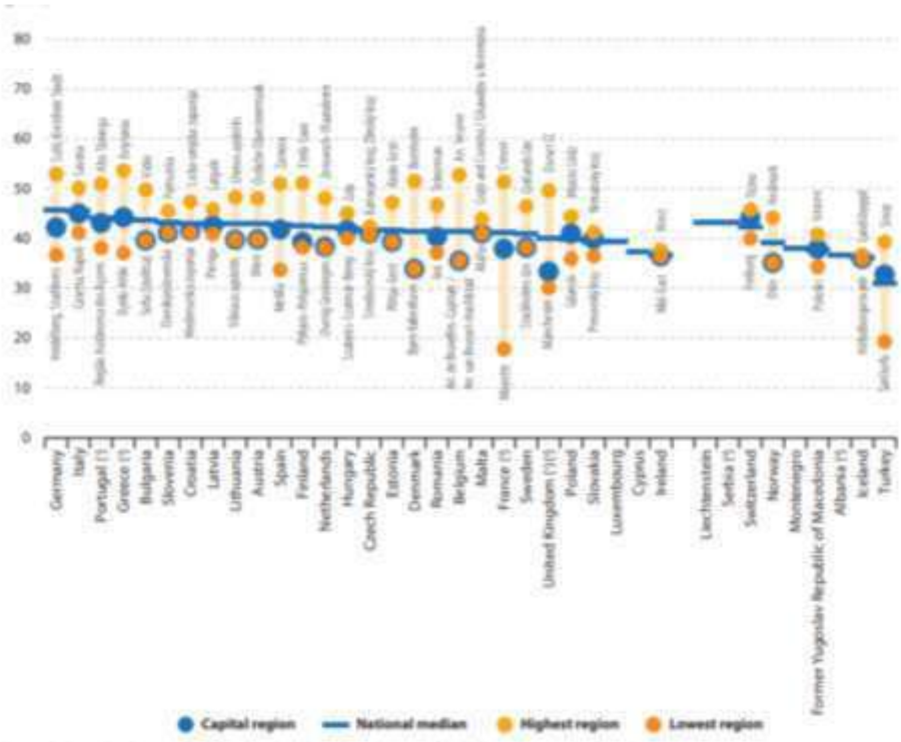

Figure 1: Median Age of Population, By NUTS 3 in Europe, 1 January 2016

Source: Eurostat

A significant part of this population can remain active, and in good physical and psychic conditions, this is the group that the active ageing programs are designed for, like the SUs.

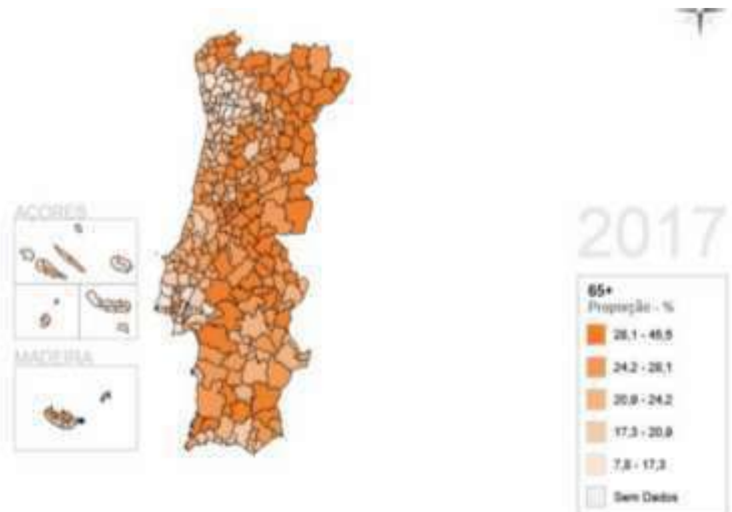

Figure 2: Percentage of the population with more than 65 years old

Source: Pordata

With this demographic characteristics, the population with more than 65 years must be looked at with a different approach. This population should be valued, within the area of this research project, for its numerical importance but above all for its capacity to evaluate local and regional heritage. And the areas where it is almost half of the entire population, and there are no large urban agglomerations, can be considered an endogenous resource of great importance.

4. Senior Universities in Portugal

The movement of Senior Universities in Portugal began, in the 80s of the last century supported mainly by the social sector and local authorities concerned with the quality of life of the elderly population.
Based on the demographic data presented above, in Portugal, the movement of Senior Universities has a great potential for development.
According to with the legislation the Academies and Senior Universities (SU) are "as socio-educational responses that aim to create and streamline activities regularly in the social, cultural, knowledge, and social areas, from the age of 50, pursued by public or private entities, with or non-profit " in RCM 76/2016.
They are very well distributed in the territory, in 2015, they were in 171 municipalities, 60% of the 278 municipalities in the continent.
They are organised in 300 associations with + 45000 students and 5500 volunteer teachers. With groups of theatre and music; with music in 67% of the SU and theatre in 47% of them. (RUTIS, 2015).
The SU is organised according to both models, the French and the English models if they are more connected with universities or self-organised groups.
In the territory chosen as the first approach of this research where don't exist universities is the English model that is in use.

5. Municipalities and Senior universities

To study the potential of SU in the local development and the positive impact, was chose a group of six municipalities with rural characteristics (low density and without cities) on the banks of the Tagus River and with SU.
These municipalities belong to three different NUTS 3 and are in:

Beira Baixa – Idanha-a-Nova e Vila Velha de Rodão,
Alto Alentejo – Gavião e Nisa,
Lezíria do Tejo – Chamusca e Golegã

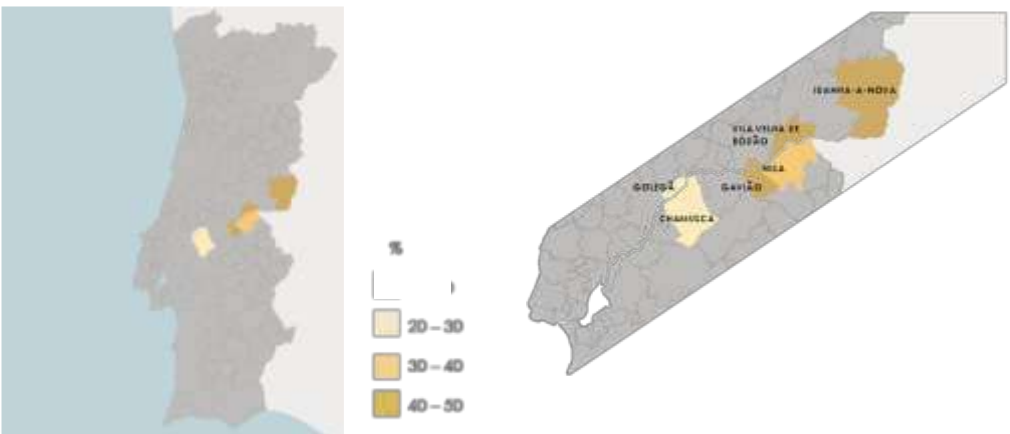

Figure 3: Municipality case studies and % of the population with +65years

Sorce: INE 2011

All of them have a population of over 65 years old, above the national average, Golegã as 25% till Vila Velha de Rodão with 44% (fig. 3) and a negative variation of the population between 2001-2011 (fig 4).
The more the municipalities are far from Lisbon, the more is the negative variation of the population. Golegã has only -4% of the variation of the population and Idanha-a-Nova in the border with Spain has -27%.

Municipality	Var. Pop. 2001-2017
Chamusca	-17%
Gavião	-28%
Golega	-4%
Idanha-a-Nova	-27%
Nisa	-26%
Vila Velha de Rodão	-21%

Figure 4: Variation of the total population in the municipality (2001-2011)

All the municipalities have at least one SU, some with the designation of Academia others with University in the name.
The first SU appeared in 2003 in Golegã, the municipality nearer Lisbon, and the last in Nisa in 2017. The number of students is very disparate (fig.5) and not directly related to the amount of total population of the municipality.

SU Designation	Municipality	nº students/ members	year of foundation
Universidade Sénior Da Carreira - Chamusca	Chamusca	68	2014
Universidade Sénior da União das Freguesias da Chamusca e Pinheiro Grande	Chamusca	100	2016
Universidade Senior do Gavião	Gavião	68	2008
Academia Sénior da Golegã	Golegã	102	2003
Universidade Senior de Idanha a Nova	Idanha-a-Nova	34	2015
Universidade Senior de Nisa	Nisa	294	2017
Academia Sénior de Vila Velha de Ródão	Vila Velha de Rodão	123	2015

Figure 5: SU characteristics

All the SU offer training in cultural areas linked to local heritage like musical instruments, coral, lace and embroidery, gastronomy, local history or theatre in addition to other topics more related to current needs such as information technology or foreign languages. The tourism activity is also considered and is important to keep some areas and functions with clients in dead days.
As for the form of organisation of the SUs (fig.6), they correspond more to the model of self-organisation, similar to the English model, but with the logistical support of the municipal or parish councils. Teachers either belong to the group itself or are made available by local power, such as a teacher to lead the choral groups.

Figure 6: Examples of SU logos
Source: sites of the SUs

The research is now trying to relate the offer with the characteristics of the population and make a more detailed analysis of the subjects.
When is compared to the offers of training music (coral or instruments) and theatre are common to all. The subject bullfighting and gastronomy are specific to a single SU.

Figure 7: Participation of the SU of Idanha-a-Nova in a public festivity of a village of the municipality

Many of the groups (musical, coral or theatre) organized around US activities actively participate in various cultural events in their communities and municipalities promoting shows that are seen by the entire population (fig.7).

6. Conclusions

The associations which promote the active and healthy ageing of the population have been multiplying, around the world and in Portugal, even in municipalities with substantial population losses, in this century.

From the analysis made, it can be concluded that the Senior Universities are valuing the local culture.

All make shows or participate in traditional public festivities that disseminate the cultural characteristics of each municipality.

The research will continue with a more detailed analysis of these associations in low-density areas, but it would be interesting to study the associations of some towns and cities to evaluate their potential to the local development.

Spaces of Non-State Actors in the Urban Development Process: Rethinking the Community-based Planning in the Housing Sector

Mahesti OKITASARI, United Nations University Institute for the Advanced Study of Sustainability (UNU-IAS), JAPAN

Abstract

This paper examines how community-based planning in Indonesia changes with the shifting roles of non-State actors in the development process and the introduction of international urban development agenda and approaches focusing on sustainability and resource efficiency approaches. Within this period, Indonesia planning system went through decentralization and transition. By using longitudinal study as a heuristic device, the paper aims to capture a more nuanced model of community-based planning. This paper intends to identify the key factors of systems changes and the realization of collective action that facilitate acceptance of sustainability and resource efficiency approaches for urban development.

1. Introduction

For the last half century, urban development theory and practice has increasingly focused on how people engage in the planning and implementation processes. Citizen participation in planning and development, in turn, is continuously being influenced by changes in urban development approaches, from participation for incremental to radical and transformational change. This focus is exemplified by works on community-based planning in synoptic planning, radical planning, and collaborative planning. Taken together, this continuum represents the varying degrees of citizen participation depending on their agency and power and social and political consciousness.

Recent international development approaches following the development and implementation of global agreements (e.g. Habitat Agenda, Millennium Development Goals, Rio+20, and as recently the 2030 Agenda, Paris Agreement and the New Urban Agenda) increasingly require collective action in delivering and managing urban area to attain its goals and, in broader context, sustainable development. These pressures from international community has influenced the way urban development approaches are taken, particularly through development assistances and introduction of new development measures. From the socio-economic and political administrative point of view, the decentralization which took place in Indonesia in 1999 has further accelerated the role of community and non-state actors in the planning system. These have inevitably changing the relationships between the State and non-State actors in approaching planning and development. With presence and participation from non-state actors continue growing, the government is moving away from their traditional way of working with non-State actors; from consulting to policy-making; from beneficiaries to partners. Amidst increasing demand of resources to catch up with rapid urbanization, it is expected that spaces are opening up for non-State actors to actively participate the development process. However, the questions remain whether the new approaches will contribute to urban development in a collaborative manner for the community.

While collective planning presence in development gain broader audience, constraints continue to exist throughout the changes of development approaches. The externalities affecting collaborative planning relies on the local circumstances and context where the planning takes place. To understand these constraints, there is need to understand local collective action initiatives in the context of government policies, to explore ways in which such policy is interpreted and enacted by strategic actors and to examine the perception of members of the society themselves. As planning exists in a multi-level governance setting, it is pertinent to also examine government policies at its vertical interplay, between the national and local government. In the community-based planning, it means to take account of the perspective from the strategic actors in the community and examine the perception of deliberative community. Furthermore, the implementation of any policy, in turn, is influenced by different factors, one of which is assumed to be people's acceptance (Ekins, 2004).

Building upon this understanding and challenges, the paper examines how community-based planning in Indonesia changes with the introduction of resource efficiency as a platform to achieve sustainable urban development. It tries to understand how innovation and implementation of integrated resource efficiency measures on an urban scale shift the roles of non-State actors in delivering urban services in the housing sectors. At the community level, it looks at the intersection between community collective action and resource efficiency by identifying the residents' acceptance of resource efficiency and the ways of incorporating the concept into community planning, using waste management in the social housing as a case study

Following this introduction, this paper is elaborated into four parts. First, it looks into literature covering resource efficiency in the housing sector, its linkage to sustainable development concepts and the role of social acceptance. Second, it attempts to conceptualize the role of non-state actors in the community-based planning. Third, examine the space of non-state actors in the community-based planning through the case study. The final part offers conclusion on how to move forward with the community-based planning in the housing sector by maximizing community acceptance over collective issues.

2. Sustainable Development Concepts: Resource Efficiency in the Housing Sector

Urban responses to climate change have been the driver of the sustainable development movement in cities. Climate change mitigation and adaptation measures are incorporated in planning, construction and management of urban infrastructure (Walsh et al, 2011; Zimmerman and Faris, 2011). Yet, despite using the climate change approach relevant to many cities' needs and demands, the contradictions of sustainable development and urban priorities remain. In the last two decades, the need to dematerialize economies to preserve natural resources, to reduce the environmental impacts and to reduce pressure on ecosystem services led to the bringing of resource efficiency approaches to the forefront of sustainable development debates (Steinberger et al, 2010). These approached understand that environmental pressures, such as greenhouse gas emissions, are closely related to material consumption and its flows (Barrett and Scott, 2012). One of the shifts in how cities response through these policies is moving from increasing energy efficiency of local government assets to reducing a broad array of emissions linked to urban sectors. Rather than relying on producing single isolated plans, cities are putting effort to mainstream through a complex of technological, spatial and financial aspects.

2.1. Integrating Resource Efficiency Measures in Urban Housing

To this end, there are various entry points to examine the existing urban responses to sustainable development through resource efficiency approach. At least several major sectors could be identified, including transportation, energy, waste, industry, commercial, housing, and spatial plan. Housing sector, in particular, plays a crucial role to sustainable cities at the same time it is an integrating element to urbanization, planning and the use of resources through its linkage with the built environment. Further, the concept of housing encompasses the social, cultural, environmental and economic facets of cities. The future of cities depends on how well the quality and the accessibility to sustainable housing are in place.

Yet in many cities, it is unclear to what extent sustainable housing as the solution for the built environment through resource and energy efficiency, environmental, resilience contributes to the overall work of resource efficiency, considering gaps between the physical (e.g. resource and energy use, design) and social economic system of housing policies (e.g. affordability, social justice, cultural and economy). Among many, the search for affordable land at the edge of urban areas to make the construction of affordable public housing financially feasible has the potential of creating a greater cost burden for the local government, as well as a global environmental burden through the emission of greenhouse gases caused by extended vehicle commuting distances (World Bank, 2011). Resource wise, the selection of materials and quality of assembly do not always go hand-in-hand with reducing long-term operations and maintenance cost, and minimizing environmental impacts as housing projects are not motivated by sustainability policy, but by the need to improve economic indicators in the generation of housing stocks (Gordillo and Hernandez, 2014).

In the light of the realities of existing urban housing responses, it is necessary to design policies for sustainable housing in a manner that provide opportunities to achieve social and economic goals through its contribution to reduce resource consumption and emission production. This involves not only developing sustainable housing technologies applicable to various climate regions, economic conditions and residential customs, but also the management innovations for urban governance targeting housing sector. To this end, comprehensive science-based housing policy options are needed to guide planners and policy makers in achieving trade-off between environment and urban growth. These include evidence-based insights on green buildings, sustainable housing, green infrastructure, climate change resilience and urban industrial symbiosis.

From the perspective of resource efficiency, sustainable housing can be defined from design, social, economic and eco-efficient points of view. Notwithstanding certain characteristics of sustainable development, sustainable housing is coherent to the idea of self-reliant development within natural resource constraints and the idea of cost-effective environmental development (Choguill, 2007). Those ideas are in line with a developmental concept which should not degrade environmental quality, nor should it reduce productivity in the long run. It is pertinent to note that housing sector significantly contributes to sustainability due to its large amount consumption of natural and man-made resource in construction, maintenance and continued use by society. Through its design, construction and operation, housing represents a significant point of direct consumption of natural materials, water and energy (World Bank, 2011). As a fixed asset with a long operational lifespan, housing is amenable to produce embodied energy equal as much as 15 years of the operational energy requirement during its construction only (Reardon, 2001). While sources of emissions vary depending on climate, designs and behavior, housing sector remains as the predominant land use in most cities and a major contributor to greenhouse gas emission (Jowsey, 2012).

The housing sector offers substantial opportunities to improve environmental performance and, in the long run, to contribute to the betterment of consumption and production. Recently, a large number of technology and innovations are available for efficiently operating the buildings, including wastewater treatment and use, energy efficiency, solar heating, passive cooling, and creating green spaces in proximity to compact housing. Taking into account the greenhouse gas emissions embodied in housing, incorporating those technologies and innovations into housing developments, particularly public housing and large-scale programs, provides opportunities to minimize local and global environmental programs. However, as housings are highly energy intensive through their life cycle, to shift will require taking into consideration demand-side parameters such as availability, reliability and effective consumption as well as improving energy efficiency and urban density (Rehman et al, 2012).

Sustainable housing policies can be designed to incorporate sustainable materials with potentially large-scale economic impacts. The housing sector is in a unique position to help achieving the triumvirate of sustainable growth; the social goal of reducing the housing deficit, the economic stimulus goal of creating jobs in the construction industry, and the environmental goal of developing healthy homes and communities (World Bank, 2011). Through current observations on existing housing policies, particularly in developing countries, there are still rooms for the betterment of sustainable housing policies and programs to greatly improve urban sustainability. Taking the example of Indonesia, its existing housing policies have yet to fully comply with environmental policies and there is not a comprehensive urban policy in support to the provision of sustainable housing sector.

2.2. Social Acceptance of Resource Efficiency

Social acceptance has been a key part to measuring sustainability and quantifying the social dimension of sustainability (Alcorn). The social sustainability dimension is approached from an angle of social acceptance due to accepted understanding that for a technical approach to be deemed socially sustainable, it should enjoy wider social acceptance (Assefa and Frostell, 2007). Social acceptance is increasingly important factor in the design of effective policy (Steg et al., 2006). Acceptability is also a particularly important issue to manage transitions to sustainability as policies for a transition to sustainable resource use require a significant degree of behavioral change (Geels, 2013). It, thus, depends on the consent of actors at various levels, from multinational to the individual (Bicket and Vanner, 2016). For example, individuals are more likely to accept certain policies if they are well informed of the consequences of issues addressed by the targeted policies and the benefits are well described. A string social norm is associated with higher public acceptability (Schade and Schlag, 2003).

While broadly can be applied to many issues related to technology, the concept of social acceptance is particularly popular in the area of energy and other large-scale infrastructure initiatives (Fournis and Fortin, 2016). The concept of social acceptance has also been frequently applied in the waste management (Seguin, 2005). Contributions to the literature from broader and over encompassing umbrella issue of resource efficiency is less popular compared to specific sector such as energy. Focusing on acceptance and resource efficiency is supposed to offer an opportunity to explore dimension associated with mainstream considerations with social acceptance.

On the operationalization of social acceptance approach, a triangle of social acceptance was introduced by Wustenhagen, Wolsink and Burer (2007) based on the synthesis of three dimensions; socio-political acceptance of technologies and policies by major social actors; community acceptance of local actors and deliberative community themselves; and market acceptance that representing the process of market adoption of an innovation. Szarka (2007) offered a complementary approach of ‘social acceptability’ which link technology to an evolving social contract which involves three levels of collective choice; socioeconomic and technological choice; public policy choice; and governance choice. The addition of the latter takes social acceptance to be a symbolic decision-making framework and a contested and dynamic process (Fournis and Fortin, 2016), informed by collective norms, diverse evaluation processes, political struggles, and the legitimacy of behavior (Szarka, 2007). From governance perspective, social acceptance then is understood as a collective choice of technology-social contract that often conditional and affected by politics. In this framework, conceptualization of acceptance is differentiated through the hierarchisation of distinct levels instead of the plurality of dynamics (Fournis and Fortin, 2016).

This paper follows both lines of thought in order to understand the interplay of complex processes. It focuses on the micro-social level associated with processes such as coordination, social interpretation and the construction of perceptions and meanings by individual in relation to specific situations, activities, and policies. The terms social defined in this paper as encompassing all agents involved. The primary focus of this paper, however, is community acceptance.

3. Conceptualizing the Role of Non-State Actors in the Community-based Planning Process

Community-based planning is considered a fundamental aspect of bringing urban planning closer to its target constituents. Further, the last two decades have seen a global movement promoting democracy, justice and sustainability through active involvement of people, often representing through community participation. The principal implication is that community-based planning has become one of the key requirements to legitimize planning process. The experience in the ground shows that establishing inclusive community-based planning is very challenging. It is often pointed out that disadvantage groups and the poor are struggling to have access to actively participate in the planning processes (Mahjabeen, Shrestha and Dee, 2009).

3.1 Collaborative Planning

From the urban planning's perspective, community participation is considered fundamental to achieve inclusive decision making and sustainable development (Shrestha and McManus, 2008). The idea behind was with community groups actively engaged in planning and implementation processes, plans are likely to be respond well to stakeholders' needs, interests, and expectations (Healey, 1999). Community involvement in planning is also seen as means to bring together information, knowledge and skills from various stakeholders involved to improve the planning outcomes.

The systems of governance of a society or community refer to the processes through which collective affairs are managed (Healey, 1997). Collaborative planning is grounded in the theory of relation-building process creating intellectual and social capital through shared understandings and mutual trust (Healey, 1997). Thus, governance activity is diffused through the multiplicity of social relations we have, and may take many forms. It is a matter of specific geography and history how responsibilities as distributed between formally-recognized government agencies and these other arenas of governance.

Participatory planning approach are often based on the assumption that non-state actors, particularly civil society, are definable, homogenous, relatively organized and actively consensus seeking (Cooke and Kothary, 2001). On the other hand, the societal complexity and conflicts are present in many parts of the world and non-state actors take on very different. At the community level, the differences among community groups are due to various reasons, including socio-economic, culture, political, etc. The situation is exacerbated where the state is the weaker locus of authority (Watson, 2009). Assumption over the characteristics of non-state actors cannot be blamed as the reason why collaborative planning have been less than adequate in addressing urban development issues. In the global South, for example, the inherited planning system and approaches are often not equipped with consideration for inclusiveness, even though the context in which they operate has changed (Watson, 2009).

Baresford (2002) has identified two fundamental contradictions of collaborative planning and public participation: "enhanced political interest, but public dissatisfaction; official priority but very limited achievements and resourcing", implying that public participation initiatives do not always translate into a shift towards a more collaborative planning. In order to make sense of this, he calls for more focus on the social policy of public participation; its ideological, political and socio-economic relations behind.

3.2 Decentralization and Transition

Decentralization in the global South is often seen as the predominant measure of governance structure for delivering to the poor the basic services tasked in the international agenda, such as the Millennium Development Goals (MDGs), as it would be achieved primarily through sub-national governments (Ingram and Hong, 2008). Consequently, in the 1990s, decentralization is considered as a tool to improve public service, economic development, and other social development, particularly when governments are seen less capable in doing so at the rate desired by citizen (e.g. Manor, 1999; Blair, 2000; Ito, 2005). There are many reasons that drive decentralization beside international pressures for governance restructuring, including the failure of centralized planning for economic development (see Freire and Stern, 2001), lack of transparency and exclusive decision making process exercised by the central government (e.g. De Angelis, 2005).

Indonesia was decentralized in 1999, following subtle movements started in early 1990s. The change marked a movement from a centralized and hierarchical government structure to a decentralized system. The decentralization law was enacted in 1999 and was implemented starubf January 2001. Indonesian decentralization was designed to bring a greater role on the local government, bringing a functional and responsibility shift of the central government, designated to lower levels of government through policy reform. The responsibility shift generally revolves around three main principles, i.e. de-concentration, decentralization and co-administration. The sub-national authorities in Indonesia (e.g. provinces, regencies (*Kabupaten*) and municipalities (*Kota*)) were granted autonomous status as local government. The head of regencies and municipalities are no longer directly respond to the provincial government, but to the local assembly.

Decentralization in planning system followed in 2004 after the national assembly passed the new law about national development planning system (Law 25/2004) and the new spatial planning law in 2007 (Law 26/2007). According to the new national development planning system, local governments are not obliged to make their local development plans as the direct extension of the national development plan. Instead, the national plan acts only as guidance and reference. Further, planning is governed at the local level with higher level governments as coordinating partners for regional planning.

Decentralization is not without governance issues. Bottom-up accountability and deficiencies in the existing capacity are often seen as the lacking part of Indonesian decentralization (see Shah and Thompson, 2004; Local Development International, 2013). Decentralization failed to sufficiently integrate elements of decentralization (e.g. political, economy, administration) with other public sector reforms. This lack of coherence was due to weak coordination of key actors where consensus is rarely reached. It is also found that the implementation has been uneven across municipality which largely depends upon the leadership quality of the local elites (see Firman, 2003). Municipalities with better capacity have better records in policymaking and implementation.

Collaborative planning, including local community-based planning, was affected by decentralization as it is closely related to the relationship formed between involved actors and their willingness to collaborate. The resources, objectives and roles that particular actors bring determine the nature of social relations forged within and across networks (Koliba et al, 2011). In a fragmented decentralized system such as Indonesia, actor relations vary across administrative jurisdiction, various levels of governments and between government and nongovernmental sector.

4. The Case Study

The concept of social acceptance towards sustainability and resource efficiency measures through community planning is illustrated with an example of community group that planned, established, and maintained a community based waste management. To facilitate an understanding of the increasing role of communities in the case study, the local sense of social relations and the institutional relationships created by the local administrative structure are explained.

4.1 Data

This case study is drawn from a longitudinal study of low income residential housing. The study was conducted in the city of Surabaya and focused on two housing communities located in the city center (Rusun Urip Sumoharjo and Rusun Grudo). The broader purpose of the study was to analyze the social acceptance of people towards sustainability and resource efficiency measures applied in the low income housing projects. For this paper, the study specifically looks into the role and capacity of community to support people's acceptance through community-based planning.

The initial round of field research gathered secondary data from the local officials regarding the targeted community and changes in community-based planning in the city of Surabaya. In later rounds, the study sought a more in-depth understanding of the social acceptance of the low income housing communities. The study used a combination of qualitative and quantitative methods. Data were collected in a series of intervals begin in 2014 and currently is still ongoing. Research methods included questionnaire surveys, analysis of transcripts based on in-depth interviews and oral histories. The questionnaire surveys to the households were conducted to gather information on household structure, education, employment, consumption and use of resources, housing ownership, access to services, and participation in community-level decision making processes. For each housing complex, 100 samples were collected.

4.2 Social and Economic Characteristics

As of 2018, Surabaya has 78 low-income housing blocks in 14 locations. From the start, development of low-income residential housing in Surabaya was aimed to provide affordable housing and to reduce squatters through relocation.

Rusun Urip Sumoharjo

As one of the oldest low-income housing in Surabaya, Rusun Urip Sumoharjo was built to replace residential houses burned down in a 1982 fire accident. Residents were not allowed to rebuild their houses and instead were temporary relocated while the local government built the multi-store housing which was finalized in 1985. Unlike other low-income housing blocks, Rusun Urip Sumoharjo was not a rental housing. The building undergone a reconstruction in 2003-2005 to replace the structure. Since the budget to rebuild and to maintain the building came from the local government, rental fee exclusive of utilities was imposed to residents starting in 2006.

The majority of the residents living are the owner of houses replaced in 1982. The housing block housed a total of 120 households. Most of them has non-wage source of income. Each unit consists of living-dining room, one bedroom and one bathroom, totaling about 24sqm.

Rusun Grudo

Rusun Grudo was originally built to improve the living condition of slum settlements and to provide housing for low-income local government retirees. It is a rental based housing with subsidy from the local government. Each of the five stories building housed 96 households. The size of housing unit is 24sqm each.

4.3 Planning at the Community Level

In Indonesia, how local residents engage in planning at the community level is defined by the institutional relationships created through the urban political-administrative structure. For the administrative purposes, urban area is subdivided into districts and sub-districts with civil servants as officers. At the community level, there are two units of community group, *Rukun Warga* (RW) and *Rukun Tetangga* (RT) whose leaderships are on voluntary basis and directly elected by community members. In the residential housing complex, unlike in landed housing-based urban settlement, prior to establishing a RT, the community has to set and register a Residents Group in the sub-district office. With each RT consists of 30 to 40 households, each building with 5-6 floors could have two or more RTs. In the political-administrative structure, these community groups institutionally linked community and state. They also hold status as non-state actors alongside civic society organizations. For both Rusun Urip Sumoharjo and Rusun Grudo, RT was formed in each floor with 5-6 RTs in total in each building block.

Synoptic Planning

In 1982 when the first Rusun Urip Sumoharjo was built, residents were not involved in any capacity to develop the housing plan. The local government instead worked with private sector, resulting in many complaints about the quality of the building and housing units throughout 1985-2000. While community planning was enshrined in the planning law starting 1992, the practice was challenging due to a highly restrictive social and political context in which there exists a threat of repercussions for any activism considered political. Any community planning activity was highly controlled and directed by the government. The participatory process available was to improve the living conditions of the housing, including infrastructure and services. It was not an openly participative experience and instead local government adopted a problem-solving approach. Thus, resident participated in a formal, institutionalized planning process with limited power that allow residents to engage in negotiations with public officials.

Decentralization influence the change of process. It gave rise to new social debates on planning where the residents start gaining power to present suggestions and statements to local government to improve the condition of the housing block. The process led to approval of reconstruction. The process leading to the designing and developing the new housing block was more participative than the previous development process. The planners employed by the local government adopted a consultative approach where they offered meetings and participated in public consultation with the residents.

Collective Planning

In Rusun Grudo, residents were not involved in the planning and development of the housing blocks. However, the RT managed to reorganized themselves and establish a local waste recycling and management right after they started inhabiting the housing blocks. Their community-based waste management was considerably more advanced and organized compared to similar activity in Rusun Urip Sumoharjo despite the community group in the latter residential housing complex was established earlier with decades of experience in community organizing for social movement.

Collective local waste management was introduced at the city level in early 2000s following the green city movement and the successful settlement improvement program of affordable housing in the 1980-1990s. Eco city programs were introduced in mid 2000s targeting local communities to develop sub-district level community-based planning for waste management as part of the community green and clean advocacy. Local communities targeted were mostly in the densely-populated urban areas and many of them were low-income, including residential housing complexes.

4.4 Community Acceptance of Resource Efficiency

The level of social acceptance is partly determined by community acceptance, a practical acceptance of new program within the targeted communities. The attitude toward resource efficiency, particularly on issues such as energy and water supply efficiency and waste management, is shaped by deep rooted cultural and ideological identities. It is also influenced by changing forms of information and advocacy. Reward and incentives from other local actors were also influential, including better outlook of general public opinion toward their living areas and neighborhood. For the waste management advocacy, it is the issue of NIMBY in the development of landfill. It is not necessarily close to the communities observed, but as the landfill serves the whole city the debates surrounds it affects the communities at large. Media, in particular, has a string influence on the community acceptance of resource efficiency as it sets emphasis on certain stories and link them with the ongoing supra-local and global movement on similar issues. This structures the public and community debate with perspectives and viewpoints.

We conducted a questionnaire survey on community acceptance of resource efficiency in Rusun Urip Sumoharjo and Rusun Grudo using the indicators listed in table 1 below to gather community perception. Our study found that the overall attitude over resource efficiency is tied to the social-economic factors of sustainable housing, including economic sustainability, accessibility and affordability. The better these factors are, the stronger community acceptance towards resource efficiency. Community satisfaction over their housing quality and quality of life also influences its acceptance towards resource efficiency. If they see exercising resource efficiency affect positively towards their housing quality and quality of life. The positive attitude towards community participation also significantly affect resource efficiency and the strength and coverage of resource efficiency initiatives being implemented in the housing sites.

The table below show the theme of resource efficiency and related community acceptance indicators used to collect the data through the questionnaires. A more detailed analysis using regression is currently being undertaken.

Theme	Type of community acceptance
Economic	Income generation
	Return investment
Accessibility	Accessibility
Affordability	Affordability of rent and utilities
	Quality of electricity
	Quality of water supply
	Overall affordability
Resource efficiency	Efficiency of electricity usage
	Efficiency of water usage
	Efficiency due to housing design
	Waste management
Housing quality	Design adaptability
	Quality of the sanitation
Well-being and neighborhood quality	Quality of the housing
	Quality of the housing amenities
	Quality of the housing environment
	Overall quality of life
Community participation	Community engagement and planning

Table 1: Survey indicators for community acceptance.

5. Conclusion

There are both similarities and differences between community acceptance over resource efficiency within the same urban jurisdiction as shown by Rusun Urip Sumoharjo and Rusun Grudo. On the other hand, the citizen participation possible in both cases was determined more by the leadership in each housing complexes and the socio-economic opportunities generated by different local factors than by the influence of supra-local and global dynamics. The local enabling factors in the community-based planning, however, were influenced by supra-local and urban dynamics as the city introduced new urban development approaches through its planning programs.

Urban Living Lab: Towards more Legitimate and Inclusive Participation in Urban Planning? Experiences from Bodø Living Lab

Mathias B. REINAR, Nordland Research Institute, Norway
Aase Kristine LUNDBERG, Nordland Research Institute, Norway

1. Introduction

In recent years, Urban Living Labs have been promoted by both practitioners and scholars around the world as a desirable approach for local governments to engage with different stakeholders and citizens in discussions about urban development. Urban Living Labs are both physical and virtual arenas, allowing the public to contribute to urban planning in various ways. Although carried out differently across different urban scales and contexts, key ideas in the concept of Urban Living Labs are public participation, deliberation and co-creation between different stakeholders.

The UN's sustainability goal on cities and communities has as one of its targets to, by 2030, "enhance inclusive and sustainable urbanization and capacity for participatory, integrated and sustainable human settlement planning and management in all countries". Cities account for three quarters of global carbon emissions, and to reach the goals in the Paris Climate Agreement, drastic steps are needed to be taken in urban planning. This requires the involvement and commitment of the urban population in ways reaching far beyond traditional public hearings and written statements to plans. Moreover, developing innovative solutions that address both climate adaptation and mitigation demand new ways of engaging the private and public sector as well as the citizens at large.

During the last decade, several Urban Living Labs have been set up in different Norwegian cities (Hvitsand and Richards, 2017). Ranging from various initiatives in the capital of Oslo, to medium sized cities as Hamar, Moss and Fredrikstad. Even small towns as Svelvik.
As pointed out by Hvitsand and Richards (2017), these initiatives seem to happen independent from each other, drawing on inspiration from abroad. Moreover, there is not a shared definition or understanding of what an Urban Living Lab is, rather, different adaptations to different urban contexts and challenges.

In this paper, we use Bodø Living Lab as a case to explore how such Urban Living Labs can contribute to secure and improve the legitimacy of urban planning in the face of climate change. We examine where the idea to establishing Bodø Living Lab came from and what the aim was envisioned to be. Further, we focus on how participation from diverse actors with interests in the future development of the city is enabled through the Living Lab and who participate in the Living Lab's activities. At the same time, we are interested in actors not participating in the physical and virtual Lab and the possible alternative voices and perspectives omitted through the processes. In this paper, we combine document studies, including social and traditional media coverage of the Living Lab, participatory observations from activities in the Living lab in Stormen library in Bodø and interviews with involved stakeholders.

The Bodø Living Lab is a project set up by the city, with an aim to look "at the whole society perspective in city development", and by this "to connect public health, education, welfare, environment, culture, governance, business development and technology development together", according to the city municipality's web page. The Lab was formally opened at the beginning of April 2018. The findings presented in this paper, thus, focus on the experiences from the establishing process and the initial phase of the Living Lab's activities. The field work was conducted from April to June 2018, and the analysis is therefore related to public participation and citizen engagement in and through the Bodø Living Lab's establishing phase.

In the next section, we present the theoretical framework and background of the growth in Urban Living Labs, before we give a background to Bodø and the establishment of the Urban Living Lab. We then go on to describing the methods used and the empirical material the analysis draws on. In the following section, we present the findings before discussing these in light of the goal to increase urban planning's legitimacy before ending the paper with some final reflections and recommendation for future development of Urban Living Labs.

2. Theoretical perspectives

While the concept of urban living labs is not clearly defined, there is a consensus that citizen and user involvement is central, and that innovation takes place as a result of bringing together complementary knowledge, skills and resources in real-life experimentation (Bergvall-Kåreborn et al., 2015). According to Mccormick and Hartmann (2017), urban living labs can be seen as both an arena (geographically or institutionally bound space) and as an approach for international collaboration between researchers, private business, citizens and local government.

While there is no unified definition of an urban living lab, the approach is based on the quadruple helix model of partnership “whereby government, industry, the public and academia work together to generate innovative solutions” (Voytenko et al. 2016:47). The focus on innovation in urban living labs is tightly connected to the concept of co-creation. This reasoning is in line with what Lund (2018: 12) describes in her discussion of co-creation in urban governance, as “shifting the focus of participatory processes and mobilisation strategies from power distribution to competencies; a result of moving the focus away from the right to influence towards the ability to identify and solve urban problems.”

Following the aim of this paper, a key concept in the analysis of the Urban Living Lab in Bodø’s city development, is legitimacy. It is a concept with strong normative connotations. The contested and constructed nature of legitimacy makes it challenging to derive ‘objective’ criteria for assessing the legitimacy of planning processes. Parkinson (2003) has argued that legitimacy cannot be fixed on a scale and that it should be approached as an ideal. Moug (2011: 130) has underlined that “Focusing on legitimacy cuts to the heart of power relations offering fresh insight into how context colors what is viewed as legitimate and how particular views and decisions prevail.”

Increased participation from non-governmental actors in formulating and implementing public policies makes authority and accountability unclear and Connelly et al. (2006) have argued that diffusion of authority requires a refocusing from the formal, explicit exercise of power, to a broader definition of policy-making processes to understand how legitimacy is constructed. They underlined that the vital question affecting stakeholders’ perception of legitimacy can no longer conform to the classical formulation of ‘…“do we accept this body as appropriate to make decisions that affect us?” Rather, it becomes “do we accept this process as an appropriate way to make policy – here, now?” – with the corollary “how seriously should we therefore treat its outcomes as a guide to our actions and decisions”’ (Connelly et al., 2006: 270). This underlines the importance of approaching legitimacy and accountability of collaborative governance arrangements broadly and not limiting this to formal institutional arrangements or legal frameworks.

We approach the concept of legitimacy through the distinction between input and output legitimacy (Scharpf, 1999), along the three dimensions of participation, coordination and accountability. Scharpf’s (1999) emphasis on input and output legitimacy have been particularly influential in studies of legitimacy and while input legitimacy rests on procedural logic and the policy process’s inclusiveness, fairness, and participatory qualities, output legitimacy focuses on the problemsolving capacity of the result and, thus, rests on consequential logic (Kronsell and Bäckstrand, 2010). Following Hogl et al. (2012), we identify three dimensions of legitimacy: participation, coordination and accountability. Using these three dimensions, our framework enables an analysis of how an urban living lab may contribute to the construction of legitimacy in urban planning.

Dimension of legitimacy	**Sources of legitimacy**	
	Input legitimacy	**Output legitimacy**
Participation	Who participates? What do they do/participate in/to? What happens with inputs? Access – when?	Awareness (smart and sustainable) Acceptance (living in/at a construction site) Compliance with policies (willingness to follow restrictive climate policies)
Coordination/collaboration	Communication across sectors (private, public, civil society)	Coherence Mobilize resources Shared vision/strategy
Accountability/democratic control	Transparency Open information flows Accessibility to information	Improved local democracy Improved trust between different actors – reciprocity Improved trust to the governance system

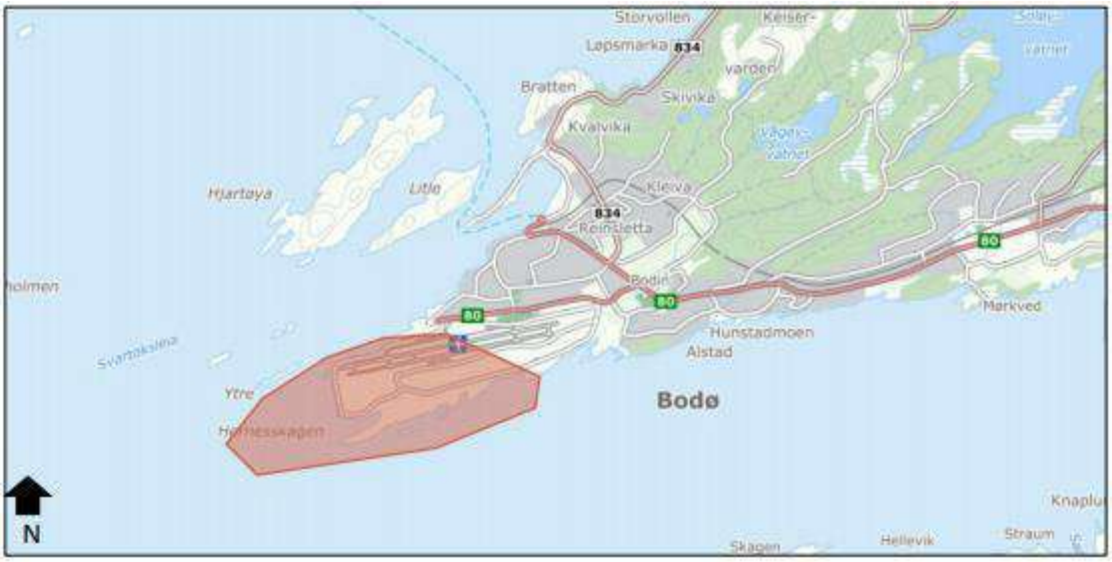
Table 1: Different sources and dimensions of legitimacy

3. **Context and case description**

Bodø is a city in Northern Norway, located on a peninsula facing the Norwegian Sea. The city was founded in 1816 and reached a population of roughly 4700 people hundred years later (Jakhelln, 2004: 16). In 2018 the population was about 50 000, and it is by this the second largest city in the northern part of the country (after Tromsø). As the capital of Nordland County, Bodø has few competitors as the main urban hub in the region, and while the rural areas of the county for the most parts have been seeing a decrease in population in the last years, Bodø is seeing an increase. The population is expected to reach around 60 000 by 2040, according to official estimates.[i]

A key driver for the growth of Bodø in the coming years, is expected to be related to the building of a new airport. In 2012 the Norwegian parliament decided to move the military airport from Bodø to another region further south. In connection with this, the civil airport, which is located right next to the city centre, will be moved 900 meters to the southeast. This will subsequently free areas roughly equal to today's city centre for future development. The municipality wants to use the freed area to build a "New City"[ii]. The area where the city wants to expand is indicated in the map in figure 1.

Figure 1 Area for Bodø's "New City"



Source: Planprogram områdeplan for ny sivil lufthavn i Bodø, Bodø kommune 2017

According to the municipality, the "New City" will be "the smartest city in the world"[iii]. Implicit in this vision, is that the urban development processes in Bodø will be both sustainable and climate friendly. As part of this "smart vision" the municipality has set up an Urban Living Lab called Bodø ByLab. As already noted, the aim of the Lab is to look "at the whole societal perspective in city development", and by this "to connect public health, education, welfare, environment, culture, governance, business development and technology development together", according to the city municipality's web page. The Lab itself is both a physical place located in the main library and a virtual place available online.

4. **Methods**

In this study, we use a single case study approach as described by Yin (1994). This has allowed for an in-depth exploration of the experiences from the initial phase of establishing the Urban Living Lab in the public library in Bodø. We combine qualitative interviews, with document studies and participatory observations from activities in the Urban Living Lab during the first few months after it opened in the beginning of April 2018.

Initially, we planned to use participatory observations from the Urban Living Lab at the library as the main empirical source in this study. We though that this would give us an opportunity to observe the interactions between municipal officials, developers, stakeholders and citizens coming to the Lab. Further, we hoped that that these meetings could provide a starting point for informal conversations with different actors interested in or involved in the development of the city. However, we experienced quickly by being present during the opening hours of the Lab (Tuesday to Thursday from 09.00 to 15.00) in the library, that there were few meetings or encounters between municipality representatives and the public. In total, we were present eight days (from one hour to full days), including the official opening of the Lab on April 5th. Some days, there would be no one from the municipality, while other days there would be no interactions. Organized events by the municipality in the Lab gave us, however, an opportunity to conduct participatory observations. This included a thematical meeting on universal design and public accessibility (May 24th). We developed a research diary from being present at the ULL, including notes from our observations of the physical environment, interactions in the ULL, presentations and discussions with people.

We conducted six semi-structured interviews with actors involved in the Urban Living Lab in Bodø, including public officials from Bodø municipality, both at the administrative and the political level. We also talked to people present at the Lab or at the public library. We developed an open interview guide, with questions focusing on the background and purpose of the Urban Living Lab, as well as experiences so far. This allowed us to explore different perceptions of how the Urban Living Lab enabled participation and/or contributed to legitimacy in urban planning. The interviews were analysed with a focus on the experiences from the establishing phase and expectations for the future.

In the document study we have included both official accounts from Bodø municipality about the Lab, presentation of the Lab on social media and in traditional media coverage. In total, the document study has involved twenty-some documents. The written material has provided us with an insight in to how the municipality justifies/presents the Lab in official documents and how the Lab is communicated to the public/citizens of Bodø through social media, primarily Facebook. The media review has contributed to understand the public debates surrounding the Lab and how urban development/urban planning is put more widely on the public/political agenda.

5. Findings:

Setting up the Lab

In different strategies and plans, Bodø municipality has over the years stated its intention of being an open and inclusive municipality. The intention is not the least clear in the municipal master plan, which points out main challenges and focal points of planning policy for the years to come. In the recently revised social element part of the municipal's master plan (spring 2018), co-creation is identified as the number one priority for the municipality. Co-creation is in the plan roughly defined as a process that will "facilitate new creative solutions, increased well-being, real involvement and meaning for the citizens" (Bodø kommune, 2018b: our translation). In the plan the municipality states that "municipalities that co-create with its citizens are better equipped to handle complex societal challenges." The solutions one choses "need legitimacy, and active participation is a prerequisite for this" (Bodø kommune, 2018b: our translation). One way of achieving this is to develop "new methods for citizen engagement and user involvement" (ibid.)

The urban living lab is emphasised as one method for achieving co-creation in planning documents and interviews. The idea of the setting up an urban living lab came from The Green Party (Guttormsen, 2015). In the political negotiations after the local election in 2015 the urban living lab ended up in the formal agreement between the governing coalition, as "an easily accessible branch of the planning office where citizens may familiarise themselves with and give input to the municipality's planning processes" (Bodø kommune, 2015).

The city council adopted the mandate for the Lab in February 2018. One of the reasons for establishing an urban living lab was to involve citizens in the many development projects in the city. The project mandate stressed the need to create arenas for participation that would promote creativity, engagement and a sense of community. Participation would also ease the implementation of policies (Bodø kommune, 2018a). The project mandate built on other strategies in the municipality highlighting the importance of involvement and co-creation between the local government and the citizens. The Lab was presented as a place to "test co-creation and participation in a real environment". According to the political document the Bodø ByLab concept would be the first of its kind amongst municipalities in Norway, and the Lab would be "breaking ground in its effort to become a more open and inclusive municipality that takes democracy and the role of the citizens seriously" (Bodø kommune, 2018a: our translation). The municipality had also a few years earlier tried to strengthen the local democracy by mapping the status of democracy in the municipality and suggest measures to strengthen participation from the citizens, in a so-called "democracy project" (Bodø kommune, 2014).

Prior to the opening of Bodø ByLab, the Lab was frequently mentioned in local media. In November 2017 the major local newspaper *Avisa Nordland* (AN) published an interview with the organisers (Landstad 2017). In December AN published an interview with the project leader of the Lab and the head of The Green Party in Bodø, who was also the leader of the planning committee in the municipality. Here the ByLab was presented to the readers as one of a kind under the heading “They want to make you and me city planners: – This has never quite been done before” (Gulliksen, 2017).

A month prior to the opening of the Lab the municipality and a research institute who had insight on the workings of other urban living labs around Europe, presented the concept of urban living labs generally and the Bodø ByLab to specially invited participants in a workshop. The participant list included civil servants from the municipality and the county municipality, developers, other stakeholders and researchers. In the workshop the living lab was tightly linked to the concept of *co-creation.* This was again contrasted with that of *participation,* which was defined as the formal and legal right citizens have to be heard in consultation processes, and which applies to all citizens. In the picture presented, the urban living lab, to be successful, should first and foremost be an arena for co-creation and stakeholder involvement.

According to the project description, the Lab would first go through a trial period. The municipality would then use the experiences from the test period when planning a permanent Lab in the new City Hall, which was under construction in 2018 (Bodø kommune, 2018a). Although a pilot, the opening day on 4 April 2018 had all the spectacle of an official opening, with the major cutting the ribbon, announcing the Lab opened. Several hundred people turned out for the opening. The Lab was part of the “Smart City” project in the municipality, and the opening was announced on the Facebook page with the following teaser: “On the opening of ByLab tomorrow at 10 am you will hear from amongst others some of the world’s foremost experts in smart cities, technology, digitalisation and innovation!”[iv]

Picture 2 Model of the city centre in Bodø ByLab

Following up

The Bodø ByLab was in the trial period located in the city’s main public library. The Lab was located on the library’s ground floor. The was no clear distinction between the Lab and the rest of the library. Tables often occupied by students and elderly people in the library, overlapped with the Lab. One of the markers of the Lab was a physical model a few meters wide visualising the city centre. There were also posters with the ByLab logo on them.

It was clear from the beginning that the Lab was a work of progress, and several items were added to the Lab during the first couple of months, including information posters, a projector and couches. Measures to more clearly contrast the Lab from the rest of the library, like carpets and plants, had proved difficult to put in place because it broke with the interior design of the library, according to an informant. The installation of a mail box where people could insert their ideas about urban planning and other issues, was under negotiation between the organisers and the library when we conducted the fieldwork. Bureaucratic slowness was explained as being one of the challenges of making an Urban Living Lab within the framework of a local administration.

The opening hours of the Lab were announced to be Tuesdays to Thursdays from 9 am to 3 pm. The fact that most events happened during daytime on workdays, might have put limits on who could attend, as this would require people to take time off from work to present themselves at the Lab at the public library. The opening hours also seemed to be a little off-target if the goal is to reach those who usually doesn't speak their voice. As several informants from the municipality told us, one of the groups that is hardest to reach in ordinary planning processes, are families with small children. As one informant from the municipality put it: "At public meetings there is a lot of grey hair. The category we want to reach the most are families with children. They are a little bit invisible in the big picture, but very engaged when it comes to their own neighbourhood." It would seem difficult to attract this group given the opening hours on daytime. As a project run by the municipality, it is of course challenges associated with adjusting the opening hours. This would necessarily demand that civil servants spent their evenings or weekends working, a measure that is likely to meet some obstacles in the well-organised working environment of Norwegian public sector.

As important as the opening hours is of course the content of the Lab itself. As the Bodø ByLab project was organised directly below the Municipal Chief Executive, with a goal to involve and give ownership to the Lab to different parts of the municipality, different departments of the municipality were given responsibility to host their own thematic days. One of the ideas of the Lab was that by putting municipal officials together in an open setting – in the public space like the library – this would spur creativity and interactions between officials and the public, but also across established bureaucratic barriers. During the first few months the Lab was therefore hosted by civil servants with their laptops, working with issues concerning planning, building, welfare, public health, children and adolescents and digitalisation, amongst others.

Some of these days consisted of presentations or demonstrations (of welfare technology, the municipality's new website, etc.), others were more loosely organised, with one or more civil servants making themselves available to the interested citizen. The Lab was also being used for different types of meetings, as it was conveniently located in the city centre. For instance, the standing committee of planning, industry and environment put its monthly committee meetings in the Lab to open it up to the public. There was also a Children's City Lab on a Saturday.

Picture 3 Meeting of the standing committee on planning, industry and environment in Bodø ByLab

During the time we were observing the Lab, the turnout from the public was low, with some exceptions. This impression was confirmed by the Lab hosts we talked to. They didn't seem too surprised by this, however. They had several thoughts on how to attract more people, including better marketing of the Lab, expanding the opening hours and making it clearer who the civil servants actually were, so they didn't blend in with the rest of the library visitors.

One of the more successful events, in terms of interest from the public, was when the local building authorities hosted the Lab. According to the reports, a total of 14 building applications were discussed that day. This shows an apparent need for small developers to meet with the authorities, something that the Lab offered an arena for. In this case the participants had their own private interest in turning up. It was more challenging to get people interested in regulation plans – which was the topic of one of the days the local planning authorities hosted the Lab. According to one informant, those stakeholders who had an interest in regulation processes, had already given their opinion in the consultation process. Another day the topic was development of the "New City" that will double the size of the central parts of Bodø. This is a long-term development project with at least a fifty-year perspective. This also proved to be a challenging topic to sell to the public, with few people appearing at the Lab.

Despite that there clearly were some challenges in the establishing stage, everyone we spoke to in the municipality were eager to keep the laboratory going. They all agreed that the Lab was a useful initiative to get people interested in local affairs. A common theme among the urban planners we spoke to was that the municipality needed to do *something else* than what it was already doing to reach and involve the citizens. It was stressed that a lot of people were likely to have an interest in urban development, but it was a challenge to get them to participate.

Picture 4 The municipality lends it ear to the citizens: "You are the expert. We listen."

From our observations and interviews, strengthening the communication about what Bodø

ByLab is, seemed to be a key issue. According to one informant, the marketing of the Lab should strive to be less "municipal" – meaning it should less resemble what usually comes from official channels. The main marketing and information channel of the Lab was its official Facebook page. The Lab also had its own website – the "virtual" part of the Lab – as well as an account on Instagram. These channels however lacked much in content and seemed to generate little attention in the first couple of months. The Facebook page contained for most parts information about coming events at the Lab and pictures of prior events. There was little response on the Facebook page from people outside the municipality, indicating that this first and foremost functioned as an information channel. Like the Facebook page, the Bodø ByLab website also demanded that the visitor created an online user to comment or "like" different posts on the site. There were some instances of input from the people outside the municipality on the website. One of these welcomed the Bodø ByLab initiative and asked for more information on the website about different development projects, before he could give input and participate.

6. Discussion:

In this paper we ask if an urban living lab is a viable method for making urban planning processes more legitimate. We have presented the Bodø ByLab as a case of an urban living lab in its initial stage, focusing on how this lab was initiated and justified, how it was marketed, what happened in the lab the first few months and who participated.

First it should be noted that Bodø ByLab was more than a laboratory for urban planning. Although that was where the idea of the Lab started – that is should be a branch of the local planning authority's office, – in the first months it was a potpourri of different municipal initiatives. One way of interpreting this is to say that urban development was broadly defined by the municipality. As one of our informants told us: urban development is about much more than making regulation plans. This way of thinking was clear with the inclusion of for instance the health and welfare sectors, and this may be an effort from the municipality to create awareness both inside its own organisation and among the citizens that urban development concerns many more than those who are usually involved in consultation processes and so on. One more pragmatic way to look at this, is that to fill three days a week with content, a broad understanding of urban development was necessary.

The Lab was marketed as an arena for testing ground-breaking new methods for citizen participation in urban development. In one way, this marketing strategy is understandable, given the need to “break through the noise” in the information age, and to get the necessary attention before opening. It seemed to have worked as a lead up to the opening day, when hundreds of guests appeared. The contrast to what took place in the Lab after opening day, is on the other hand striking. It was difficult to see the ground-breaking elements and turnout from the public was disappointingly low. This is one of the risks of making high promises.

From the viewpoint of urban planning, rather than being an alternative to traditional planning processes or offering something completely new, the Lab can be seen a supplement. The thought was that by being present at the Lab, civil servants from the planning authorities would engage in conversations and receive input from the citizens in matters concerning urban development – together they would “co-create” the new city. For this to work, some adjustments seem necessary. The planners in the municipality knew a great deal about what the challenges were, and this knowledge could be used in the design of the Lab. For instance, if one of the challenges in urban planning processes is connecting to families, the Lab could be used to target this challenge more precisely. This requires a close collaboration between the organisers and the planning professionals.

Looking beyond the “ground-breaking” rhetoric and the start-up problems, Bodø ByLab may be a way to open public policy processes, or “demystify the municipality” as one of our informants called it. Moreover, using Facebook as the main channel of information sharing could be problematic in a legitimacy perspective, as it excludes some groups who are not "logged in".

One challenge that was mentioned several times by the organisers, was the strong “municipal grip” on the Lab. This concerned both practicalities of setting up the Lab within a bureaucratic system, but more important for our discussion of legitimacy, is the possible exclusion of other actors that this might lead to, whether this is developers, private actors or organisations. Even though several factors might explain the low turnout in the first period, like the lack of knowledge about the Lab among the public, there is a risk that the Lab was perceived as just another channel for information from the municipality. This is in some sense true; part of the content of the Lab was in large degree information from the municipality and had little to do with engaging or interacting with citizens.

7. Concluding remarks:

Bodø ByLab was established against the backdrop of large development plans in the city of Bodø, and a realisation amongst decision makers that this called for a greater deal of involvement from the public. There was, in other words, a need to secure the legitimacy of the development processes. As we have shown in this paper, some challenges stood in the way of making the Lab an immediate success in the establishment phase. This included practical as well as more content specific obstacles. Based on our findings, we would argue for making some adjustments, and have the following suggestions:

- The organisers should ask themselves who they want to involve in the specific events and target these groups more directly. What kind of input the municipality wants from the public could also be specified.
- If the Lab is to be a successful method for more legitimate urban planning, a close collaboration between the planning professionals and the organisers of the Lab seems necessary.

- As several of our informants pointed out, people are more likely to get involved in matters concerning them, so perhaps more locally specific events could be a way to attract people.
- A more clearly defined Lab, with more visual elements, maps and so on, might be a good way to create engagement and interest concerning urban development amongst the public.
- A way for people to interact with the municipality, give input and so on without the need to talk to official representatives, might lower the threshold to participate in the Lab.
- The marketing of the Lab, including the communications platforms, could be opened to a bigger public. To create more attention about the Lab, a collaboration with local news media might be effective. This proved to be a good strategy in another small city not far from Bodø, who wanted attention about urban development.

Gaming simulation as policy planning tool in a racially diverse neighborhood: a case study of Lardproaw district, Bangkok

Paola, RIZZI, University of L'Aquila, Italy

Pongpisit, HUYAKORN, UDDI Thammasat University, Thailand

The researcher implemented Gaming Simulation as a method to assess the awareness toward climate change and the perception regarding the collaboration for local policy development from different local racial groups which include Thais, South East Asians, Europeans, etc. Ultimately, we recommend the progressive approach for elevated local community-based planning.

1. Background

Local community policy planning has never been an easy issue, most of the time the policy was generalized for the whole country or at best for the provincial level. Unfortunately, they will be the first actor that are going to face the adverse effects of climate change, in the decade to come the local ability to tackle with emerging issues of resiliency, immigration, diversity and inclusiveness will be extremely crucial. Presently, the district of Lardproaw is facing the impacts of ASEAN Economic Community (AEC) that was initiated in the year 2015 to promote the movement of people in 10 South East Asian countries. Unfortunately, in his research Huyakorn also learned that “In Thailand, the majority of Thai people still refer the low-skilled migrant worker as an “alien resident” instead of immigrant and as such, they have been regarded as so-called alien residents. It has been extremely difficult for them to find a place in the community”. (Huyakorn et al., 2018). And due to that, there have been growing tensions among the local residents and the newcomers in several neighborhoods. Consequently, as Thai local planning authorities neither familiar with the context of climate change nor the immigrant integration, we direly need a novel tool to creatively deal with this unaccustomed local phenomenon.

Interestingly, this research utilized the Gaming Simulation (GS) as a primary tool, due to its efficacy in both complex learning and risk communication tool, in the view of different scholars, GS allows participants to develop a global perspective, to connect learning with real-world situations and to get close to the realities of a complex world (Duke, 1974; Faria & Dickinson, 1994; Haapasalo & Hyvonen, 2001; Hoberman & Mailick, 1992; Lainema & Hilmola, 2005).

In term of risk communication tool, Promsaka and his team have found that “the gaming simulation offers representatives of stakeholders the opportunity to meet each other, discuss and exchange their different information and opinions on a specific issue, which enable a fruitful communication avoiding a risky judgment on wrong terms” (Promsaka et al., 2014).

More importantly, Huyakorn found out that in GS is truly useful for the neighborhood that has the complex relationship among diverse group of resident “It seems to have an extremely elevated potential for urban planning and design context wherewith. Regardless, in this new era of diversity, several nations will require collective policy planning in the local community level. Neighborhood planning is the best arena that urban policymaker and immigrant integration initiator should start implementing this tool” (Huyakorn & Rizzi, 2017).

The Arrival City Game was introduced to research participants, aiming at the local stakeholders that include natives and immigrants, while the participants have to accommodate the complicated issue about immigration, particularly the fact that in the GS the local and newcomer have to compete for jobs, house and other utilities. According to the role in the game, their action would affect not only the district but also the citywide and nationwide area, i.e. the investor could decide to invest in an old type of factory plant, the government can invest in costlier but more sustainable public transport. Hoping that we can comprehend how the racial difference affect their understanding and wherewith a solution for better collaboration and contribution toward local planning policy from different groups of stakeholder.

Accordingly, the research objectives are 1) to assess the local community awareness toward climate change, 2) to assess the local community perception about the collaborative local policy planning that have impact on the citywide area and 3) to propose appropriate policy recommendations for the local community-based planning efforts.

2. Research methodology

In order to assess the local community awareness toward climate change we observed their actions and decision during the game. And we let them do the pretest and posttest questionnaire. Firstly, we let them list the causes of climate change, the impact of climate change and then we let them assess from 1. Strongly disagree, 2. Disagree, 3. Neutral, 4. Agree and 5. Strongly agree about these 5 statements,

1. Giving the chance I will join the participatory planning event
2. Climate change is a problem for everyone
3. Climate change impacts effect my life
4. I am willing to contribute to climate change reduction and mitigation
5. Urban planning relates to climate change issues.

As per the local community perception about the collaborative local policy planning that have impact on the citywide area we observed the participant during the game activity and we also did a focus group interview activity to collect the data. The essential discussion topics were about the GS activity, participatory planning issue in Thailand and in the neighborhood.

The neighborhood we implemented the game in was within Lardproaw district. Due to lower average rent compare to other district that is connected with decent public transport, it becomes easier and easier to see the foreign faces in the area. While the national statistic institution is still too rigid and slow to collect the data about immigrant residents we have learned that beside the low-skilled migrant that you can easily find in other neighborhood, there are a huge number of immigrant residents who have moved in to the area. Some of them even live in Lardproaw for more than 25 years.

The date of the game activity was on the 20th Mar 2018, the planning activity was on the 30th May 2018 and also the follow up interview on the 13th July 2018. The main languages of the activities are English and Thai. There were 50 locals and 50 migrants who took part in our research. We tried to have as diverse as possible group of samples for the research through snowball method. Our research samples include people of 15 countries, who identify their ethnicity as: Thai, Chinese, Japanese, British, American, German, Russian, Taiwanese, Indian, Mexican, Australian, Burmese, Lao, and Cambodian. The largest ethnic groups among the immigrants are Burmese. Interviewees' duration of stay in the neighborhood varies from a few weeks, months, a couple of years, to several decades. The longest consecutive durations of stay in the neighborhood are 25, 20,16 and 15 years.

There are 60 women and 40 men. Most samples are between 31-45 years of age. The second largest age group is 46-60 years old. We have also people aged 18-30 and over 60. The youngest four samples are 18, 21 and 25 years old, while the eldest three are 65, 67 and 70. The group contains the person who live by themselves, couples, single-parents, couples with children, a multigenerational family, and people who live in a form of shared housing (e.g. shared house with relative). The largest groups of interviewees live alone, have a partner and children, or are single parents with children.

Furthermore, in terms of the socio-economic status (SES) of the samples, referring to income and education levels and type of occupation, there are extremely diverse but the majority is in a lower-middle or middle SES and at least high-school degree. Nevertheless, these attributes are not the main consideration for this research as we focus more on the racial difference context. we randomly assigned them to 5 groups of 20 people (10 immigrants, 10 native resident) then in each group they formed a team of 5 people (must include both immigrant and native) to play for 4 roles of the game. The game session took up to 2 hours for each group.

3. Arrival city game

Arrival city game implement this mechanism for the simulated situation; 1. The immigrants are motivated by the job and quality of living, and then they migrate to the city (Arrival city), resulting in 2. The lack of urban resources/ utilities such as healthcare, police, electric power, then the player need to 3. Use land use management as a main tool to try to plan the land use policy, develop the infrastructure and control the vulnerability and lastly, 4. There will be a chance for every player to take part in mayoral election. (Refer to figure 1)

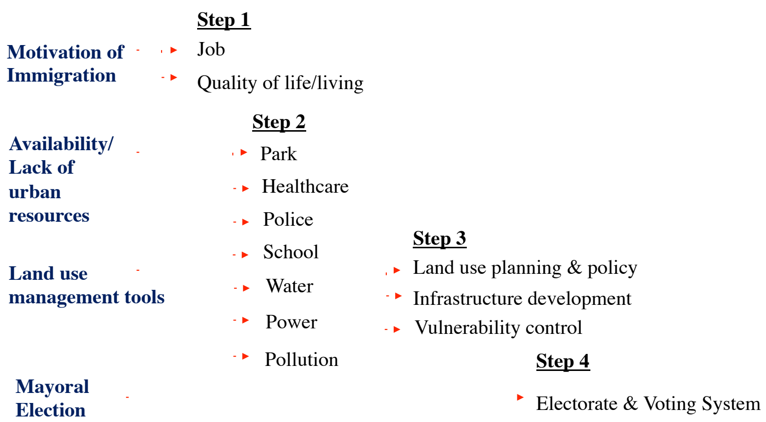

Figure 1: Processing mechanism

The game is a square-shape board with the circular-shape town center in the middle, the land lots are owned by both the public sector (in this case government) and private sector (investor). All the players will take part in managing the land; for their income, for their house, and for their livelihood. Accordingly, as illustrated in figure 2, all the players from the 4 different roles of immigrant, resident, investor, and government have to contribute to the development of the city (Arrival City). The government is the main decision maker of the city policy and land management, the investor is the job contributor in the city as well as developer of the land, lastly, the resident and immigrant are compelled to compete for the jobs and the accommodations.

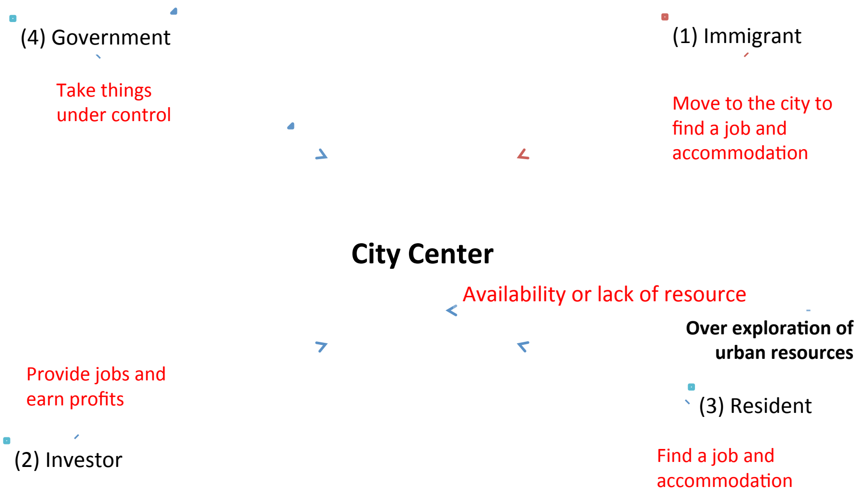

Figure 2: The simulated model.

After all the players complete their action according to their roles, all four teams are obliged to participate in city planning, which they must try to find solutions for Arrival City. Each turn becomes increasingly challenging as bigger waves of immigrants continue to come into the city that could cause additional problems and disruption to Arrival City.

The figure below is the example of the option cards. As the players are not experts in the field of planning, in the game we provide option cards for them to help them make decisions. For example, the government team can choose to provide incentives to the investor, adjust the property tax, or evict the illegal settlement. Not only that, the role of government is quite complex and they have to examine about a number of issues compare to others, the government role has access to the Excel sheets that provide detailed information of the situation of Arrival City and simulated index and graph such as the consumption, crime index, city vulnerabilities, etc.

Figure 3: Example of option cards for the player.

Throughout the game, it will become harder and harder for the player if they just work alone without considering the impact of their actions, they need to learn to work with each other, and eventually realize that they can also live and work with immigrants, wherewith they understand the role of immigrant in an urban system. They will also learn about the reality of urban planning impact on the climate change issue. Especially, the mode of transportation, the type of infrastructure and land use management. (See figure 4)

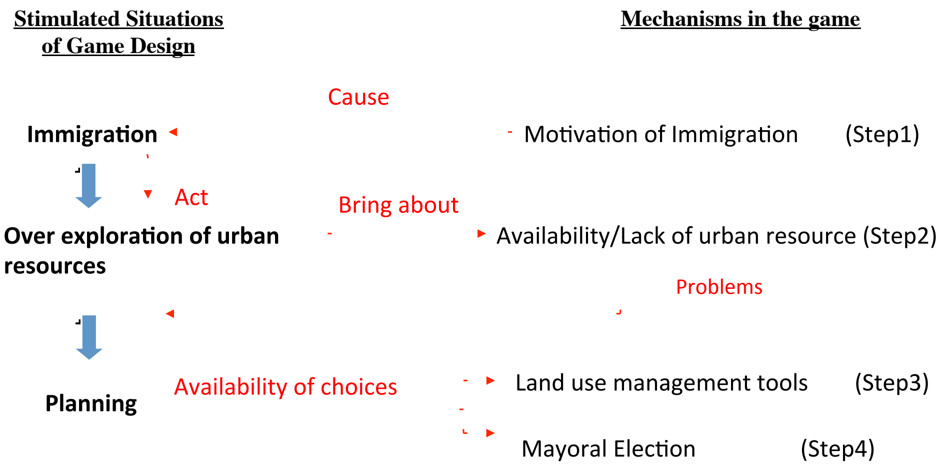

Figure 4: Game mechanism

4. The result of gaming simulation activities

The results indicated that the majority of the research participants aware of the climate change problem, however, they prioritize their current livelihood, income security and housing first. Noticeably, the group from developed countries chose their actions more consciously if it concerns the issue of climate change. While, the natives are more familiar with the local planning processes, the immigrants seem to be more enthusiastic and eager to participate in the activity.

Importantly, as there was a huge gap between the immigrant and native resident samples' perception, we are convinced that it is necessary to show three different figures, which elaborate three sets of sample group as follow, figure 5 shows all 100 samples, figure 6 represents the pre and posttest results of immigrant group perception toward diversity and figure 7 shows pre and posttest results of native resident perception toward diversity.

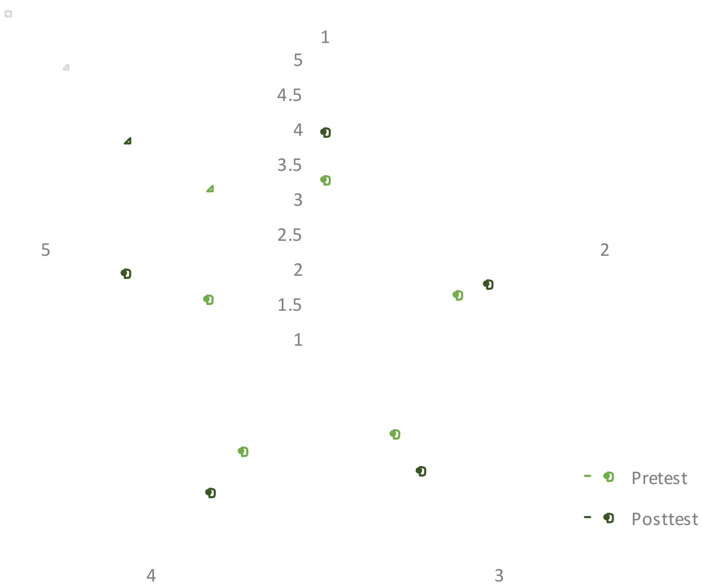

Figure 5: Pre and post test results of resident climate change awareness (N=100)

Overall, all the 5 categories are in neutral level (3.3, 3.0, 2.7, 3.0, 2.8 respectively) which "Climate change impacts effect my life" and "Urban planning relates to climate change issues." were among the lowest. After the game, there were apparent changes in all categories (4.0, 3.5, 3.4, 3.8, 4.0 respectively). They all agreed that "Giving the chance I will join the participatory planning event", "Climate change is a problem for everyone", "I am willing to contribute to climate change reduction and mitigation" and "Urban planning relates to climate change issues", while they still remained neutral about climate change impacts effect my life. (see figure 5)

As figure 6 shows, the Thai resident seems to have lower awareness about climate change situation as the pretest reflexed that they disagree that climate change impacts effect my life (2.3) and urban planning relates to climate change issues (2.2) while "Giving the chance I will join the participatory planning event", "Climate change is a problem for everyone" and "I am willing to contribute to climate change reduction and mitigation" are in neutral. (2.9, 2.5, and 2.5). After they played the game they agreed with statement 1,4 and 5 (3.7, 3.6 and, 4.0), statement 2 and 3 still remained in neutral level (both 3.1).

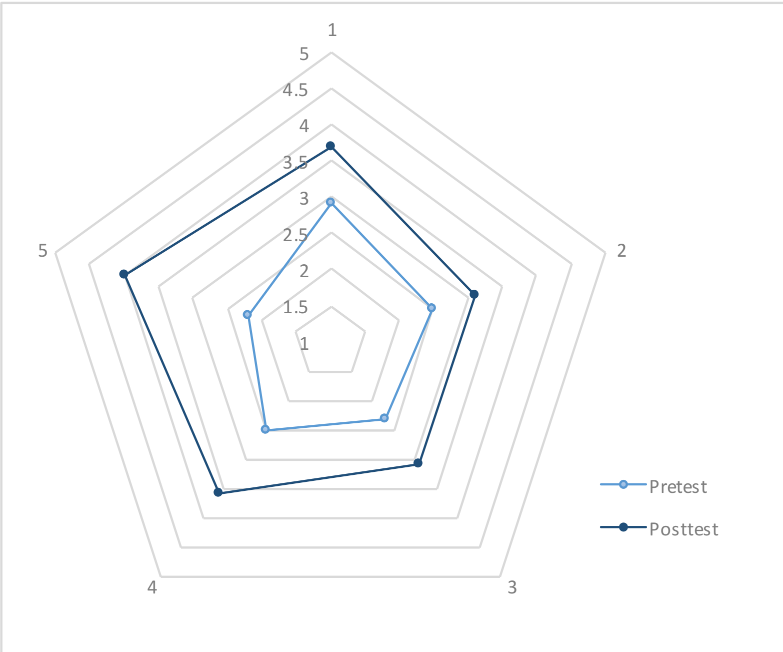

Figure 6: Pre and post test results of native resident climate change awareness (N=50)

Howbeit, for the immigrant residents they seem to have more elevated awareness about climate change as they wanted to participated in the planning process (3.6), they also think that climate change is a problem for everyone and they are willing to contribute to climate change reduction and mitigation both (3.5). However, the statement regarding "Climate change impacts effect my life" (3.1) and "Urban planning relates to climate change issues" (3.3) were in neutral. Eventually they came to agree with all statement as there were improvements in each category (4.2, 3.8, 3.6, 3.9, 4.0 respectively).

In term of causes and impacts of climate change, before the game they could just list around 2-3 causes and impacts of climate change. But after the game they could list around 6-7 answers. This was forasmuch the opportunity during the game which they can learn about the phenomenon as well as the interaction and exchange of ideas, case studies during the game and essentially in the planning activity.

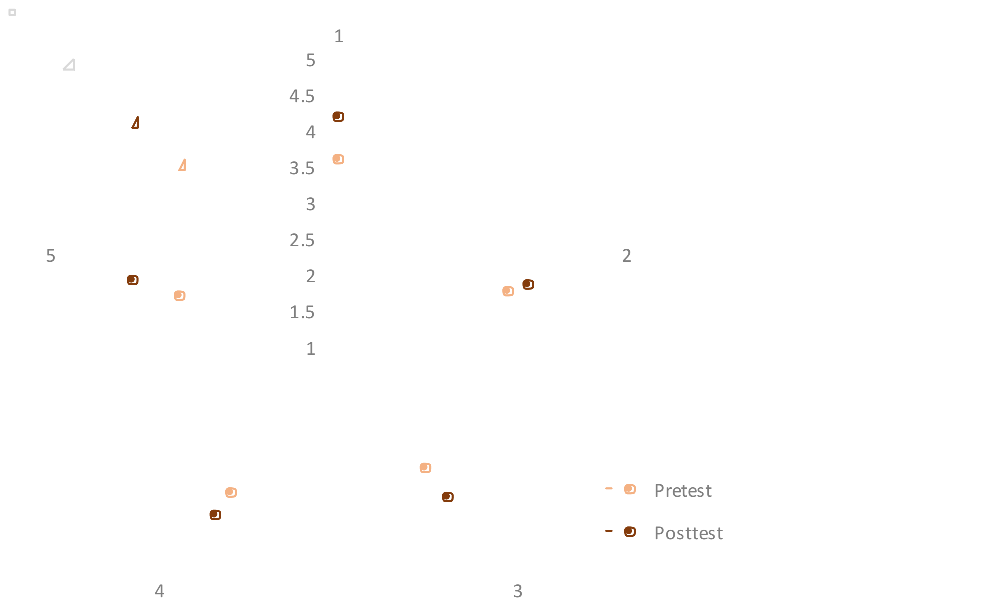

Figure 7: Pre and post test results of immigrant climate change awareness (N=50)

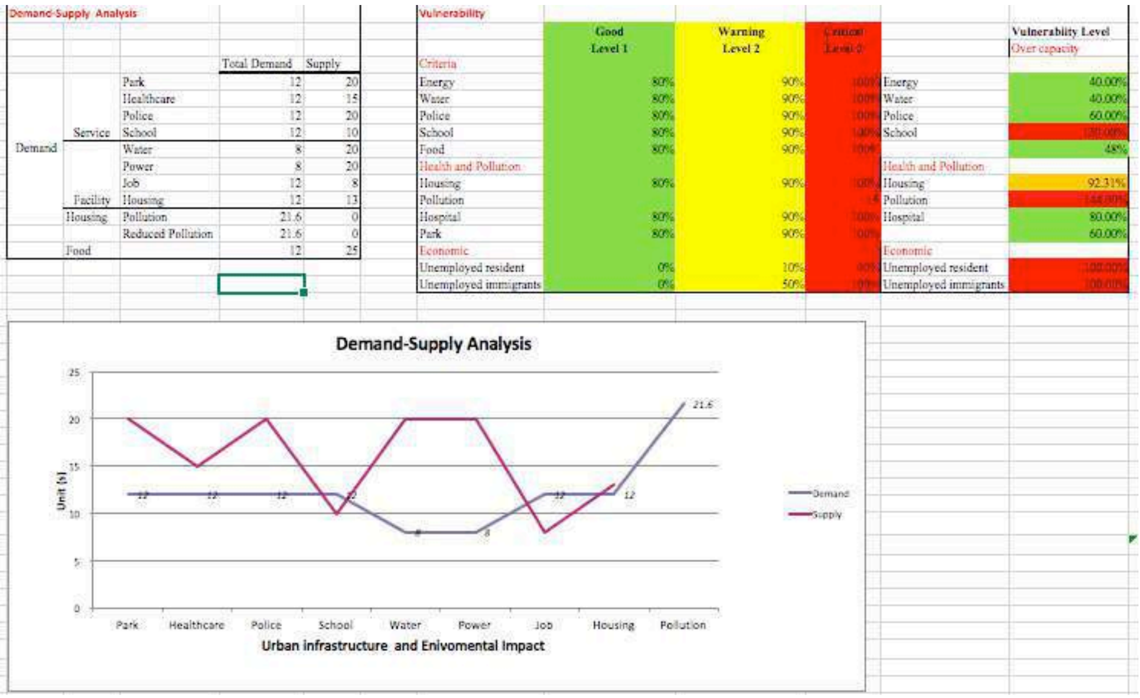

Demand-Supply Analysis

			Total Demand	Supply
Demand	Service	Park	12	20
		Healthcare	12	15
		Police	12	20
		School	12	10
	Facility	Water	8	20
		Power	8	20
		Job	12	8
		Housing	12	13
	Housing	Pollution	21.6	0
		Reduced Pollution	21.6	0
	Food		12	25

Vulnerability

Criteria	Good Level 1	Warning Level 2	[illegible]		Vulnerability Level Over capacity
Energy	80%	90%	100%	Energy	40.00%
Water	80%	90%	100%	Water	40.00%
Police	80%	90%	100%	Police	60.00%
School	80%	90%	[illegible]	School	[illegible]
Food	80%	90%	100%		48%
Health and Pollution				Health and Pollution	
Housing	80%	90%	100%	Housing	92.31%
Pollution			[illegible]	Pollution	[illegible]
Hospital	80%	90%	100%	Hospital	80.00%
Park	80%	90%	100%		60.00%
Economic				Economic	
Unemployed resident	0%	10%	[illegible]	Unemployed resident	[illegible]
Unemployed immigrants	0%	50%	[illegible]	Unemployed immigrants	[illegible]

Figure 8: In-game excel sheet

Principally, in all of the 5 groups that we played the game with, in general they had similar result during the game. In the first phase they only focused in making profit and competed with other teams in order to try to win the game. The Arrival city could function for some time but eventually there will be an abruption such as over demand, high rate of crime, unemployment rate, pollution problem and disaster situation as you can see from this example (figure 8). Consequently, when they all had to face with the crisis, they started to realized that while they prioritized the short-term need and individual benefit they can make do for a certain period of time. But ultimately, the world (in this case Arrival city) will face with several problems, some of those relate to climate change. Then all the 5 groups showed a change in mindset and the way they played the game, all of the team in each group acted as they need to work and rely on each other. The government teams communicated more before making decision. The resident and migrant teams tried to work together, while the investor teams contributed more to the city.

If we take a look deeper within the team member and group composition, Japanese, British, American, German, Russian, Taiwanese and Australian participants concerned more about green infrastructure, public transport and alternative energy resources. The German, American and Australian are in particular more willing to collaborate with other players, while Chinese, Russian, Cambodian are the three groups that seem to be less cooperative. And it was not a surprise that Thai are the most sensitive to immigrant role but some of the British, American and German also voiced their concerns toward low-skilled migrant worker.

Seeing the positive result of gaming simulation activity, we asked all the participant to come again to do the neighborhood planning policy development by themselves with the help from our team and local experts. Not only that they demonstrated better understanding, more expression and connection between ideas and several climate change related issue. They could come up with a considerable number of policy recommendations for their neighborhood to tackle with climate change issue. The notable policies are as follow,

1. The urgent need in the neighborhood master plan development in all the local area.
2. Improvement on the infrastructure that connect between mode of public transportation as well as origin and destination. Because it is not walkable enough people still need to use other paratransit mode (motorbike taxi) to connect between nodes of public transport.
3. Several small and medium size park are needed.
4. More incentive and compensation to motivate people to do positive behavior.
5. Alternative public space that focus on socio-cultural activity such as museum, art gallery and library.
6. Higher parking fee, and policy that discourage people to use car, i.e. CBD entering fee, zoning pass, odd and even driving plate permit.
7. Standardized and improvement to local school and kinder garden so that parent can just send their children to the local school.
8. Better management of the water resource, in particular the improvement to waste water treatment, sewage as well as the revitalization of canal and river.

The following are some of the interesting interview answers that we need to quote. The Thai participant want to work more with other and contribute more to urban planning and climate change reduction but they still criticized the current urban planning system in Thailand "We must plan in advance, government must be proactive and we need to start to consider about the immigrant resident if we still want to support AEC. Well I still feel that urban planning may not contribute that much due to the limitation in our planning law and regulation" (R4, M, 32, Native resident) "we love to work together more if we are allowed and supported, bringing new ideas is a beautiful matter, in particular the cases from developed country, but I do not think our government will allow the foreigner to take part in Thai urban planning" (R13, F, 29, Native resident), While the immigrant participant showed that they want to work more with other and contributed somehow to planning. "In my home country participation is a must and it is easy to join but I never join the activity in Thailand, I am not sure that we can." (R67, F, 45, German). "Well as I may not be so fluent in speaking Thai, in order for a successful planning event, we need a medium to share and help bridging people as well as communicate in the language that everyone understand" (51, F, 33, Mexican) and "local planning is the basic of everything in Japan, people can make change through this opportunity for participation" (R87, M, 50, Japanese).

5. Discussion and recommendations

Correspondingly, from the result we can supplement our finding to the past research that utilized GS as the tool for the planning to implement in the neighborhood which is experiencing the dynamic of population movement. "The game shows a very good potential as an education tool for immigrant integration and neighborhood co-existing diversity. Players also learn about land use planning and its relation with the immigrant phenomenon. It has proved to be a very attractive tool for urban planners, to use as a tool to teach people about land use management planning" (Huyakorn et al., 2018). But not only that, judging from this research experiment results, the Arrival city game is also an excellent planning tool in the context of participation and climate change problem.

We have unearthed the essential pronouncement that GS is exceptionally appropriate to be the tool in the arena of immigrant integration as it could stimulate progressive dialogue between the local and the migrant populations that result in a rewarding partnership afterward.

In essence, the key attributes of GS are the simulated events, action and reaction as well as the ability to bypass time. And these lead to the in-game experience that the player can learn about the consequent of action. We believe that this is extremely important when you want to campaign for climate change.

Taking the research finding in mind, hopefully with further improvement the GS can become the novel toolkit for other neighborhoods in AEC region respectively. More investigation on the actions and roles that were taken during the Arrival city game should be triangulated with other factor such as the participant attribute, period of stay and the impact of participant background, in order for us to understand better this complex situation. Importantly, with this new local reality of diversify neighborhood and ongoing changes of population, we can rely on the GS to be the tool that help the local planner communicate more progressively with both the resident and the immigrant population. Wherewith, it is proved again to be an effective participatory planning tool for extensive group of stakeholders.

Endnotes

1. Regarding Thai urban planning regulation, it still limited to land use planning but it does not include several aspects such as public transportation, local grid, compensation and advance incentive scheme, etc.
2. Thai urban planning participation processes have been mainly focus on public hearing to just present the result of land use plan.

Embedding energy user's behaviour into multi-criteria analysis: providing scenarios to policy-makers to design effective renovation strategies of the housing stock

Angela SANTANGELO, Alma Mater Studiorum – University of Bologna, Italy

Simona TONDELLI, Alma Mater Studiorum – University of Bologna, Italy

Abstract

Nowadays, policy-makers are facing the challenge to design and implement effective housing renovation strategies both for the public and the private housing stock, able to support not only the technical and physical renovation, but also a change of paradigm in energy consumption. Indeed, energy transition takes place on a local level and needs to involve individuals. The importance of tackling behaviour change to improve energy efficiency, especially in case of building retrofit, is increasingly recognised, as well as the urgency to combine the renovation of the housing stock with informative and feedback strategies, in order to reduce the gap between expected and actual energy consumption. The paper presents a methodology based on multi-criteria assessment of different strategies, aiming at providing support to policy-makers for their decisions concerning the reduction of energy consumption in buildings. The methodology has been designed to explicitly incorporate the impact of user's behaviour into the planning strategies and renovation measures to be assessed. Through the development of a multi-criteria analysis based on the Analytic Hierarchy Process (AHP), this study demonstrates that, to increase the sustainability of cities and communities, a holistic approach is required, and considerations on citizens' behaviour need to be embedded into energy renovation policies to address energy reduction targets.

Keywords: energy behaviour; renovation strategies; housing stock.

1. Introduction

Nowadays, urban environment is considered to be a key player in addressing climate change. The inclusion of energy considerations into the planning process has grown the awareness that spatial and urban planning can be the strategic framework where both mitigation and adaptation measures are positioned in the broader perspective of sustainable development.
The EU building sector is the largest single energy consumer in Europe. While the efficiency of new buildings has steadily improved over time, most of European existing building stock has yet to be affected by energy performance requirements. In fact, in most EU countries, half of the residential stock was built before 1970, prior to the first thermal regulations. Buildings in EU are responsible for approximately 40% of energy consumption and 36% of CO_2 emissions. Currently, about 35% of the buildings are over 50 years old and almost 75% of the building stock is energy inefficient, while only 0.4-1.2% of the building stock is renovated each year, depending on the country. Therefore, the increase of the renovation extent of existing buildings has the potential to lead to significant energy savings and the residential
